How It All Got Put Together

Once upon a time when the world
was young,
Oh best beloved.
There came to the banks of the Monongogo River,
All muddy and brown,
Oh best beloved,
A djinn who was one thing on the inside
But many things on the outside.
And he camped by the banks of the Monongogo River,
All muddy and brown,
Oh best beloved.
And he stayed and stayed and he never went away.
And he did his magic there.
He had many hands, each hand with many fingers,
Oh best beloved.
More hands and fingers than you and I
More hands than you have fingers,
More fingers on each hand than you have toes.
Each hand played a tune on a magic flute,
Oh best beloved.
And each fluted tune floated out on a separate flight.
And each was a tune for a separate dance,
And each was heard in a separate place,
And each was heard in a separate way,
And each was merged in the dance it swayed.
But it was still all the same tune,
For that was the magic of the djinn.
Now, best beloved, listen near—
Each separate place, when the world was young,
Danced in a way that was all its own,
Different from all of the others.
But the melody told of how it could be
That creatures out of an ancient sea,
By dancing one dance on the inside,
Could dance their own dance on the outside,
Because of the place where they were in—
All of its ins and outs.
For that was the magic of the djinn.
And little by little, each swayed a new way,
Taking the melody each its own way,
But hearing the melodies far away
From other places with separate dances,
But the very same melody
That told the dance to be done on the inside.
So, each started to step in the very same way,
Putting together one dance on the inside
For many dances on the outside.
So the melody grew, and it drifted back
To the Monongogo River, all muddy and brown,
And the river came clear and sweet.
Ah, best beloved, I must tell the truth.
The river is not yet clear and sweet,
Not really so.
Because putting together is a task forever.
And no one—not even a djinn with kilohands and megafingers,
All of which play a different-same tune—
Can put all things together in a single breath,
Not even a breath of fifty years.
It is not all put together yet,
And it never shall be,
For that is the way of the world.
But even so, when the world was young,
Was the time of the need for the single tune
To guide the dance that would move together
All of the steps in all of the places.
And it happened by the banks of the Monongogo River,
All muddy and brown,
Best beloved.
And the river will never be the same.
Just so.

Allen Newell
Carnegie Mellon University

Foreword

This volume contains the papers and posters selected for presentation at the 23rd Annual Meeting of the Cognitive Science Society in Edinburgh, August 1–4th 2001. This meeting is the first in the history of the society to be held outside North America, and reflects the increasing internationalisation of cognitive science. More than 500 submissions were received from all over the world. The breadth of topics treated, together with the evident themes that recur are testimony to the development of a distinctive field. We were reminded of the multidimensionality of the field when the several papers on topics related to categorisation proved to be the hardest of all to categorise.

It is our belief that the virtue of cognitive science comes from its deep engagement with the full range of disciplines that contribute to informational theories of mind. Cognitive science began with the realisation that several disciplines studied what is ultimately the same subject matter using different concepts and methods. Observation and experiment had become separated from simulation, engineering, formal analysis, historical, cultural and evolutionary study, and philsophical speculation. It is our hope that this conference will play its small part in substantiating the vision that it is important to put back together what the disciplines have cast asunder.

This multidimensionality of the field makes scheduling a major headache. It is impossible to ensure that clashes do not occur. At one point in scheduling we resorted to statistical corpus analysis on the presented papers to reveal implicit structure. (You will perhaps be relieved to hear that human analysis still appears to be ahead of LSA at this task). We hope that you enjoy the program that has resulted.

We would like to acknowledge help from the following sources, without whom this event would certainly not have been possible:

The Cognitive Science Society Board for inviting us to host the meeting and providing the framework, expertise and support.

The Program Committee assigned submissions to referees, read their resulting reviews and made judgments on the five hundred submissions.

The Reviewers (and there were more than 250 of them) reviewed the papers and gave feedback to committee and authors. Interdisciplinary reviewing is not an easy task. Submitting interdisciplinary papers sometimes feels like being tried by the legal systems of several cultures simultaneously. A necessarily imperfect process was carried out with good grace and some assurance of the quality of decisions. These tasks of assigning and performing reviews are second only to the quality of submissions in determining the calibre of the meeting.

The Tutorial Chair (Frank Ritter) who was responsible for the construction and organisation of the tutorial program.

The many volunteers who helped with the myriad local arrangements for a meeting of this size, and especially Jean McKendree who chaired the local arrangements committee.

The meeting certainly would not have happened without Frances Swanwick who coordinated the submissions process and Jonathan Kilgour who kept the software working, or without Mary Ellen Foster's tireless work on the Proceedings.

Janet Forbes and her successor David Dougal, and their secretarial team: Margaret Prow, Eva Steel, and Yvonne Corrigan for providing administrative support.

Financial support: British Academy, NSF, Erlbaum, Elsevier, Wellcome, the Glushko Foundation, and the Human Communication Research Centre.

The plenary speakers Jon Elster, Wilfred Hodges and Dan Sperber.

And lastly, and most importantly, the authors and symposium participants who presented their work, and made the conference what it was.

The Cognitive Science Society

The Cognitive Science Society, Inc., was founded in 1979 to promote interchange across traditional disciplinary lines among researchers investigating the human mind. The Society sponsors an annual meeting, and publishes the journal Cognitive Science. Membership in the Society requires a doctoral degree in a related discipline (or equivalent research experience); graduate and undergraduate students are eligible for a reduced rate membership; and all are welcome to join the society as affiliate members. For more information, please contact the society office or see their web page at *http://www.cognitivesciencesociety.org/*

Cognitive Science Society, University of Michigan, 525 East University, Ann Arbor MI, 48109-1109; cogsci@umich.edu; phone and fax (734) 429-4286

Tutorial Program

August 1st, 2001

How to Deal with Modularity in Formal Language Theory: An Introduction to Grammar Systems, Grammar Ecosystems and Colonies

Carlos Martin-Vide, Rovira i Virgili University

APEX: An Architecture for Modeling Human Performance in Applied HCI Domains

Michael Matessa, NASA Ames Research Center
Michael Freed - NASA Ames Research Center
John Rehling - NASA Ames Research Center
Roger Remington - NASA Ames Research Center
Alonso Vera - NASA Ames Research Center

An Introduction to the COGENT Cognitive Modelling Environment (with special emphasis on applications in computational linguistics)

Dr. Richard Cooper, Birkbeck College
Dr. Peter Yule, Birkbeck College

Eye Tracking

Roger P.G. van Gompel, University of Dundee
Wayne S. Murray, University of Dundee

ACT-R 5.0

John R. Anderson, Carnegie Mellon University

Tutorial Co-Chairs

Frank Ritter, Penn State University
Richard Young, University of Hertfordshire

Tutorial Committee Members

Randy Jones, University of Michigan
Todd Johnson, University of Texas, Houston
Vasant Honavar Iowa State University
Kevin Korb, Monash University
Michail Lagoudakis, Duke University
Toby Mintz, University of Southern California
Josef Nerb, University of Freiberg and University of Waterloo
Gary Jones, University of Derby
Padraic Monaghan, University of Edinburgh

Speakers and Symposia

Invited Speakers

Jon Elster, Columbia University
Wilfred Hodges, Queen Mary and Westfield College, University of London
Dan Sperber, CNRS, Paris

Invited Symposia

Emotion and Cognition
Chair: Keith Stenning, University of Edinburgh
Speakers:
Ziva Kunda, Waterloo University
Paul Seabright, Toulouse University
Drew Westen, Boston University

Representation and Modularity
Chair: Jon Oberlander, University of Edinburgh
Speakers:
Lawrence Hirschfeld, University of Michigan
Annette Karmiloff-Smith, Institute of Child Health, London
Dylan Evans, King's College, London

Submitted Symposia

Computational Models of Historical Scientific Discoveries
Chairs:
Pat Langley, ISLE, Stanford
Lorenzo Magnani, University of Pavia
Presenters:
Peter Cheng, Adrian Gordon, Sakir Kocabas, Derek Sleeman

When Learning Shapes its own Environment
Chair:

"Computational Scientific Discovery and Human Problem Solving"

Fernand Gobet, University of Nottingham
"Is Experts' Knowledge Modular?"

Kevin Gluck, Air Force Research Laboratory
"The Right Tool for the Job: Information Processing Analysis in Categorisation"

"For us life is, as Shakespeare and many others have described it, a play—a very serious play whose meaning lies in living it. Like any play, in order to have meaning, it must have a beginning, a middle and an end. If an act spans about a decade, eight acts are already a very long play, making heavy demands on the dramatist (oneself) to give it shape.

"Dot and I have had remarkably happy and lucky lives (the first requires the second), which continue to be interesting and challenging, and we have no urge to end them. On the other hand, the realization that these lives are likely, in fact, to end at almost any time now evokes no resentment of fate—at most, sometimes a gentle sadness. We are resigned, not in a sense of giving up or losing, but in a sense of wanting to end our years with dignity, good memories and a feeling that the play had a proper shape and ending, including a final curtain."

Herb Simon

Contents

Symposia

Papers & Posters

Referential Form, Word Duration, and Modeling the Listener in Spoken Dialogue
Ellen Bard and Matthew Aylett (University of Edinburgh)

The Utility of Reversed Transfers in Metaphor
John Barnden (The University of Birmingham)

A model theory of deontic reasoning about social norms
Sieghard Beller (Department of Psychology, University of Freiburg, Germany)

Cue Preference in a Multidimensional Categorization Task
Patricia Berretty (Fordham University)

A Perceptually Driven Dynamical Model of Rhythmic Limb Movement and Bimanual Coordination
Geoffrey Bingham (Psychology Department and Cognitive Science Program, Indiana University)

Inferences About Personal Identity
Sergey Blok, George Newman , Jennifer Behr and Lance Rips (Northwestern University)

Graded lexical activation by pseudowords in cross-modal semantic priming: Spreading of activation, backward priming, or repair?
Jens Bölte (Psychologisches Institut II)

Understanding recognition from the use of visual information
Lizann Bonnar, Philippe Schyns and Frédéric Gosselin (University of Glasgow)

Taxonomic relations and cognitive economy in conceptual organization
Anna Borghi (University of Bologna) and Nicoletta Caramelli (University of Bologna)

The Roles of Body and Mind in Abstract Thought.
Lera Boroditsky (Stanford University), Michael Ramscar (Edinburgh University) and Michael Frank (Stanford University)

The time-course of morphological, phonological and semantic processes in reading Modern Standard Arabic
Sami Boudelaa and William Marslen-Wilson (MRC-CBU)

Reference-point Reasoning and Comparison Asymmetries
Brian Bowdle (Indiana University) and Douglas Medin (Northwestern University)

Deference in Categorisation: Evidence for Essentialism?
Nick Braisby (Open University)

Meaning, Communication and Theory of Mind.
Richard Breheny (RCEAL, University of Cambridge)

The Effects of Reducing Information on a Modified Prisoner's Dilemma Game
Jay Brown and Marsha Lovett (Carnegie Mellon University)

Mice Trap: A New Explanation for Irregular Plurals in Noun-Noun Compounds
Carolyn Buck-Gengler, Lise Menn and Alice Healy (University of Colorado, Boulder)

Simulating the Evolution of Modular Neural Systems
John Bullinaria (University of Birmingham, UK)

The Hot Hand in Basketball: Fallacy or Adaptive Thinking?

Constraints on Linguistic Coreference: Structural vs. Pragmatic Factors
Frank Keller (Computational Linguistics, Saarland University) and Ash Asudeh (Department of Linguistics, Stanford University)

Training for Insight: The Case of the Nine-Dot Problem
Trina Kershaw and Stellan Ohlsson (University of Illinois at Chicago)

Theory-based reasoning in clinical psychologists
Nancy Kim (Yale University) and Woo-kyoung Ahn (Vanderbilt University)

Effect of Exemplar Typicality on Naming Deficits in Aphasia

Computational Models of Historical Scientific Discoveries

Pat Langley, Institute for the Study of Learning and Expertise
Lorenzo Magnani, Department of Philosophy, University of Pavia
Peter C.-H. Cheng, School of Psychology, University of Nottingham
Adrian Gordon, Department of Computing, University of Northumbria
Sakir Kocabas, Space Engineering Department, Istanbul Technical University
Derek H. Sleeman, Department of Computing Science, University of Aberdeen

The discovery of scientific knowledge is one of the most challenging tasks that confront humans, yet cognitive science has made considerable progress toward explaining this activity in terms of familiar cognitive processes like heuristic search (e.g., Langley et al., 1987). A main research theme relies on selecting historical discoveries from some discipline, identifying data and knowledge available at the time, and implementing a computer program that models the processes that led to the scientists' insights. The literature on computational scientific discovery includes many examples of such studies, but initial work in this tradition had some significant drawbacks, which we address in this symposium.

One such limitation was that early research in law discovery ignored the influence of domain knowledge in guiding search. For example, Gordon et al. (1994) noted that attempts to fit data from solution chemistry in the late 1700s took into account informal qualitative models like polymerization and dissociation. They have developed Hume, a discovery system that draws on such qualitative knowledge to direct its search for numeric laws. Hume utilizes this knowledge not only to rediscover laws found early in the history of solution chemistry, but also to explain, at an abstract level, the origins of other relations that scientists proposed and later rejected.

Early discovery research also downplayed the role of diagrams, which occupy a central place in many aspects of science. For example, Huygens' and Wren's first presentations of momentum conservation took the form of diagrams, suggesting they may have been instrumental in the discovery process. In response, Cheng and Simon (1992) have developed Huygens, a computational model for inductive discovery of this law that uses a psychologically plausible diagrammatic approach. The system replicates the discovery by manipulating geometric diagrams that encode particle collisions and searching for patterns common to those diagrams. The quantitative data given to the system are equivalent to those available at the time of the original discovery.

Another challenge concerns the computational modeling of extended periods in the history of science, rather than isolated events. To this end, Kocabas and Langley (1995) have developed BR4, an account of theory revision in particle physics that checks if the current theory is consistent (explains observed reactions) and complete (forbids unobserved reactions), revises quantum values and posits new particles to maintain consistency, and introduces new properties to maintain completeness. BR-4 models, in abstract terms, major developments in particle physics over two decades, including the proposal of baryon and lepton numbers, postulation of the neutrino, and prediction of numerous reactions. Background knowledge about symmetry and conservation combine with data to constrain the search for an improved theory in a manner consistent with the incremental nature of historical discovery.

We hope this symposium will encourage additional research that extends our ability to model historical scientific discoveries in computational terms.

Introduction

Cognitive mechanisms are shaped by their environments, both through evolutionary selection across generations and through learning and development within lifetimes. But by making decisions that guide actions which in turn alter the surrounding world, cognitive mechanisms can also shape their environments in turn. This mutual shaping interaction between cognitive structure and environment structure can even result in coevolution between the two over extended periods of time. In this symposium, we explore how simple decision heuristics can exploit the information structure of the environment to make good decisions, how simple language-learning mechanisms can capitalize on the structure of the "spoken" environment to develop useful grammars, and how both sorts of cognitive mechanisms can actually help build the very environment structure that they rely on to perform well.

Programme

There will be three talks, as follows:

1. Peter Todd, "Simple Heuristics that exploit environment structure",

   Traditional views of rational decision making assume that individuals gather, evaluate, and combine all the available evidence to come up with the best choice possible. But given that human and animal minds are designed to work in environments where information is often costly and difficult to obtain, we should instead expect many decisions to be made with simple "fast and frugal" heuristics that limit information use. In our study of ecological rationality, we have been exploring just how well such simple decision-making heuristics can do when they are able to exploit the structure of information in specific environments. This talk will outline the research program pursued by the Center for Adaptive Behavior and Cognition as developed in the book, *Simple Heuristics That Make Us Smart* (Oxford, 1999), and highlight how the match between cognitive mechanism structure and environment structure allows the Recognition heuristic and Take The Best heuristic to perform on par with traditionally rational decision mechanisms.

2. Simon Kirby, "The Iterated Learning Model of Language Evolution",

   The past decade has seen a shift in the focus of research on language evolution away from approaches that rely solely on natural selection as an explanatory mechanism. Instead, there has been a growing appreciation of languages (as opposed to the language acquisition device) as complex adaptive systems in their own right. In this talk we will present an approach that explores the relationship between biologically given language learning biases and the cultural evolution of language. We introduce a computationally implemented model of the transmission of linguistic behaviour over time: the Iterated Learning Model (ILM). In this model there is no biological evolution, natural selection, nor any measurement of the success of communication. Nonetheless, there is significant evolution. We show that fully syntactic languages emerge from primitive communication systems in the ILM under two conditions specific to Hominids: (i) a complex meaning space structure, and (ii) the poverty of the stimulus.

3. Peter Todd, Simon Kirby and Jim Hurford, "Putting the Models Together: how the environment is shaped by the action of the recognition heuristic",

   To explore how cognitive mechanisms can exert a shaping force on their environment and thus affect their own performance, we begin by considering the actions of a very simple cognitive mechanism, the recognition heuristic for making choices. This heuristic specifies that when choosing between two options, one of which is recognized and one not, the recognized option should be selected. The recognition heuristic makes good choices, in environments where recognition is correlated with the choice criterion. Many natural environments have this structure, but such structure can also be "built": By using the recognition heuristic, agents can create an environment in which some objects are much more often and "talked about" and recognized than others. An agent-based simulation is used to show what behavioral factors affect the emergence of this environmental structure.

The Cognitive Basis of Science: The View from Science

Session Organizer: **Nancy J. Nersessian (nancyn@cc.gatech.edu)**
College of Computing, 801 Atlantic Drive
Atlanta, GA 30332 USA

The issue of the nature of the processes or "mechanisms" that underlie scientific cognition is a fundamental problem for cognitive science. A rich and nuanced understanding of scientific knowledge and practice must take into account how human cognitive abilities and limitations afford and constrain the practices and products of the scientific enterprise. Reflexively, investigating scientific cognition opens the possibility that aspects of cognition previously not observed or considered will emerge and require enriching or even altering significantly current understandings of cognitive processes.

The Baby in the Lab Coat: Why child development is an inadequate model for understanding the development of science

Stephen P. Stich, Department of Philosophy, Rutgers University

In two recent books and a number of articles, Alison Gopnik and her collaborators have proposed a bold and intriguing hypothesis about the relationship between scientific cognition and cognitive development in childhood. According to this view, the processes underlying cognitive development infants and children and the processes underlying scientific cognition are identical. One of the attractions of the hypothesis is that, if it is correct, it will unify two fields of investigation – the study of early cognitive development and the study of scientific cognition – that have hitherto been thought quite distinct, with the result that advances in either domain will further our understanding of the other. In this talk we argue that Gopnik's bold hypothesis is untenable. More specifically, we will argue that if Gopnik and her collaborators are right about cognitive development in early childhood then they are wrong about science. The minds of normal adults and of older children, we will argue, are more complex than the minds of young children, as Gopnik portrays them. And some of the mechanisms that play no role in Gopnik's account of cognitive development in childhood play an essential role in scientific cognition.

Scientific Cognition as Distributed Cognition

Ronald N. Giere, Center for Philosophy of Science, University of Minnesota

I argue that most important cases of cognition in contemporary science are best understood as examples of distributed cognition. Here I focus exclusively on the acquisition of new knowledge as the paradigm of scientific cognition. Scientific cognition, then, does not reduce to mere distributed computation. The simplest case is that in which two people cooperate in acquiring some knowledge that is not directly acquired by either one alone. It is even possible that neither person could physically perform the task alone. This is an example of what has been called "socially shared cognition" (Resnick) or "collective cognition" (Knorr). The most elaborate example is the case of experimental high-energy physics at CERN, as described by the sociologist, Karin Knorr in her recent book, *Epistemic Cultures*. I go beyond Knorr's analysis to include the particle accelerator and related equipment as part of a distributed cognitive system. So here the cognition is distributed both among both people and artifacts. Such artifacts as diagrams and graphics and even abstract mathematical constructions are also included as components of distributed cognitive systems. This makes it possible to understand the increasing power of science since the seventeenth century as in large measure due to the creation of increasing powerful cognitive systems, both instrumental and representational.

The Cognitive Basis of Model-based Reasoning in Science

Nancy J. Nersessian, Program in Cognitive Science, Georgia Institute of Technology

Although scientific practice is inherently "socially shared cognition," the nature of individual cognitive abilities and how these constrain and facilitate practices still needs to be figured into the account of scientific cognition. This presentation will focus on the issue of the cognitive basis of the model-based reasoning practices employed in creative reasoning leading to conceptual change across the sciences. I will first locate the analysis of model-based reasoning within the mental modeling framework in cognitive science and then discuss the roles of analogy, visual representation, and thought experimenting in constructing new conceptual structures. A brief indication of the lines along which a fuller account of how the cognitive, social, and material are fused in the scientist's representations of the world will be developed. That the account needs to be rooted in the interplay between the individual and the communal in the model-based reasoning that takes place in concept formation and change. Modeling is a principal means through which a scientist transports conceptual resources drawn from her wider cultural milieu into science and transmits novel representations through her community. Scientific modeling always takes place in a material environment that includes the natural world, socio-cultural artifacts (stemming from both outside of science and within it), and instruments devised by scientists and communities to probe and represent that world.

The Interaction of Explicit and Implicit Learning

Ron Sun (rsun@cecs.missouri.edu)
University of Missouri-Columbia

Robert Mathews (psmath@unix1.sncc.lsu.edu)
Louisiana State University, Baton Rouge
Baton Rouge, LA

The Focus of the Symposium

The role of implicit learning in skill acquisition and the distinction between implicit and explicit learning have been widely recognized in recent years (see, e.g., Reber 1989, Stanley et al 1989, Willingham et al 1989, Anderson 1993), Although implicit learning has been actively investigated, the complex and multifaceted interaction between the implicit and the explicit and the importance of this interaction have not been universally recognized; to a large extent, such interaction has been downplayed or ignored, with only a few notable exceptions. [1] Research has been focused on showing the *lack* of explicit learning in various learning settings (see especially Lewicki et al 1987) and on the controversies stemming from such claims. Similar oversight is also evident in computational simulation models of implicit learning (with few exceptions such as Cleeremans 1994 and Sun et al 2000).

Despite the lack of studies of interaction, it has been gaining recognition that it is difficult, if not impossible, to find a situation in which only one type of learning is engaged (Reber 1989, Seger 1994, but see Lewicki et al 1987). Our review of existing data has indicated that, while one can manipulate conditions to emphasize one or the other type, in most situations, both types of learning are involved, with varying amounts of contributions from each (see, e.g., Sun et al 2000; see also Stanley et al 1989, Willingham et al 1989).

Likewise, in the development of cognitive architectures (e.g., Rosenbloom et al 1993, Anderson 1993), the distinction between procedural and declarative knowledge has been proposed for a long time, and advocated or adopted by many in the field (see especially Anderson 1993). The distinction maps roughly onto the distinction between the explicit and implicit knowledge, because procedural knowledge is generally inaccessible while declarative knowledge is generally accessible and thus explicit. However, in work on cognitive architectures, focus has been almost exclusively on "top-down" models (that is, learning first explicit knowledge and then implicit knowledge on the basis of the former), the bottom-up direction (that is, learning first implicit knowledge and then explicit knowledge, or learning both in parallel) has been largely ignored, paralleling and reflecting the related neglect of the interaction of explicit and implicit processes in the skill learning literature. However, there are a few scattered pieces of work that did demonstrate the parallel development of the two types of knowledge or the extraction of explicit knowledge from implicit knowledge (e.g, Willingham et al 1989, Stanley et al 1989, Sun et al 2000), contrary to usual top-down approaches in developing cognitive architectures.

Many issues arise with regard to the interaction between implicit and explicit processes, which we need to look into if we want to better understand this interaction:

- How can we best capture implicit processes computationally? How can we best capture explicit processes computationally?
- How do the two types of knowledge develop along side each other and influence each other's development?
- Is bottom-up learning (or parallel learning) possible, besides top-down learning? How can they (bottom-up learning, top-down learning, and parallel learning) be realized computationally?
- How do the two types of acquired knowledge interact during skilled performance? What is the impact of that interaction on performance? How do we capture such impact computationally?

Titles of the Talks

Axel Cleeremans: "Behavioral, neural, and computational correlates of implicit and explicit learning"

Zoltan Dienes: "The effect of prior knowledge on implicit learning"

Bob Mathews: "Finding the optimal mix of implicit and explicit learning"

Ron Sun: "The synergy of the implciit and the explicit"

[1] By the explicit, we mean processes involving some form of generalized (or generalizable) knowledge that is consciously accessible.

Abstract

Spatial and temporal metaphors are often used interchangeably, and thus, offer a unique way of exploring the relationship between language and thought. Both spatial and temporal speaking incorporates two systems of motion. The first is an ego-moving system, when the individual moves from one point to another, spatially, or from the past to the future, temporally. The second is the object- (or time-) moving system, when the individual is stationary and observes objects, or time, moving towards him/her. This study explored the effect of a spatial environment on the ambiguous temporal question: *Next Wednesday's meeting has been moved forward two days--What day is the meeting now?* Results reveal that when participants are immersed in an ego-moving spatial environment, such as a virtual reality game, and receive a prime that causes them to think in an object-moving way, they are more likely to perform a target task in a way consistent with the way they have been primed to think, although it contradicts the spatial motion they subsequently experience in the testing environment.

Introduction

What is the relationship between language and sensory experience? According to one recent claim (Lakoff and Johnson, 1999), abstract concepts, such as time, are substrated in concrete concepts like space that can be experienced directly. The representations of these concrete concepts are formed directly, by experience. Thus, our spatial experiences form "a neural structure that is actually part of, or makes use of, the sensorimotor system of our brains. Much of conceptual inference is, therefore, sensorimotor inference" (Lakoff and Johnson, 1999, p. 20). On this view, our understanding of concepts such as time is predicated on our spatial experiences, and thus the idea of motion in time relies on our understanding of motion in space.

There is evidence for this relationship between motion in space and time in the structure of language. We can talk of *putting things forward* in time, as well as *moving forward* through space (see Lakoff & Johnson, 1999; 1980). According to Lakoff and Johnson's (1980; 1999) Conceptual Metaphor hypothesis, metaphors are not justa manner of speaking but a deeper reflection of human thought processes. Metaphoric speaking is reflective, say Lakoff and Johnson, of deeper conceptual mappings that occur in our thinking and is depicted as an over-arching and general metaphor termed asthe Conceptual Metaphor. Consider the following statements:

Your claims are *indefensible*.

He *attacked every weak point* in my argument.

He *shot down* all of my arguments.

According to the Conceptual Metaphor (metaphoric representation) hypothesis when we use statements such as these we are making use of a larger conglomerate metaphor, in this instance, ARGUMENT IS WAR.[1]

The thrust of the Conceptual Metaphor argument is as follows: arguments are similar to wars in that there are winners and losers, positions are attacked and defended, and one can gain or lose ground. The theory of Conceptual Metaphor suggests that we process metaphors by mapping from a base domain to a target domain. In this particular example, the base domain is ARGUMENT IS WAR and the target domain is asubordinate metaphor such as *Your claims are indefensible.*

Motion in Space and Time

Lakoff and Johnson extend the idea of Conceptual Metaphor to spatio-temporal metaphors by invoking the

[1] Following Lakoff and Johnson's convention (1980), all Conceptual Metaphors are typed in the uppercase to distinguish them from the subordinate metaphors

locative terms of FRONT/BACK to represent how we view time and space. FRONT is assigned on the assumption of motion (Fillmore, 1978). According to this theory, in the *ego-moving* system, FRONT is used to designate a future event because the ego is moving forward and encounters the future event in front of him. In the *time-moving* system, the FRONT term denotes a past event where the ego or the individual is stationary but the events are moving. Thus it is possible to define (at least) two schemas of motion in space.

1) Object-Moving Metaphor (OM)

In this schema of motion,the individual is seen as stationary and objects seem to come towards him/her. For an example of this schema, consider an individual waiting at a bus stop and observing vehicles coming towards him/her. In this schema of motion, the individual assigns the term FRONT to the object closest towards him. In the diagram below, the term FRONT would be assigned to the white rock.

Figure 1

2) Ego-Moving Metaphor (EM)

Inthis schema of motion, the objects are stationary and it is the individual that is in motion. Here, the term FRONT would be assigned to the object furthest away from the individual. In the picture below, it is the black rock that would be labeled as FRONT.

Figure 2

Thus in the EM system, *front* is used to designate an object furthest away from the individual, as the trajectory of motion is in that direction. While in the OM system, the term *front* is assigned to the object closest to the individual.

Motion in Time

The schemas of motion represented in the domain of time reflect the representation of motion in the domain of space.

1) Time Moving metaphor (TM)

The motion of time provides the framework in which temporal metaphors are comprehended. In this schema, *front,* or *ahead* is determined by thefuture moving to the past. For example, in the month of February, Christmas is now in the future. In time it will move to the present and then to the past (e.g. Christmas is *coming*). The individual is a stationary observer as times "flows" past. This schema is the temporal equivalent of the OM metaphor in the domain of space.

2) Ego-Moving metaphor (EM)

The ego or the individual moves from the past to the future such as the sentence His vacation to the beach lay *ahead* of him . In this metaphor, the observer is seen as moving forward through time, passing temporal events that are seen as stationary points. It is thus the temporal equivalent of the spatial EM system, where the observer moves forward through space

When discussing motion in time, temporal events are viewed as points or locations in space, and a similar rationale is used when assigning deictic terms such as *front* and *back*. For example, in the EM system, FRONT is used to designate a future event because the ego is moving forward and encounters the future event in front of him, while in the TM system the FRONT term denotes a past event where the ego or the individual is stationary but the events are moving.

Studies of Spatio-temporal Metaphors

Gentner and Imai (1992), and McGlone and Harding (1998) confirmed the idea that the different schemas of motion (EM and TM in the domain of time) are indeed psychologically real systems.Gentner and Imai found that participants responded faster to questions that were schema consistent with regards to temporal schemas in priming than to questions that were inconsistent with their primes. Gentner and Imai argue that this supports the theory that metaphors are mapped in distinct schemas: the shift from one schema to another causes a disruption in the processing, reflected in increased processing time. They argue that their study indicates that the relations between space and time are reflective of a psychologically real conceptual system as opposed to an etymological relic.[2]

A study by McGlone and Harding (1998) involved participants answering questions about days of the week - relative to Wednesday - which were posed in either the *ego-moving* or the *time-moving* metaphor. *Ego-moving* metaphor trials comprised statements such as We passed the deadline two days ago , whilst *time-moving* metaphor trials involved statements such as The deadline passed us two days ago ; in each case,

[2] Although McGlone and Harding (1998) criticised some aspects of Gentner and Imai s methodology, their corrected replication of the original study confirms its findings.

participants read the statements and were then asked to indicate the day of the week that a given event had occurred or was going to occur. At the end of each block of such priming statements, participants read an ambiguous statement, such as The reception scheduled for next Wednesday has been moved forward two days [3] and then were asked to indicate the day of the week on which this event was now going to occur. Participants who had answered blocks of priming questions about statements phrased in a way consistent with the*ego-moving* metaphor tended to disambiguate moved forward in a manner consistent with the *ego-moving* system (they assigned forward - the front - to the future, and hence thought the meeting had been re-scheduled for Friday), whereas participants who had answered blocks of questions about statements phrased a way consistent with the *time-moving* metaphor tended to disambiguate moved forward in a manner consistent with the *time-moving* system (they assigned forward - the front - to the past, and hence thought the meeting had been re-scheduled for Monday).

This work has been further developed in a recent set of experiments by Boroditsky (2000) which explicitly explored the relationship between the domains of space and time. Boroditsky found that temporal priming significantly influenced temporal reasoning in a cross-domain extension of the paradigm used in earlier experiments. Spatially priming participants with the ego moving schema led them to infer that an ambiguous meeting ("Next Wednesday's meeting has been moved forwards two days") had been moved to Friday, whereas spatially priming participants with the object moving schema led them to assign the meeting to Monday. This study provides good evidence to support the notion that our representation of motion in space is mapped on to our understanding of motion in time, although it leaves open the question of what is directing this representational mapping spatial representations that are contiguous with our embodied experience, or functionally separable, abstract conceptual representations of space and time.

Experiment 1

This experiment directly explores the claim that our embodied experiences in space direct our conceptual understanding of time. Participants were immersed in an embodied environment, a virtual reality game, and were presented with an ambiguous spatial task, either after either a purely embodied prime, or after embodied priming during which a linguistic prime had cued them to *think* in terms of a contrary spatial schema. The experiment was designed to explore the role of experience and thought between the two schemas of motion in the domain of space.

[3] All trials were conducted on a Wednesday.

Participants

61 University of Edinburgh students volunteered to take part in this experiment.

Materials

In order to create a particularly convincing Ego Moving environment, participants played a slightly modified version of a pre-existing section of the virtual reality computer game, *UnReal*. This is a first person perspective game and involves the participant walking through a courtyard environment to complete a task. All monsters and other artifacts of the game that were not relevant to the experiment were removed from this section of the game. The objects in the target task appeared upon completion of the game. These were two chests, with no discernible front or back (unlike other objects, such as a car, or a TV), one of which was closer to the player than the other. The game was projected onto a 368cm by 282cm size screen in order to magnify the virtual effects of the game.

Procedure

Pre-Test

25 participants were tested individually seated in front of the projector screen. The game was set at the point in front of the two chests. Participants did not play the game and were only instructed to *Move to the front chest* . In this condition, the target task was performed in isolation, and the results provided a baseline for how the term *front* in this task is interpreted.

Out of the twenty-five subjects, twelve of them interpreted the term *front* to refer to the chest closest to them, while the rest assigned front to the chest furthest from them, confirming the ambiguity of the assignment of *front* in the target task.

Experimental Conditions

36 participants were tested individually. They were asked to fill in a brief questionnaire requesting demographic information, as well as familiarity with video games and computers. At the end of the questionnaire were the following instructions: Your task is to find the location of a young woman. Try your best to navigate around the environment in order to find her. During this game, it is important to try to remember some key landmarks, such as a **pair of brightly coloured pillars as you enter a path,** as well as the **doors on the buildings.** After you have been playing for some time, you will hear a question requiring a true or false answer. This question will be about the game. Try to answer it correctly and speak your answer loudly."

The participants were then shown how to use the arrow keys on the keyboard when navigating through the environment and then left alone to play the game. (The experimenter was on hand, should the volunteers

have any difficulty maneuvering around the environment; however, all volunteers seemed adequately proficient at navigating around the environment.)

There were two experimental conditions. In the first condition, volunteers received a pre-recorded true/false question specific to the assignment of the term *front* approximately four minutes into playing the game. The question they were posed -- During the game, the green pillar is in front of the red pillar — prompted them to think in an Object Moving manner about space (the green pillar was closer to the participants than the red pillar in the game environment, thus this question is true from an OM perspective).[4] We were interested to see if the thinking in an OM way in answering the question would result in a different assignment of *front* from the EM perspective that was embodied in the game.

The order of the pillars in the question was reversed for half of the participants to counter-act an affirmative response bias. Thus, half the participants answered the true/false question: During the game, the red pillar is in front of the green pillar . The answer to this question was false from an OM perspective.

In the second condition, volunteers received a pre-recorded non-spatial question rather than a spatial prime approximately four minutes into playing the game. They had to provide a true or false answer to the following question: During the game, most of the doors are open". The correct answer to this question was true, however, the amount of doors the volunteer saw depended on the route he or she chose in navigating around the environment to complete the task. However, the question was also presented in the inverse to avoid any particular response bias, and half of the participants in this condition answered the following question: During the game, most of the doors are closed". The question in this condition served as a control to ensure that simply answering a question would not cause people to re-represent their perspective of front or back (but that rather a question must cause people to specifically think in a way that involves a representation of front/back for this to occur).

Playing the EM game served as the embodied prime in this condition.

Once the participants had completed the task, the virtual young woman they sought congratulated them and they were asked to complete the target task: "*Move to the front chest*". The two chests were located on the left of the virtual woman and were added from the *UnReal* directory of furniture to maintain continuity in the environment. Upon completion of the target task, participants were given a short debriefing.

[4] Pre-testing had shown that this question, which is true from an OM perspective, was unambiguous and ordinarily answered from the OM perspective. Out of 20 participants, 90% allocated the term *front* in an OM perspective. A binomial test confirmed this as significant; $p<.001$.

Results

Participants responses for the target task are shown in Figure 3. Out of the total 36 participants, two (5%) did not answer the prime question consistently (i.e., to the OM prime: During the game, the green pillar is in front of the red pillar , they answered false when the correct answer was true). Their data were not used in the following analyses.

Analysis showed that when participants received the OM prime, requiring them to specifically think in a way that represented a particular schema of motion, 75% of them interpreted the *front* chest in an OM consistent manner, despite playing the EM game for a further 2-3 minutes *after* answering the prime question. However, when participants were simply immersed in a game which embodied EM motion, and were not required to specifically (or explicitly) think about that motion (instead, they were required to think about doors), 83%of them were influenced by the nature of motion in the game and interpreted the *front* chest command in an EM schema consistent manner.

A chi-square analysis revealed a significant effect of the type of prime participants received on how they interpreted the term *front* to apply to an ambiguous target task: $\chi^2(1)=11.691$; $p<0.001$.

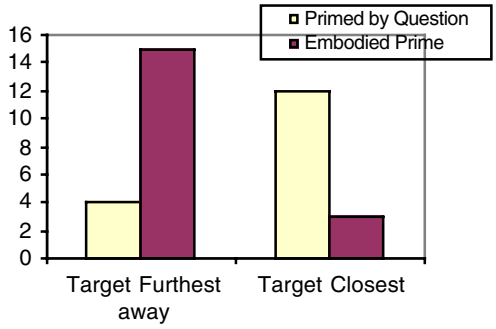

Figure 3: Target responses in each prime condition

Discussion

This experiment seems to suggest that thinking about space can override the role of spatial experience in our understanding of spatial concepts. Participants who were cued to think using a particular schema of motion (OM), overcame the schema of motion they were experiencing (EM), and responded ina consistent manner with the way they had been cued to think about space. Participants who received a random question, unrelated to any system of motion, were influenced by the schema of motion in the game (EM) and responded to the spatial task consistently with their experience.

Although the video prime in this experiment involved the participant in an EM schema of motion, there might be some criticism against the embodied prime as participants only perceived the visual environment, rather than physically experienced it. Such criticism seems unjustified in this case. As Lishman and Lee (1973) argue, perception is powerful enough to direct kinaesthesis or movement. They claim that a person relies heavily on visual kinaesthesis, in many situations, for example, driving, and swimming in a current, a person is *dependent* on vision to sense how he is moving relative to the static environment (p. 288, emphasis theirs). They also argue that individuals experience a sensation of motion when visual scenes change, but they are stationary. They conducted a series of experiments where individuals were placed in a stationary trolley in a moving room. The room was moved independently from the trolley located in it, so the participants saw the room move, although thetrolley they were standing in was completely stationary. Lishman and Lee record participants as perceiving the trolley to move as well, eventhough they were stationary. The participant also swayed together with the room in an apparent attempt to keep himself stable with respect to his static environment (p.292). Participants felt the experience was like being on a boat, and several felt quite nauseated afterwards.

In this virtual reality experiment, several participants had similar experiences and even commented on feeling rather ill after playing the video game for a few minutes. One participant asked if she could leave because she felt so nauseated. Often, participants shoulders were seen to move in sync with a right or left turn they made in the virtual environment, and many participants remarked on feeling dizzy after completing the experiment. This confirms the importance of perception in directing our sense of motion, and suggests that visually experiencing motion in virtual reality provides a similar sensation to a physical experience of motion.

Experiment Two

While the first experiment examined the influence of simple experience versus explicit thought in our understanding of motion in space, this experiment explored whether simple spatial experience or thinking about space would be more influential in mapping information about motion from the domain of space to time. Participants were immersed in an embodied environment and were presented with an ambiguous target temporal task after receiving either a purely embodied priming, or embodied priming during which a linguistic prime had cued them to think in terms of a contrary spatial schema.

Participants

Thirty-nine Edinburgh University students volunteered to take part in this experiment.

Materials

The participants played the same video game as described in Experiment 1.

Procedure

All trials were conducted on a Wednesday. Participants were tested individually in the virtual reality lab and were asked to fill in a brief questionnaire containing the same instructions given in Experiment 1. They were also informed that they would be required to return next Wednesday if they were successful in accomplishing the task in the game. This information provided a connection between the target question (see below) and the experiment, as the participants would interpret Next Wednesday s meeting in the target question as a further experiment, rather than an unrelated question.

Participants were then shown the game and began playing. There were two conditions. Approximately four minutes into playing the game, the participants in the first condition received the linguistic prime cueing them to think the in an OM perspective. Again, they had to respond with either true or false to the question During the game, the green pillar is in front of the red pillar . (Once again, half of the participants in this condition received the inverse question.)

In the second condition, instead of receiving a prime that cued spatial thinking, the participants received the non-spatial question approximately four minutes into playing the game During this game, most of the doors are open . (Again, half of the participants in this condition received the question in the inverse.)

Once participants had successfully completed the game task (finding a virtual young woman; all participants were successful), the experimenter congratulated them and then informed them that "*Next Wednesday's meeting has been moved forward two days* and asked *What day is the meeting now that is has been rescheduled?*" (the ambiguous temporal question used in McGlone and Harding, 1988, and Boroditsky, 2000). After participants had given their answer, they were given a short debriefing.

Results

Out of the total 39 participants, three of the participants (8%) did not answer the prime question consistently (i.e., to the OM prime: During the game, the green pillar is in front of the red pillar , they answered false when the correct answer was true). Data from those participants who provided incorrect answers to the prime were eliminated from the analyses.

Participants responses to the ambiguous target question were examined, and once again, the results revealed that the type of prime participants were presented with significantly affected their disambiguation of the target temporal question. The participants who received the cued OM prime during the game (which required them to adopt an OM schema for thinking of motion in answering the question) were more likely to interpret the term *forward* from Wednesday as Monday (65%) rather than Friday. In comparison, 74% of the participants who were influenced by the embodied EM game, but did not have to explicitly think about schemas of motion in answering the in-game question considered the new meeting day to beFriday rather than Monday (see figure 4).

A chi-square revealed that the type of prime the participants received significantly affected how they disambiguated *forward* in the temporal target task: $\chi^2(1)=5.355$; $p<0.05$ (one-tailed).

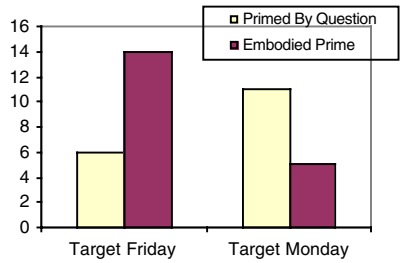

Figure 4: Target responses in each prime condition

Discussion

These results suggest that our concepts of motion in the domain of space can influence how we understand motion in the domain of time. However, while the embodied position suggests that it is our experiences in space that ultimately affect how we think of time, this experiment reveals that how you *think* about motion — even in abstract terms, such as in response to a question — also plays a significant role in influencing our concept of time. Although they participants continued to play a game which embodied an EM spatial perspective *after* they answered their question, participants who answered questions which required them to think in an OM manner answered an ambiguous temporal question in a TM (and thus OM, see Boroditsky, 2000) consistent manner, whereas participants who had played the EM game but not been required to explicitly think about time answered the ambiguous temporal question in an EM consistent manner. This indicates that although spatial experience can influence temporal thought, this influence can be over-ridden by explicitly thinking about space, suggesting that people s conceptual representations of space and time are functionally separable from their embodied experiences of space and time (see also Boroditsky, Ramscar, & Frank, this volume).

General Discussion

In two experiments, we have shown that explicitly thinking about space — in order to provide answers to questions cueing the *object-moving* metaphoric system - could significantly reverse a task bias to assign FORWARD in an *ego-moving* manner.

If, as Lakoff and Johnson (1999) suggest, language is ultimately the slave of our (universal) embodied thought, then we would have expected pure embodied priming to have at least as much an influence as abstract thought. However, this was not the case (see also Boroditsky et al, this volume).

These results suggest that a proper characterization of conceptual thought will need to look beyond the information that comes from physical experience, and consider as well the ways in which languages and cultures affect thought.

Acknowledgements

We thank Lera Boroditsky for many insightful discussions, and Jon Sykes for his assistance in programming the virtual environment.

Coordinating Representations in Computer-Mediated Joint Activities

Richard Alterman, Alex Feinman, Josh Introne, Seth Landsman
Department of Computer Science
Brandeis University
Waltham, MA 02454 USA

Abstract

This paper develops, in the context of the interdisciplinary literature on coordination, the concept of a *coordinating representation* as an everyday method for structuring the coordination of actors engaged in a non face-to-face joint activity. Evidence is provided by applying the idea of coordinating representation to the development of a computer-mediated cooperative activity.

Introduction

A critical reasoning problem confronted by actors as they engage in their everyday activities is the maintenance of coordination (Clark, 1996). Within a community of actors, designs that organize (structure) behavior in recurrent situations of cooperation develop over time. Once developed, the expectation that a given sort of structure might be in place for a given kind of situation simplifies the interaction among the participants while reducing mental effort, physical work, and errors (Alterman & Garland, 1998). In non face-to-face interactions, structures that simplify the coordination of a conventional behavior are coded into a *coordinating representation*. The coordinating representation helps the participants to jointly make sense of the situation in the absence of a face-to-face interaction.

An everyday example of a coordinating representation is the "stop sign". The stop sign is a representation shared among the participants at a traffic setting. The stop sign presents a structure for organizing the collective behavior of drivers, pedestrians, and cyclists at a busy intersection. The interpretation of the structure imposed by the stop sign is negotiated during the activity. Things may run smoothly at the intersection - but there will also be interruptions. An impatient driver piggybacks on the driver in front of him. A pedestrian decides to ignore the stop sign altogether.

The first part of this paper will develop the notion of a coordinating representation in the context of the interdisciplinary literature on coordination. The second part focuses on the cognitive engineering task of building coordinating representations for computer-mediated joint activities. The last part of the paper presents an experimental evaluation of the utility and function of the coordinating representation.

The Problem of Coordination

Whether it is greeting someone, or planning a potluck dinner party, or moving through a doorway, or forming a queue at the coffee shop - there are always problems of coordination. When you greet someone, depending on the circumstance, you may say “hi", shake hands, slap hands, hug, kiss, or ignore. Each form of greeting (except the last) requires coordination (and cooperation) among the participants. For a potluck dinner party, the meal must be coordinated for taste, balance, and variety. The meal can include appetizers, main courses, desserts, and beverages; a preponderance of one or the other detracts from the meal. For many doorways, there is not enough room for two people (say, in conversation) to pass through the doorway shoulder-to-shoulder. To effectively move through the doorway the participants must coordinate on an order as to which one passes through the doorway first, second, ... and who is to hold the doorway open. The queue at the coffee shop begins and ends at a certain place; people line up in the order they arrive.

Some examples of coordination problems are the assignment of roles, the establishment of location, manner, and structure, and issues of sequencing; timing and co-reference.

Suppose Tipper and Al are re-arranging furniture in the house. Each of the above kinds of coordination problem may come into play as they move the old couch from the living room, down the stairs, around the corner, through a doorway into the basement. Al's role may be to back down the stairs holding the front of the couch; Tipper walks forward holding the backend of the couch. Initially they meet in the living room. Their path as they carry the couch begins in the living room and ends at the basement. Their manner may be slow and cautious, so as to avoid bumping into walls and doorways. At certain points they are tilting the couch at an angle so they can move down the stairwell without bumping the couch into the ceiling. Coordination at *the boundaries between phases of the activity* (Clark, 1996), must be jointly engineered by Tipper and Al as they shift from moving down the stairs to moving through the doorway. In order to move the couch down the stairs, Tipper and Al need to establish co-references for features of the stairwell (e.g., the low ceiling) or the situation (e.g., an unexpected problems they encounter). Some of the coordination problems are 'solved' before

action begins (e.g., Al walks backwards and Tipper walks forwards); others are resolved as the action proceeds (e.g., the coordination problems entailed by the low ceiling in the stairwell).

The term *structure for behavior* is used here to refer to the kinds of information exchanged between Tipper and Al in order to achieve their joint task and maintain coordination - examples of which are the assignment of roles, the path, the manner… Not all the information exchanged is a structure for the current behavior. For example, Tipper and Al are also socializing as they proceed with their activity. Nor are all structures for joint behavior exchanged at runtime: both Tipper and Al are likely to have prior experience at moving a couch through a doorway. Using both the social exchanges of information about structure and the recollection of prior related experiences, the participants must jointly reason out and construct a behavior which achieves their shared goal of moving the old couch from the living room to the basement.

The structures relevant to a given act in the current activity that are available before the act may be either recalled, planned, the result of an explanation, or designed. Both Tipper and Al may remember previous occasions when they moved furniture. For the difficult portions of their task, they may explicitly create a shared plan (Grosz & Sidner, 1990), an agreed to structure - you do this and I'll do that - for the behavior. If the structure for behavior is produced after a given behavior is completed, it is called an explanation (Mitchell, et. al., 1986), which can become realized in future related episodes of joint activity. Over time, for joint activities that Tipper and Al regularly do, behaviors become conventionalized and designs for the structure of those behaviors will begin to emerge (Alterman & Garland, 1998).

As Tipper and Al perform their activity, the fact that they are co-present allows them to monitor the progress of their joint activity. Because they can see one another, they can use body position to communicate information. Throughout their activity they can speak to one another in order to co-develop, for example, a procedure for moving the couch down the stairway. Their comments to one another are exchanged without delay, in the course of their joint behavior. The actions that form their conversation and activity occur sequentially.[1]

Other kinds of joint activity do not allow for a face-to-face interaction, so other methods or mediums must be introduced to support the exchange of structural information. Performance depends on the participants communicating - by these altered means - information relevant to design, plan, and commitment. For computer-mediated tasks, the trick will be to convert structures (designs) that are naturally produced in conversation by the users into external representations that can mediate similar sorts of cooperative activities in the future. The design of the external representations that are developed will focus on simplifying the most difficult coordination problems that typically confront users.

The Coordinating Representation

A coordinating representation is an external representation shared among participants in a joint activity. It is designed for the activity-at-hand and reduces the complexity of the coordination task. It mediates and structures the activity. It has the designated purpose of helping participants to achieve coordination in non face-to-face cooperative activities. Its meaning is based on conventional interpretation. It signals to the participants - without dictating action - that a convention of behavior is in place.

Consider the scene at the airport. For the passenger, the printed itinerary that her travel agent sent her helps her to stay coordinated. The itinerary identifies her flight destination and number. When she arrives at the airport, she uses the listed flight number to select among the flights and gates listed on the departure monitor for American Airlines. The design of the destination monitor (first listed in alphabetical order of destinations and then by time of departure) reduces her cognitive load in finding the departure gate for her flight. When it comes to finding her departure gate, the itinerary and the departure monitor are two coordinating representations that help to replace a face-to-face interaction with a mediated one.

Alternately, suppose the passenger needs to "check in" some luggage before proceeding to her gate. What coordinating representations are used to insure her bag makes the trip? Now, upon arrival at the airport, the passenger looks for the check-in counter for the airline from which she purchased her ticket. Large signs displaying airline logos indicate where each airline is located. Smaller signs divide the queue into first class and regular passengers. As the passenger puts her bag on the scale, the clerk attaches a tag indicating airline, flight destination, and flight number. Later, a bagger must transport in a truck the bags to the cargo space of the plane. A *complex sheet* that links flights to destinations and unique aircraft identification numbers is used by the bagger to achieve his goal (Goodwin & Goodwin, 1996). The organization of the complex sheet makes the access of information more efficient.

Each of the coordinating representations used to get both the passenger and her luggage on the correct plane has both a social and an individual function. From the perspective of the social, the coordinating

[1] This list is adapted from an analysis developed by Clark & Brennan (1991) to explicate differences among various kinds of mediated communication.

representation preserves a set of references for objects shared among the participants. From the perspective of the individual, the coordinating representations simplify access to the information that is being exchanged.

There are many other examples of coordinating representations in everyday life. An appointment slip helps a patient to return to the dentist's office on the right day at the right time. A mail order catalogue helps the customer and the sales office reach agreement on purchase items, sizes, and prices. Tax forms help to coordinate citizens and IRS personnel in their efforts to exchange information....

Experimental Platform: VesselWorld

For the last several years we have been building a same time/different place groupware system (VesselWorld) as an experimental platform for analyzing real time computer-mediated collaborations. A demo of the system was run at CSCW 2000 (Landsman et. al., 2000).

There are several important characteristics of the joint activity of participants in a VesselWorld problem-solving session. Participants have different roles (both predefined and emergent). Cooperation and collaboration are needed to succeed. Participants must develop a shared understanding of an unfolding situation to improve their performance. Uncertainty at the outset makes pre-planning inefficient in many circumstances. There are numerous problems of coordination.

In VesselWorld, there are three users engaged in a set of cooperative tasks that require the coordination of behavior in a simulated environment. In the simulated world, each participant is a captain of a ship, and their joint task is to find and remove barrels of toxic waste from a harbor. Two of the users operate cranes that can be used to lift toxic waste from the floor of the harbor. The third user is captain of a tugboat. The cranes are able to individually lift and carry small or medium toxic waste barrels, jointly lift large barrels, and jointly lift (but not carry) extra large barrels. The tugboat cannot lift barrels, but can attach to, and move, small barges. Small barges may hold multiple barrels. Each captain has a small radius of perception. Many barrels require the use of other equipment in addition to the cranes. The tugboat captain is the only one who can examine barrels to determine equipment needs. Barrels can be leaking - or will begin to leak if they are dropped - in which case the leak must be contained by the tug.

The VesselWorld interface provides to each user several different windows of information. The World View (not shown) depicts the harbor from the point of view of a participant, who can only see a limited region at one time. The World View graphically represents several kinds of information about the location and status of objects from the perspective of an individual participant. A second window of information is used for planning. A third window allows a user to access more detailed information about visible objects. A chat window allows participants to communicate with one another using an electronic chat.

In a base version of the VesselWorld system, participants can only coordinate by electronic chatting. Most of the participant dialogue is centered on the barrels, and how effort can be coordinated in removing the barrels from the harbor and transporting them to a large barge. During a problem solving session, the flow of information between participants using the base system is continuous. It is the responsibility of each actor to add information conveyed to him by another actor to his or her private representation (either by taking notes, marking the map, or remembering), or be prepared to examine the history of chatting at some appropriate future time. Any information that is lost, misunderstood, never recorded, or never transmitted in the first place, can lead to discrepancies between the participants' individual assessments of the situation.

An analysis of participant dialogue determines a set of problem areas in organizing behavior in relation to a shared domain object. So, for example, a large volume of information must be exchanged over the naming, status, location, and properties of the toxic wastes. In a second version of the system, coordinating representations are introduced that basically structure and simplify the exchange of information in the problem areas of coordination.

Analysis of Electronic Chatting

The electronic chatting amongst participants is used as a basis for developing some coordinating representations. As the analyst reviews the discourse, she needs to look closely at using coordinating representations to simplify the most common interactions, fix repeated errors in coordination, and replace conventions developed by users during the course of a problem-solving session. The goal is not to entirely replace other forms of communication with coordinating representations. Rather the analyst wants to use coordinating representations to improve performance - thereby simplifying the interaction - at critical points in the ongoing cooperation among participants.

The analysis was framed by cognitive work on the problem of coordination that was presented at the beginning of the paper. Figure 1 shows a list of the kinds of methods that were used by participants to coordinate their joint activities. The participants did some planning by assigning roles or agreeing to sets of actions. During the activity, a fair amount of chatting was used to initiate joint actions that were tightly coupled; for example, to lift an extra large waste, the cranes have to begin lifting during the same time

segment. Also found in the discourse were examples of the participants creating conventions to simply the exchange of information for recurrent problems of coordination. Chatting was continuously used throughout each session to establish references and exchange information about shared domain objects.

- Plan (provide orientation: delimit tasks)
  - Plan to do; Role assignments
- During Activity (Entry & Exit into Phases)
  - Synchronization; sequencing; step; turn-taking; Action taken; See; Initiating Statement
- Develop conventions
- Co-Referencing and the exchange of information
  - Refer to status, location, feature, identity of object

Figure 1: Taxonomy of coordination methods.

Figure 2 shows a sample dialogue of the kind of close coordination users needed to do in order to time closely coupled activities. At 1 and 2, after jointly lifting a large barrel, Crane1 and Crane2 agree to do a joint carry followed by a joint load onto a barge. It will take three moves to reach their destination. In lines 3, 4, and 5, they tell each other they submitted their first move. At 8 the tug suggests a convention to simplify coordination. At 9 and 10, Crane1 and Crane2 tell each other they are ready to do the second part of the move. At 14, Crane1 states she is doing the third move. At 15-18 they plan, and then they submit actions, to do the joint load. At 21 and 22, they celebrate.

1. Crane1: now a joint carry, clicked at 375,140 got 3 carrys
2. Crane2: i will do same
3. Crane2: move to first location
4. Crane1: submitted first
5. Crane2: ditto
6. Crane1: again?
7. Crane2: yes
8. Tug1: do you want to just type something in after submitting each turn
9. Crane1: submitted second
10. Crane2: ditto
11. Tug1: just some shorthand or something, for everyone so we know whats going on
12. Crane1: submitted third
13. Tug1: submitted
14. Crane2: submitted third
15. Crane2: Crane1: load, and then i'll to the same
16. Crane1: submitted load
17. Crane2: ditto
18. Tug1: submitted move
19. Crane2: hey, i think that worked!
20. Crane1: looks like it's Miller time. I think we did it.

Figure 2: A sample dialogue

Three Coordinating Representations

The analysis of the pilot study discourse identified three recurrent areas of coordination activity:

1. Timing of closely coupled activities
2. Establish references for, and exchange information about, shared domain objects and their status.
3. Higher-level planning to manage multiple cooperative activities

None of these should be surprising as possible areas of difficulty: each of these has been suggested by prior theoretical analysis. But there are also other potential problem areas. So the problem for the cognitive engineer is to determine which things are problematic for the task-at-hand.

Some sketches of three coordinating representations were developed and later refined through an interview with one of the test groups in the pilot study.[2] After the interview, the iterative design process continued by a cycle of (re)design, implementation, and evaluation. The periodic evaluation came in several forms, including expert reviews, in-group experimentation, and study groups paid for at Brandeis University. What resulted from this process were three coordinating representations that were designed both to simplify the interaction among participants (the social part) and structure it so as to reduce the cognitive load of each user (the individual part) in her use of the mediating representation.

The coordinating representation showed in Figure 3 allows a user to compare his projected actions to those of the other participants. The next few projected steps of each actor is displayed in a labeled column for each participants. The actions are listed in order from top to bottom. (So, the next projected step of Crane1 is to do deploy equipment and then he will lift some waste.) Each user has control of only one column, his/her own. This representation improves timing on exit and entry of phases for tightly coordinated phases of activity by allowing participants to compare each other's next few projected actions.

Figure 3: Timing of joint actions.

The second coordination representation is the *object list,* which contains a list of objects with relevant

[2] S. Kirschenbaum at NUWC collected the data for this pilot study.

properties in a table format. Columns provided information about the name, object type, location, and equipment needed for a given object. The organization of this information reduces the cognitive load for the individual, by organizing information relevant for decision making into predetermined representational structure.

A third coordinating representation was designed to allow the users to do *high-level planning*. The idea was to create a space where the participants could rapidly sketch a high-level plan that would help them to manage multiple open tasks. There are three columns in this window: one for each actor. Each column could be used, for example, to abstractly represent that each actor is currently searching a different part of the harbor. Further down each column, the participants could indicate that they are committed to a plan to move, in order, wastes 1, 2, and 3 onto a small barge. A palette at the top the window allows users to rapidly build a description of a joint action sequence. Actions are one of a small set of action primitives, i.e., MOVE, SEARCH, and CONTAIN. Color-coding of entries in the high-level plans allows participants to indicate both accomplished tasks and future commitments.

Experimental Evaluation

An experimental evaluation conducted at Brandeis compared the performance of teams of participants with (and without) the coordinating representation. Three groups could only electronically chat during problem-solving sessions, and three groups could chat but also had access to coordinating representations. Each team was trained and then played for about 10 hours over several sessions of problem solving. All events that occur during a problem-solving session are recorded in a log file by the system. A VCR-like device was used to review and analyze the decision making of each group. A more complete discussion and detailed analysis of the experimental data, with numerous examples, can be found in Alterman et al (2001).

Quantitative Analysis

One measure of general performance is the amount of clock time it took the participants to solve a problems:[3] there was a 49% improvement in clock time to complete task for those groups using coordinating representations. Another measure of user work indicates that there was a 38% reduction in the number of events generated while completing tasks of comparable difficulty. Because the coordinating representations pre-structure certain exchanges of information we expected to see a reduction in the quantity of electronic chats: there was a 57% reduction in the amount of electronic chatting. Because one of the coordinating representations dealt with commitment (high-level planning), another with timing, and a third with the exchange of information about equipment requirements for lifting barrels, we expected to see a reduction in domain errors: total errors were down 61%. However, a closer analysis of the data reveals that the high-level planning coordinating representation was used hardly at all. Further discussion of this last point is below.

[3] These results have 95% confidence intervals and are normalized for the complexity of the problem. Problem complexity is a weighted sum over all wastes taking into account size, equipment needed, and distance from large barge for each waste.

Qualitative Analysis

For the groups that did not have access to coordinating representations, the predominant method for maintaining a common view of the world was for the participants to continuously *report* on their current activity via electronic chatting. One strategy for avoiding differences in assessment was to engage in a conversation to *review* the status of one or another of the shared domain objects. Whenever discrepancies in the assessment of a situation unexpectedly developed the participants engaged in *repair* work to re-mediated between alternate representations of "reality". Participants also regularly *confirmed* that somebody else's report or repair was received. Each of these techniques was important to the functioning of the groups using the basic system in maintaining a joint sense of their common enterprise. These groups also developed additional structures to simplify the exchange of information using the electronic chat window. The simplest of these were naming conventions. A second example was a set of conversational structures that were developed by each group to support coordination of closely coupled actions.

The general advantage of the coordinating representation was that it simplified the problem of establishing a consistent representation of the situation among the participants.

One advantage that accrued to the users who had access to the coordinating representation that supports the *timing of joint actions* is that it required no extra work on the part of the participants to build. In order to submit an action to the system the users needed to add it to their "plan" anyway. So, from the point of the view of the users who have access to the shared planning window, having to talk about their cooperative activity is just extra work. Another advantage was that one actor now has the opportunity to spot potential problems in another actor's plan.

Much of the dialogue that accompanied the discovery of a new waste in the groups using the basic system was mediated by the *object list* for the groups that had

access to coordinating representations. Identifiers were attached to each of the "objects" that were found. Pointing and clicking was used to add entries to the object list, thus precise locations for each of wastes that were found could be stored. These aspects of the object list simplified the process by which the actors established references and referents. Because the object list was a shared representation, much of the consistency checking that the users of the base system had to engage in was no longer necessary. Rather than having two private representations that must periodically be reconciled by electronic chatting, the users could share a single representation. This scheme reduced the number of conflicts between different conceptions of the shared workspace, but it also eliminated the work involved in re-mediating discrepancies between alternate views of the shared domain objects.

The high-level planning window was not used by any of the groups. The surveys we collected from the subjects show that the chief problem with the high-level planning windows was that, given the rewards it provided, it required too much work to complete. Further analysis shows that the problems that the high-level planning window was designed to fix continued to occur.

We are developing two solution paths to fixing this problem. The first is to do a better job of modeling the work of the individual user in cooperation with the other users (Feinman & Alterman, 2001). The second approach is develop some AI techniques that would allow the system to fill out portions of the high-level planning window semi-automatically (Introne & Alterman, 2000).

Concluding Remarks

The overarching interest of this research is to continue to develop a framework for Cognitive Science that depends not only on the mental operations of the individual but also on the social interaction within which it is embedded. (An underlying thesis is the cognition is irreducibly social.) Application domains involving the computer-mediation of joint activity are significant areas of research because they allow one to investigate both the social and individual aspects of cognition. The methodology that was used for developing coordinating representations for VesselWorld reflects these commitments and attitudes. There are two parts to the methodology: a social and an individual one. During the social part, the developer can collect data on the usage of the base system and do an analysis of the information exchanged among participants (a discourse analysis) that helps them to stay coordinated. A key is to identify recurrent problems of coordination that showed up in the pilot version of the system. During the individual part, the designer tunes the initial approximations for coordinating representations to the cognitive operations of the individual user. During this phase, representations are iteratively designed to simplify the work of the individual user in creating and accessing the coordination information that is shared among the participants.

An Integrative Approach to Stroop: Combining a Language Model and a Unified Cognitive Theory

Erik M. Altmann (ema@msu.edu)

Michigan State University

Douglas J. Davidson (doug@eyelab.msu.edu)
Department of Psychology
University of Illinois at Urbana-Champaign

Abstract

The rich empirical puzzle of the Stroop effect has traditionally been approached with narrowly focused and somewhat atheoretical models. A recent exception is a simulation model based on the WEAVER++ language theory. The present model, WACT, combines components of WEAVER++ with the memory and control processes of the ACT-R cognitive theory. WACT accounts for the time course of inhibition from incongruent word distractors, facilitation from congruent word distractors, the lack of effect of color distractors, and the semantic gradient in inhibition. WACT goes beyond WEAVER++ to account for Stroop performance errors as well as latencies, and its implementation in a unified cognitive theory opens doors to broader coverage of Stroop phenomena than standalone models are likely to attain. Documented and executable code for WACT is available for inspection and comment at **www.msu.edu/~ema/stroop**.

Introduction

The Stroop effect is the mental confusion (and its behavioral consequences) induced when a word such as green is printed in a color such as red and the task is to name the color (red, in this case). Word meaning (green, in this case) seems to be processed automatically, in some sense, causing it to interfere with the color-naming task. Thus, the system may think green even though it sees red, because it can't stop itself from reading the word.

The rich pool of data on the Stroop effect (see MacLeod, 1991) has to date been approached with relatively lean cognitive theory. For example, the dominant simulation models remain the connectionist models of Cohen, McClelland, and Dunbar (1990) and Phaf, Van der Heijden, and Hudson (1990). The former model shows that Stroop phenomena can be simulated with simple information-processing units appropriately wired together. However, it makes no obvious contact with other cognitive theory – there are no identifiable linguistic or perceptual constraints, for example. Also, the model fails to capture the time course of inhibition, in which inhibition falls off gradually as the distractor occurs further ahead of the target (Glaser & Glaser, 1982; Glaser & Glaser, 1989; Sugg & McDonald, 1994). Indeed, simulated interference increases monotonically with temporal separation (Cohen et al., 1990, Fig. 7), suggesting basic flaws in the model's representation. The SLAM model (Phaf et al., 1990) is embedded in a theory of visual attention, but says little about the role of memory and executive control, and fails to capture the time course of inhibition (their Fig. 14a) and the asymmetry of reading and naming (their Fig. 14b).

Our approach to modeling Stroop effects is to integrate existing theory from other cognitive domains. Our model adopts mechanisms of the WEAVER++ language theory (Roelofs, 2000c), which explains Stroop phenomena in terms of competing lemmas (syntactic properties of words; Roelofs, 2000a, 2000b). These linguistic mechanisms are integrated into the ACT-R cognitive theory (Anderson & Lebiere, 1998), which specifies memory and executive-control mechanisms. The resulting model, which we refer to as WACT, goes beyond WEAVER++ to account for errors as well as latencies, and benefits from its embedding in ACT-R in terms of potential extensions to other phenomena. ACT-R suggests how automaticity of the dominant Stroop task might develop (MacLeod & Dunbar, 1988), and implements a theory of perceptual, motor, and cognitive constraints (Byrne & Anderson, in press) that could integrate a diverse range of Stroop effects into one model.

We begin by describing the effect to be explained – the time course of Stroop inhibition, in which latency and errors increase as distractor onset approaches target onset (Glaser & Glaser, 1989). We then describe WACT and its account of these effects, as well as its account of Stroop facilitation, a semantic gradient, and the non-effect of color distractors. In the discussion, we examine WACT's limitations and some possible extensions suggested by ACT-R.

The Time Course of Stroop Inhibition

Figure 1 illustrates the Stroop effect of primary interest here. The empirical data (solid lines) are from Experiment 1 of Glaser and Glaser (1989), in which a word and a color are shown with some temporal separation. Of interest here is the case in which the word (appearing first) is the distractor and the color patch (appearing second) is the target (the stimulus to which the participant responds). Thus, the word green might precede the color red by 100 msec. This temporal difference is the stimulus onset asynchrony (SOA). By convention, SOA is negative when the distractor precedes the target.

The latency difference measure in Figure 1 is derived by subtracting neutral latencies from incongruent and congruent latencies. On neutral trials, the distractor is a stimulus that consists of letters but is not a color word (e.g., xxxx). On incongruent trials, the distractor is a color word whose meaning conflicts with the color patch (e.g, green and red). On congruent

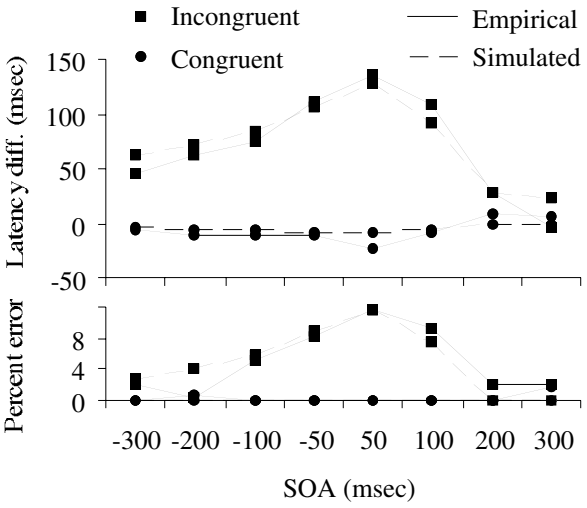

Figure 1: Stroop inhibition and facilitation. Latency difference is Incongruent/Congruent minus a neutral condition (see text). Stimulus onset asynchrony (SOA) is target onset minus distractor onset. Empirical data are from Glaser and Glaser (1989), Exp. 1, and simulated data are from WACT.

trials, the distractor is a color word whose meaning matches the color patch (e.g., red and red). In all three kinds of trials, the target stimulus is the color patch.

In Figure 1, the upper curves in each panel (square markers) are from incongruent trials, in which the distractor interferes with the target. As is typical, interference is greatest (i.e., the latency difference is greatest) when SOA is near zero – when target and distractor appear at roughly the same time. Note that even if the distractor occurs slightly after the target (e.g., an SOA of 50 msec), it still causes substantial interference. The lower curves in each panel (round markers) are from congruent trials, in which the "distractor" actually slightly facilitates performance.

The error measure in Figure 1 is the raw percentage of substitution errors, or trials on which the wrong response word was given. (With no detectable facilitation from congruence, there is no need for a difference measure.) Only incongruent naming is particularly error prone, and there, as with latency, interference is greatest at near-zero SOA.

The WACT Model

Long-term lexical knowledge in WACT is organized in a multi-layer declarative network, as shown in Figure 2. The top level of this network contains semantic nodes, or concepts. Below this is the lemma layer, which contains syntactic information (lemmas) crucial for fitting a word into the grammatical organization of a phrase or sentence. Below the lemma layer is the form layer, which contains the information necessary to produce an individual word.

In WEAVER++ and WACT, interference and facilitation occur at the lemma layer. Word stimuli have direct access to their lemmas, whereas non-verbal

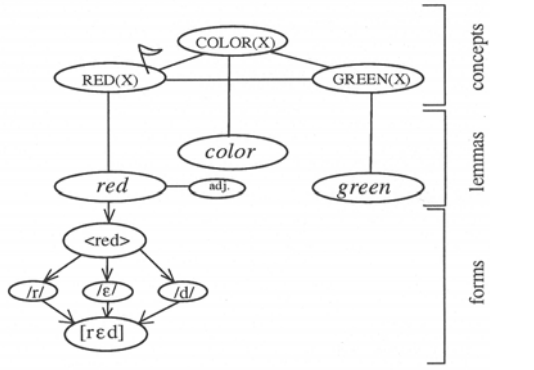

Figure 2: WEAVER++ long-term lexical knowledge (from Roelofs, 2000a). WACT represents concepts, lemmas, and the top layer of forms (e.g., <red>).

stimuli like colors gain access only indirectly, via concepts (Figure 3). The direct link from a word stimulus to its lemma is the route by which words trigger automatic language processing. The benefit of this automaticity is efficiency, helping the system to meet immediacy constraints on comprehension (Just & Carpenter, 1987). The cost of this automaticity, on our view, is that it leaves behind traces of information that can interfere with subsequent tasks like color naming.

A word stimulus automatically activates the corresponding lemma. We assume that the purpose of this activation, relative to language comprehension, is to facilitate parsing of subsequent tokens. For example, the stimulus "and" might establish an expectation for a subsequent conjunct, by virtue of causing the "and" lemma to be active when the conjunct arrives. Stroop interference (and facilitation) are caused by the activation of a lemma for the distractor word. If this distractor lemma is incongruent with the target lemma, it produces a form of response competition when the system tries to retrieve the target lemma. On the other hand, if the distractor lemma is congruent with the target lemma, then the system benefits from intrusions of the distractor lemma.

In WEAVER++ and WACT, latency to retrieve a target depends on the target's activation relative to distractors – the more active the target is relative to its distractors, the quicker it is retrieved. Relative activation is a common way to formalize interference (Baddeley & Hitch, 1993; Luce, 1959; Murdock, 1985; Neath, 1993). In ACT-R the formulation is

$$P_i = \frac{e^{A_i/s}}{\sum_j e^{A_j/s}} \qquad \text{Equation (1)}$$

where P_i is the probability of retrieving item i on a given attempt given the j items in memory at the time. A_i is the activation of i, and s is system noise.

Importantly, WACT (unlike WEAVER++) specifies the processing consequences of retrieving the wrong item on a given attempt. WEAVER++ predicts latency simply by scaling relative activation. WACT actually uses the retrieved lemma to decide how to respond, so

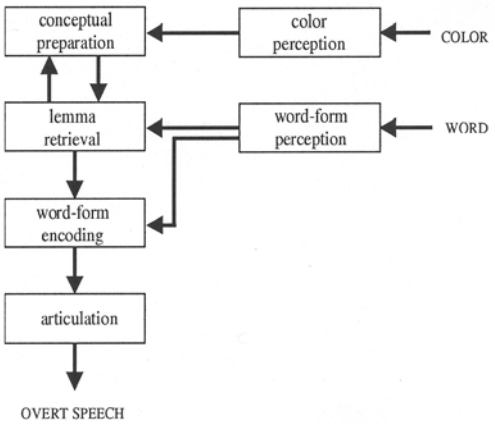

Figure 3: Stages of linguistic processing in WEAVER (from Roelofs, 2000a) and in WACT.

there is the possibility of an incorrect lemma retrieval causing a substitution error.

The lemma-retrieval process is shown in Figure 4. The figure is taken from Murdock (1974), but retrieve-decide models like this are common (e.g., Anderson & Bower, 1972; Kintsch, 1970; Watkins & Gardiner, 1979) and map naturally to ACT-R memory-retrieval productions. Such a process also explains tip-of-the-tongue effects, in which subjects appear to monitor correctness of retrievals (e.g., Levelt, 1983). Probed with a word stimulus, the system tries to retrieve the corresponding lemma. Any retrieved lemma is evaluated (in the decision process) by comparing the current concept to conceptual cues retrieved with the lemma. In case of a mismatch, the system tries again. Eventually the system retrieves a lemma it considers correct, or runs out of time. Either way, the last lemma retrieved is the basis for form retrieval (the next stage of language production; Figure 3). If the last lemma retrieved is incorrect, then form processing begins with the wrong input, likely causing a performance error. Thus, the distractor lemma interferes with the target lemma by affecting the duration and potentially the output of the lemma-retrieval process.

In WACT, the amount of interference caused by a distractor lemma depends on its activation, which in turn depends on the time elapsed since the distractor stimulus was presented. Activation in ACT-R is

$$A = \ln(\frac{2n}{\sqrt{T}}) \qquad \text{Equation (2)}$$

where n is the number of times the item has been retrieved and T is the length of the item's lifetime. For a distractor lemma, T=n=1 when the distractor stimulus is presented. After that n remains essentially constant, but T increases throughout the trial, causing A to decrease (decay). Thus, the more time elapses between distractor and target, the more the distractor lemma decays and the less it intrudes on the target lemma.

To illustrate, Figure 5 shows activation values from Monte Carlo simulations of naming trials at various SOAs. The top curve is the activation of long-term lemma representations. For these representations, n and

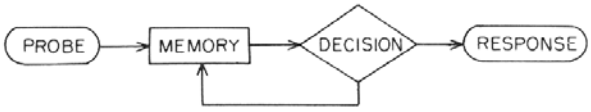

Figure 4: The WACT retrieve-decide process for lexical retrieval (from Murdock, 1974).

T are both large, so activation is stable over short intervals. The bottom curve is activation of the distractor lemma. At large negative SOAs, the distractor lemma decays by the time the target appears, but at near-zero SOAs its activation is close to that of long-term lemmas. Syntactic representations are known to decay rapidly (e.g., Potter & Lombardi, 1990; Sachs, 1967), and here this rapid decay explains the time course of Stroop interference. On an incongruent trial, the system must retrieve a long-term lemma in order to process the target correctly, and this retrieval is faster and more accurate if the distractor lemma has decayed.

Two other comments on Figure 5 are in order. First, the activation values reflect the sum of two sources: base-level activation (A in Equation 2) and associative activation from cues like the current stimulus; these are the two possible sources of activation in ACT-R (Anderson & Lebiere, 1998). The sum of these two sources is the activation factor in the item's likelihood of being retrieved (A in Equation 1). That said, the scale on the ordinate of Figure 5 is arbitrary, because relative activation, not absolute activation, is what governs retrieval probability in WACT. A second point is that the lower curve ends at SOA 100. This means only that at SOA 200 and 300, the target lemma was always retrieved before the distractor appeared. When the target is retrieved in time to avoid interference from the distractor, the model implementation simply skips the step of activating the distractor lemma, as the trial is functionally over by then.

Comparing WACT to Data

WACT behavioral data, from the same simulations that produced the activations in Figure 5, are presented in Figure 1 (dashed lines). The fits are quite respectable: r^2=.98 and RMSD=11.0 for latencies, r^2=.94 and RMSD=1.4 for errors. The model clearly captures the peak in inhibition near zero SOA and the gradual falling-off (leftward) as the distractor word is presented

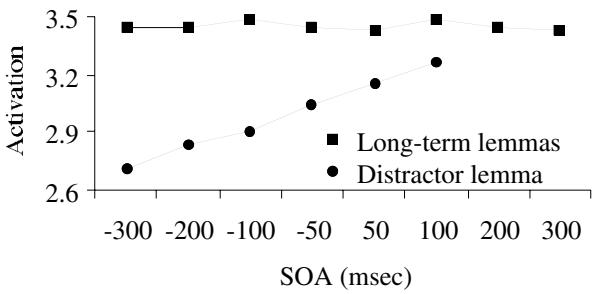

Figure 5: The time course of activation in WACT, showing decay of distractor lemma at negative SOAs.

further ahead of the target color. Inhibition also falls off sharply for positive SOAs (rightward), where the target is usually fully processed and the response formulated by the time the distractor appears.

WACT also captures Stroop facilitation, a common though relatively small effect. In the model, facilitation arises when a congruent distractor lemma is correct, in which case the "distractor" lemma is indistinguishable from the target. Functionally, activating a congruent distractor lemma is equivalent to a slight increase in activation of the target lemma.

An important "non-effect" captured by WACT is that a color distractor has no effect on word reading, either inhibitory or facilitative. In the model, color distractors have no effect because color stimuli are not processed ballistically, as words are. In response to a color stimulus, the system does not automatically activate a lemma; in terms of cognitive economy, there is no reason to process an arbitrary stimulus verbally unless the task requires it. Thus, a color distractor leaves behind no activated lemmas to interfere with the subsequent target word. This account is a point of distinction between WACT and WEAVER++, which accounts for the non-effect of colors not in terms of ballistic processing but in terms of levels of processing (Roelofs, 2000b; personal communication).

The Semantic Gradient

Beyond time course effects, another important effect captured by WACT is the semantic gradient, in which a distractor like "lawn" inhibits the naming of a target color like red. This inhibition arises presumably because lawn primes some representation of green, which then conflicts with the response to red. This effect is important because it is one of a class of effects involving higher-level semantic relations among categories (Glaser & Dungelhoff, 1984; Roelofs, 2000c). It is also an opportunity to compare WACT and WEAVER++, and to address a point of contention in how best to model gradient effects in ACT-R.

In WACT, the semantic gradient arises from operation of the retrieve-decide process (Figure 4) at the concept level. Earlier, we described this process operating at the lemma level, but in fact the process operates at each of the levels of speech production (Figure 3), as befits a general process for detecting and correcting memory errors. Thus, just as with lemma retrieval, when the model needs a concept, interference from incorrect concepts will degrade performance.

To illustrate how the semantic gradient arises, suppose the distractor word is lawn and the target color is red. When WACT sees "lawn", the lawn concept is activated as a side effect of processing the lawn lemma. The corresponding assumption in WEAVER++ is that activation spreads from lemma to concept in parallel as it spreads from lemma to form (Figure 3). In WACT, the lawn concept cues related knowledge through semantic priming. Among the concepts related to lawn is green – which also belongs to the response set for the current task (i.e., sometimes the target color is green). The combination of priming from the lawn concept and priming from the task environment is enough to cause the green concept to intrude occasionally on the concept for the actual target color. That is, having processed lawn, the model may think green, even if it sees red. Relevant data (from Exp. 5 of Glaser & Glaser, 1989) appear in Figure 6. The semantic gradient is represented by the small, positive latency difference across SOAs, reflecting modest interference from distractors like lawn. (The small peak at SOA 50, which Glaser & Glaser, 1989, attribute to random variation, is unrelated to the semantic gradient.) WACT again follows the trend, with distractors like lawn causing some interference but not as much as distractors like green.

The WACT account of semantic gradients may be another point of distinction relative to WEAVER++. In ACT-R, activation spreads only one link from whatever cues are in the focus of attention. Thus, spreading activation over a distance of multiple links requires a sequential process of chained retrievals in which each retrieval brings the next cue into the focus of attention. In WEAVER++, by contrast, activation spreads uncontrolled throughout the lexical network. Though attenuated by distance (number of intervening links) from the activation source, this uncontrolled spreading seems to make WEAVER++ quite sensitive to representational assumptions. For example, current reports (Roelofs, 2000a, 2000b) suggest that activation from the lawn word would reach the green lemma (via the concepts lawn and green), causing conflict with the red lemma. The same reports suggest that activation from the lawn word would also reach the red lemma (via the concepts lawn, green, and red), compensating for the activation reaching the green lemma. Thus, the word lawn could produce inhibition, facilitation, or neither with naming the color red, depending on the relative strengths of the various associations involved.

The WACT account of semantic gradients is also important because it shows that such effects can be accommodated by ACT-R's core theoretical premises. ACT-R assumes that performance (including memory performance) adapts to the statistical structure of the environment (Anderson & Lebiere, 1998; Anderson &

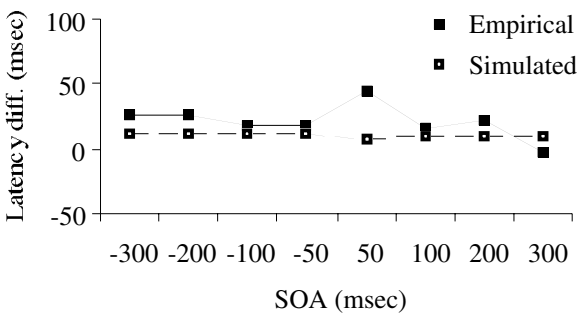

Figure 6: Inhibition from distractors like "lawn". Empirical data are from Glaser and Glaser (1989), Exp. 5, Cond. 2. Simulated data are from WACT.

Milson, 1989). Thus, WACT assumes that lawn and green concepts are associated in memory because they co-occur in the environment. Associative mechanisms also account for temporal gradients in order memory (Altmann, 2000). Nonetheless, the adequacy of such representations has been questioned, and ACT-R has come to incorporate a "partial matching" mechanism for fitting gradient data (e.g., Anderson & Matessa, 1997). The current work suggests that this mechanism, which has no clear motivation in terms of independent theoretical constraints, is best viewed as a simplifying assumption and not as a part of ACT-R theory proper.

Model Parameters

The parameters used to fit the data in Figures 1 and 6 were as follows. Activation noise (set at 0.33), or *s* in Equation 1, causes some retrieval attempts to produce the incorrect target. Encoding noise (0.0205) causes some stimuli to be encoded out of order at small SOAs. (Activation and encoding noise both index logistic variance; see Anderson & Lebiere, 1998.) The limit on retrieval attempts (3) affects how soon the retrieve-decide process gives up and outputs its last retrieval. Other parameters affect associative activation spreading from a cue. High strength (8.9 units of activation) applies to perceptual cues and medium strength (6.9 units) applies to mental cues. Low strength (4.9 units) applies to lawn as a cue for green, so is relevant only to the fit in Figure 6.

Discussion

Stroop effects are complex and diverse and it seems clear that broad coverage will elude us as long as we continue to approach them with standalone models. A comprehensive theory is required, in which the interactions of various cognitive subsystems can be simulated to investigate whether particular Stroop phenomena emerge as a natural consequence. Several directions indicated by the marriage of WEAVER++ and ACT-R in WACT are discussed below.

First, there is the question of Stroop development – how a process like reading becomes automatic enough to interfere with other tasks like color naming. MacLeod and Dunbar (1988, Experiment 3) demonstrated that this development can be induced through training. Their participants received extensive practice (daily, for a month) on associations between arbitrary shapes and color names. These associations eventually became automatic enough to interfere with color naming, which, before training, had been the more automatic task. Would ACT-R, as a unified theory that integrates learning mechanisms, allow WACT to be extended to develop automaticity?

A WACT account of automaticity would likely be grounded in ACT-R's utility-based theory of procedural skill acquisition. Procedural skills in ACT-R are represented as production rules that govern retrieval from declarative memory. Skill acquisition itself is represented in part as the acquisition of cost-benefit knowledge about individual production rules – the more a rule succeeds, the more it is preferred when the system has a choice. This mechanism has been used to account for set effects (Lovett, 1998) on the view that these are driven by frequency of rule use. In WACT, automaticity is represented by fixed settings of these cost-benefit parameters. That is, productions that read a word stimulus have high utility and thus are preferred to productions for less-used skills like color naming. It seems feasible and useful to extend WACT to simulate training data sets like that of MacLeod and Dunbar (1988). With such an extension in hand, one could assess its predictive value by manipulating system parameters like the rate at which skill acquisition takes place.

A second question concerns the relationship between Stroop phenomena and task switching. Stroop interference and executive control interact, in that switching to controlled tasks like color naming is easy, whereas switching to automatic tasks like reading is hard (Allport, Styles, & Hsieh, 1994). However, Stroop conflict is robust to task uncertainty – inhibition effects are largely unchanged when the task is determined dynamically on each trial by stimulus order (Glaser & Glaser, 1989). These disparate effects of task may inherit explanations from studies of task switching conducted within ACT-R (Altmann & Gray, in press; Sohn, Ursu, Anderson, Stenger, & Carter, 2000).

A third question concerns the relationship between Stroop phenomena and the psychological refractory period paradigm used to investigate perceptual, motor, and cognitive bottlenecks. The data in Figure 7, from which the latency-difference measure in Figure 1 was computed, hint at a bottleneck in Stroop processing. The slowing near SOA zero suggests a "jamming" of some kind (Meyer & Kieras, 1997) when stimuli appear close together in time. WEAVER++ accounts for this effect (Roelofs, personal communication) in terms of its activation dynamics. In contrast, ACT-R incorporates a structural and processing theory of bottleneck effects generally (Byrne & Anderson, in press). Extending WACT in this direction would take it well beyond current Stroop models, by integrating perception, action, language, memory, and executive control in one running model.

Finally, we hope to extend WACT to phrase

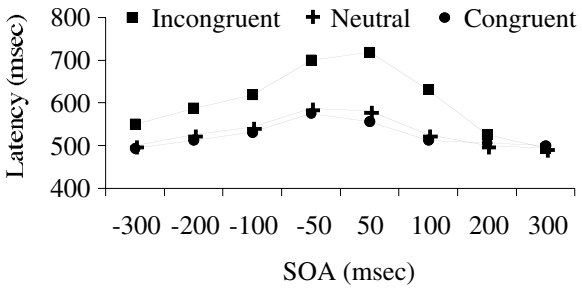

Figure 7: Latencies from which the difference scores in Figure 1 were computed, showing that processing slows near zero SOA, regardless of condition.

production, in particular the production of conjunctive phrases. When the task is to name the color and read the word, utterance onset depends on which response is to be given first. In particular, utterance onset is delayed when the color is to be named first (and the word meaning is incongruent). These data help to characterize planning in speech production, but also offer an opportunity to integrate Stroop phenomena more broadly with psycholinguistic theory.

Age of Acquisition in Connectionist Networks

Abstract

Recently, there has been a resurgence of interest in the role of the Age of Acquisition (AoA) of an item in determining subjects' reaction time in naming words, objects, and faces. Using the number of epochs required to learn an item as a direct measure of AoA in connectionist networks, Smith, Cottrell & Anderson (in press) have shown that AoA is a stronger predictor of final Sum Squared Error than frequency. In this paper, we replicate Smith *et al*. using more realistic frequency distributions for the items, and examine why some patterns may be learned earlier than others. First, we have found that the same patterns tend to be learned early and late by networks differing in their initial random weights; hence, the issue is, what property of the patterns determines AoA? We have found that even very weak pattern similarity structure is a strong predictor of AoA when frequency is controlled for. Also, we have found evidence that such a similarity structure may still be an important factor in determining AoA even when pattern frequency is varied.

Introduction

Ever since Carroll & White (1973) reanalyzed Oldfield & Wingfield' s (1965) naming latency data and discovered that frequency was not significant when AoA was considered, controversy has surrounded discussions of the import of the two variables. Technological and methodological refinements have led to agreement that both frequency and AoA play significant roles. Hence, interest has returned to the pursuit of understanding the mechanisms underlying AoA effects.

It had been proposed recently (Morrison & Ellis, 1995; Moore & Valentine, 1998) that connectionist networks would be incapable of exhibiting AoA effects because training on late patterns would cause "catastrophic interference" resulting in the unlearning of early patterns. However, this sort of interference is only found if training on early patterns ceases. Ellis & Lambon Ralph (2000) demonstrated AoA effects in a neural network by training the net on an "early" set of patterns and then simply adding a second set of "late" patterns halfway through training.

Smith et al. (in press) independently demonstrated AoA effects in networks. In contrast to the staging method of Ellis & Lambon Ralph (2000), where AoA is assumed to correspond to the time at which patterns are presented to the network (early or late), all patterns were presented to the model from the outset. AoA can then be *measured* for each pattern individually as the time during training when the pattern is learned. Using this more natural definition, Smith et al. reported significant effects of AoA on naming latency (defined as the residual error on a pattern after training is completed, a measure of the network's *uncertainty*).

What we would like to know is why certain patterns are learned earlier than others, and how early learning of a pattern comes to affect the network' s performance. Ellis & Lambon Ralph's (2000) approach cannot be used to find out why patterns are acquired in a particular order as it *imposes* an order by staging pattern presentation. Instead, we vary properties of the patterns and then measure AoA, as in Smith et al. Ellis & Lambon Ralph (2000), do suggest why early AoA is important for final performance – the network is more "plastic" earlier in training, so items that are learned first have the opportunity to make the biggest impression on the weights.

We also want to know whether our finding that AoA is a stronger predictor of final error than frequency survives a more realistic version of Zipf's (1935) frequency distribution than was used by Smith et al. Here we show that it does.

Methods

Our investigation is organized around a series of experiments in which we replicate and extend network simulations and analyses previously reported by Smith et al. (in press). We begin with one of the simplest connectionist models of lexical access, an autoencoder network. This kind of network simply reproduces its input on its output through a set of hidden units, and has seen surprisingly wide application in cognitive modeling. We then extend our simulations to more complex mappings.

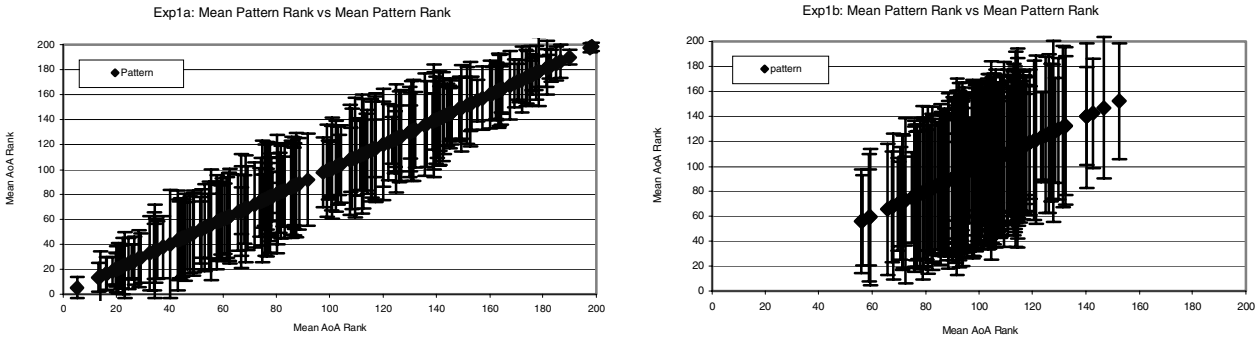

Figure 1: Comparison of pattern AoA variance between experiments using the same pattern set for all simulations (left) and 10 different pattern sets (right).

Table 1: Average correlations between pattern similarity measures and AoA.

	AoA	Mean Cosine	Mean R^2	Density	Mean Distance
AoA	1.0000				
Mean Cosine	0.0487	1.0000			
Mean R^2	-0.4751	-0.0399	1.0000		
Density	0.0806	0.9886	-0.0412	1.0000	
Mean Distance	0.1069	-0.3058	-0.0437	-0.1825	1.0000

Experiment 1

Smith et al. (in press) report finding a strong correlation between AoA and SSE in their first experiment in which they trained ten autoencoders on the same set of equally frequent patterns. Training all networks on the same set of patterns ignores the possibility that the order in which the patterns in the set will be acquired by the network may depend on some property of the training set. To examine this possibility, we replicated Smith et al.'s first experiment in two ways: first, using the same set of randomly generated patterns (an exact replication) and, second, using a different pattern set for each network. The first replication allowed us to perform an analysis of the AoA rank order correlation of patterns between pairs of networks – if networks trained on the same pattern set tend to acquire patterns in the same order then the rank order correlations between pairs of networks should be significant, implicating a property of the training set in driving acquisition order. The second replication allowed us to see whether Smith et al.'s finding concerning the correlation between AoA and SSE maintained across a larger set of patterns.

Methods For the first replication, ten groups of ten networks were trained with all of the networks in a group using the same pattern set. In the second replication, a single group of ten networks were trained with each network using a different pattern set. For both replications, the pattern sets consisted of 200 randomly generated 20-bit patterns in which each bit had a 50% chance of being on. All networks were 20-15-20 autoencoders trained via backpropagation, using learning rates of .001, momentums of .9, and initial random weights between 0.1 and -0.1. All patterns were presented every epoch. Training was continued until 98% of the patterns were acquired (where "acquired" means its SSE went below 2.0). The AoA of a pattern was taken to be the first epoch in which it was acquired.

Results Smith et al. (in press) reported a correlation coefficient of 0.749 between SSE and AoA averaged over all 10 networks. For both replications, we found similar mean correlations: 0.773 (0.038) and 0.756 (0.050), for a randomly chosen group in the first (same pattern) replication and the group in the second (different patterns) replication, respectively. Thus, our replication supports the finding of Smith et al. that AoA and SSE are strongly correlated.

Although we arrived at that same result in the first replication, our second replication does not support the conclusion that AoA is independent of properties of the training set. Our examination of the AoA rank order correlation between groups of networks trained on the same pattern set revealed that networks trained from different initial weights tend to learn the patterns in a set in a similar order. The pair-wise AoA rank order correlations between networks in the same group averaged over all pairs in all groups (N=450) were found to be 0.485 (σ=0.061), using Kendall's τ, and 0.665 (σ=0.071), using Spearman's ρ. Figure 1 illustrates this relationship. Both graphs

in the figure plot the mean AoA values for each pattern on both axes. The graph on the left is for 10 networks in one of the groups in the first replication using the same pattern set for each network. In order to estimate how chance behavior would look, we simply aligned the different pattern sets used in the second simulation based on pattern numbers and, in the graph on the right in Figure 1, we plot the means and standard deviation for all patterns with the same number. Note how the means in the plot on the left do not cluster about the center as do those in the plot on the right, and that those on the left have smaller standard deviations.

Having found that *some* property of the training set contributes to the AoA of the patterns in the set, our next goal was to attempt to identify what that property might be. Note that in choosing random 20 bit patterns, we are selecting vectors randomly from a 20 dimensional space. Since the maximum number of vectors that can be mutually orthogonal in such a space is 20, and we are selecting 200 vectors, each vector in the set will necessarily be closer to some vectors in the set than to others. This unavoidable clustering of patterns in the vector space is what we refer to when we speak of the similarity structure of a randomly chosen set of training patterns. Since the patterns are randomly chosen, the average pair-wise correlation between patterns is small (0.0581, σ = 0.0056 for an exemplary set), but non-zero.

For one of the pattern sets used in the first replication, we computed for each pattern the mean cosine, R^2, and Euclidean distance between the pattern and all others, and the pattern density (% bits "on"). The correlations between these measures and the patterns' AoA values were computed for each network and then averaged together. As Table 1 shows, the negative mean R^2 between a pattern and all others in the network is on average the best predictor of the pattern's AoA. We performed a repeated measures multiple regression analysis (Lorch & Myers, 1990) using mean R^2, mean Euclidean distance and density as predictors of AoA, and found that the null hypotheses that the mean regression coefficients are equal to 0 can be rejected with $p<<0.000001$, $p=0.000013$, and $p=.020976$ for mean R^2, mean Euclidean distance, and density, respectively. Thus, we are led to believe that the small and subtle structure reflected by the inter-pattern correlations among the patterns in even a randomly chosen set has a strong role in determining the order in which those patterns will be learned.

Experiment 2

In this experiment we again replicate and extend Smith et al. (in press). Like Smith et al., we aim to show that AoA effects persist in our model when frequency is added as a variable, and to compare the strengths of these effects to those found in human studies. We improve upon Smith et al. by first, using more realistic frequency distributions and second, by examining the role the shape of the frequency distribution has on the relative contributions of frequency and AoA to naming latency.

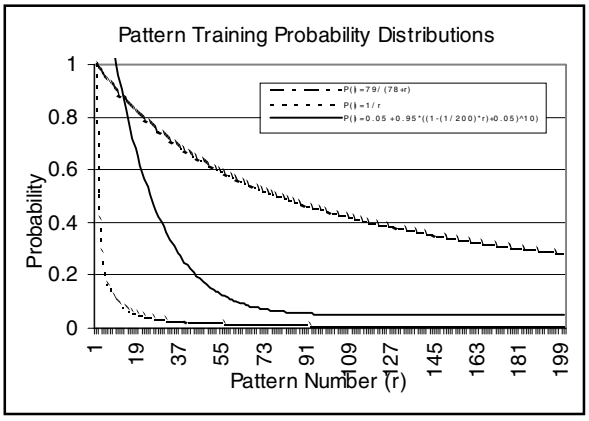

Figure 2: Comparison of training probability distributions.

Methods We again use ten autoencoders with differing pattern sets, but we vary the frequency of presentation of the patterns within each set. In manipulating pattern frequency, we aim to simulate the well-known Zipf distribution, where a small number of words occur very frequently – that is, the frequency of a word is proportional to the reciprocal of the word's frequency rank. We took two approaches to simulating this distribution. In the first approach, we randomly assign ranks to patterns and train on each pattern with probability 1/rank in each epoch. In the second approach, we take account of the fact that the most frequent words tend to be function words (like "a", "the", "and", etc.) and that human naming studies seldom use such words. Hence, a more accurate model of the frequency distribution of words used for naming stimuli should start lower on the Zipf curve. In order to determine a reasonable starting point, we needed to make an estimate of the frequency ranking of the most frequent word likely to be used in a naming study. To do so, we examined the Celex database (Baayen, Piepenbrock & Gulikers, 1985), and found the rank of the most frequent noun with an imageability rating of 500 or greater in the MRC Psycholinguistic database (Coltheart, 1981). The 500+ imageability criterion was chosen somewhat arbitrarily (the mean rating for words in the MRC database is 450), but was intended to find roughly where concrete nouns show up on the Zipf's curve. The noun selected by this process was "man" with a rank of 78. Hence, our second replication of this experiment randomly

Table 2: Network and human naming study correlation data.

	Networks			Object Naming				Word Naming
	Smith et al.	1/r	79/(78+r)	E&M	S&Y	BM&E	C&W	M&E
r(aoa, sse)	0.749	0.727	0.763	0.626	0.683	0.700	0.77	?
r(logf,sse)	-0.730	-0.462	-0.324	-0.405	-0.456	-0.455	?	-0.388
r(aoa,logf)	-0.283	-0.259	-0.212	-0.377	?	?	?	?

(E&M = Ellis & Morrison, 2000; S&Y = Snodgrass & Yuditsky, 1998; BM&E = Barry, Morrison & Ellis, 1997; C&W = Carroll & White, 1973; M&E = Morrison & Ellis, 2000)

assigned a rank, r, between 1 and 200 to each pattern and then presented that pattern with probability (79/78+i) for training on each epoch.[1]

Our central motivation for using more than one frequency distribution in this (and subsequent) experiments is to determine how the shape of the distribution might influence the relative contributions of AoA and frequency to SSE. We hypothesized that training with a frequency distribution from the beginning of Zipf's curve would tend to make the frequency of a word a stronger determinant of its final SSE than would training with a distribution that started after the curve began to flatten. We were also interested in verifying the results obtained by Smith et al., since they used only a single pattern set and just a Zipf-*like* frequency distribution. In particular, they presented pattern r for training each epoch with a probability given by:

$P(r) = 0.05 + 0.95*((1-(1/200)*r)+0.05)^{10})$

Figure 2 shows a graph comparing all three distributions. Note that the Smith et al. distribution has many more "high-frequency" words than does the 1/r distribution, and that it spans a larger range of probabilities than does the 79/(78+r) distribution.

Results Table 2 shows the correlation coefficients obtained from the three network models, as well as regression coefficients obtained from human object and word naming studies. The results show that the network model correlations look much more similar to the object naming data than to the word naming data. This is a bit counter-intuitive given that the networks are being trained to autoencode — word naming is a less arbitrary mapping than object naming and, hence, seems like a better match to the autoencoding task. The results of our next experiment suggest a reason for this discrepancy. We put off further discussion until then.

The main difference between the network models' correlations is that Smith et al.'s r(logf,sse) is much greater than both the other two network models and the human data. Examining Figure 3, we might suppose that the 79/(78+r) distribution has a weaker frequency effect than Smith's distribution since the frequency differences among patterns are not as pronounced. The 1/r distribution may be weaker than Smith's for a similar reason — while it covers a maximal range of frequencies like Smith's, it has relatively few at the high frequencies and, so, little differentiation in terms of frequency for the vast majority of its patterns. As both the models with 1/r and 79/(78+r) are closer to the human data than the model with Smith's curve, though both are at somewhat opposite extremes in terms of frequency distribution, support is lent to the notion of using a true Zipf based distribution. Furthermore, the slight weakening of the effect of frequency on SSE in the 79/(78+r) model compared to the 1/r model suggests that the choice of data set used in human naming experiments (object names will not be at the top of the Zipf curve) could influence the observed strength of correlation between naming latency and frequency and, possibly, explain some of the differences in findings reported in these studies.

Experiment 3

Having demonstrated AoA effects in the presence of frequency in networks trained to perform an autoencoding task, Smith et al. (in press) then examined how different levels of consistency in the mapping task represented by the pattern set influenced AoA and frequency effects. While spelling to sound is reasonably consistent mapping, spelling to meaning or faces to names are not. Again, we were interested in replicating Smith et al. to see whether their results still held when using the more realistic 1/r and 79/(78+r) frequency distributions and unique training pattern sets for each simulation.

Methods The networks were modified compared to the previous experiments in order to make learning the less consistent pattern sets possible: the number of hidden units was increased to 50, and the objective function was changed from SSE to cross-entropy.

[1] The scale factor of 79 is used only to minimize the number of epochs required for learning the set – it simply guarantees that the most frequent pattern is presented exactly once every epoch, while the relative frequencies of the patterns remain unchanged.

Ten pattern sets were randomly created, as before. From this set of ten, eleven sets of ten were created by randomly flipping bits of the target patterns with eleven levels of probability evenly distributed between 0.0 and 0.50 − in 100% consistent pattern sets, the target patterns were exactly the same as the input patterns (autoencoding); in the 0% consistent case, each bit in the target pattern had a 50% chance of being flipped from the input setting (a completely random mapping, like sound to meaning).

Results The graphs in Figure 3 plot for each level of mapping consistency the mean correlation coefficients and the mean coefficient p values of multiple regressions (N=10 for each point) on network SSE with AoA and frequency as the independent variables. The plots reveal that AoA is a stronger and more significant predictor of naming latency than is frequency in our model across all levels of consistency. As we previously noted, these charts may help explain why the data from Experiment 2 look more like object naming than word naming. Even though word naming is a more consistent mapping than object naming, it is still not 100% consistent, as was the task used in Experiment 2. From the graphs of variable significance on the bottom in Figure 3, it is obvious that the case of 100% consistency is somewhat of a discontinuity, resembling 0% consistency more than it does 90% consistency. Autoencoding is not a good model of word naming tasks.

Experiment 4

We view the mean pair-wise AoA rank order correlation between simulations trained using the same pattern set as a measure of the contribution of pattern set similarity structure to determining the order in which words are acquired. In analysis of the AoA effects observed in the networks of experiment 1, we computed this measure for several groups of simulations and found it to be significant. Since experiment 1 was concerned only with autoencoding networks, we wondered whether the effect of pattern structure has as much influence on pattern AoA in networks trained to perform less consistent mapping tasks. We were also curious as to whether the order in which patterns were presented for training would have much effect on the ordering of AoA among the patterns. To answer these questions, we designed our final experiment.

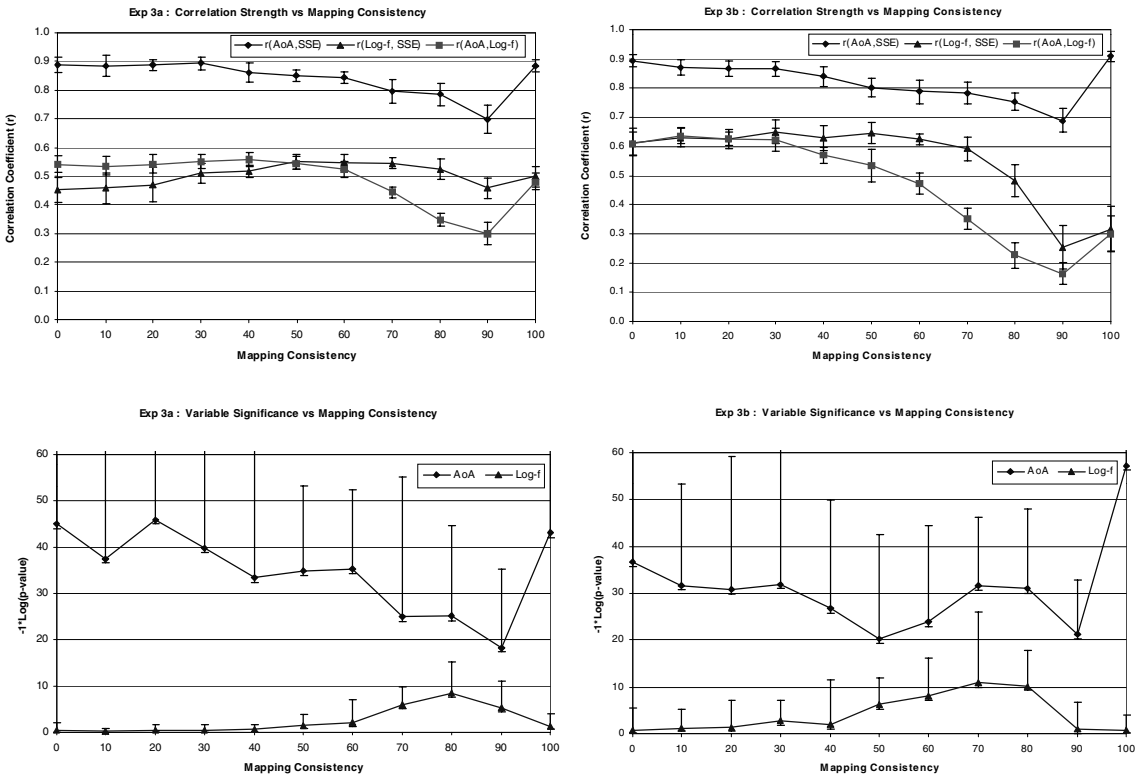

Figure 3: Comparison of the effect of consistency on correlation strength (top) and significance (bottom) between models trained with a 1/r frequency distribution (left) and a 79/(78+r) frequency distribution (right).

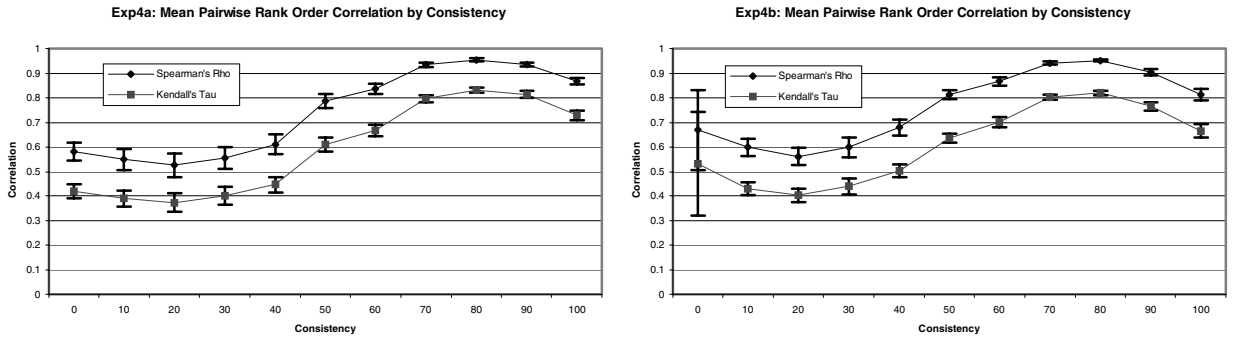

Figure 4: Comparison of pairwise pattern AoA rank order correlations across consistency levels between sets of networks trained with (right) and without (left) randomized pattern presentation order.

Methods One pattern set was arbitrarily selected from each consistency group used in experiment 3, to create a set of eleven training sets with varying levels of consistency ranging between 0% and 100%. For each level of consistency, two sets of ten networks were trained from different random initial weights. The first set was trained with every pattern presented for training in the same order on every epoch. For the second set of ten, all patterns were presented in a new and random order each epoch. Because we were interested only in observing the influence of pattern set similarity structure across training set consistency levels, all patterns in all sets were trained with a uniform frequency distribution. Otherwise, the networks were the same as those in experiment 3.

Results The graphs in Figure 4 plot the mean rank order correlations for each level of consistency. They reveal that, not only is pattern set similarity structure important at all levels of consistency, but that it is also mostly independent of pattern presentation order. The one notable difference between random and non-random presentation ordering occurs at 0 consistency, showing up as a large standard deviation in the plot on the right in Figure 4. This experiment also reveals that similarity structure is generally more influential on AoA at higher levels of consistency.

Conclusion

We have shown that the similarity structure among items is an important determinant of AoA across a variety of mapping tasks. Future work will concentrate on more realistic similarity structures within the domains and ranges of the mappings, such as similarities between words, between faces, and between meanings. On the issue of frequency vs. AoA, the regressions performed in experiment 3 reveal that AoA is a stronger predictor of naming latency in our models than frequency. While AoA and frequency are clearly correlated, there appears to be a fundamental effect of an item becoming encoded in the network weights before other items. Frequency may be the key, but AoA is the door to performance.

Acknowledgments

We wish to thank GURU, Rich Golden, Mark Smith and Dave Noelle for their contributions and support.

The Processing & Recognition of Symbol Sequences

Abstract

It is proposed that learning a language (or more generally, a sequence of symbols) is formally equivalent to reconstructing the state-space of a non-linear dynamical system. Given this, a set of results from the study of nonlinear dynamical systems may be especially relevant for an understanding of the mechanisms underlying language processing. These results demonstrate that a dynamical system can be reconstructed on the basis of the data that it emits. They imply that with minimal assumptions the structure of an arbitrary language can be inferred entirely from a corpus of data. *State-Space reconstruction* can implemented in a straightforward manner in a model neural system. Simulations of a recurrent neural network, trained on a large corpus of natural language, are described. Results imply that the network sucessfully recognizes temporal patterns in this corpus.

Introduction

Complex pattern recognition is often characterized by means of a simple geometric analogy. Any object or pattern may be described as a single point in a high-dimensional space. For example, a square grayscale image that is 256 pixels in length, may be described as a point in the 256^2 dimensional space of all possible images. A collection of such images is a set of points in this space. If these patterns are not entirely random, this set will reside in a subspace of lower dimensionality. To learn the structure of these images, an organism or machine must discover a compact parametric representation of this subspace. This might take the form of, for example, finding a reasonably small set of basis vectors that will span the subspace and projecting each image onto these vectors. Having done this, each image can be classified in terms of a new and more meaningful coordinate system. You effectively describe 'what is there' in terms of 'what is known'.

This geometric approach is routinely employed in the study of visual object recognition, but may easily be extended to a wide range of categorization and classification tasks. In almost all cases, however, the patterns under study have been multi-dimensional *static* patterns. In contrast, the study of *temporal* pattern recognition using this or related approaches has not been well-developed. For example, one of the most widely employed techniques for temporal pattern recognition, Hidden Markov Models are limited in their generality due to their fundamental inability to handle patterns above a certain complexity. This absence of general models for temporal pattern recognition is evident in the study of human language processing, which traditionally has eschewed serious consideration of statistical learning and pattern recognition.

This paper aims to introduce a general framework for the study of temporal pattern recognition. This is developed in the context to language processing, but it could be extended in a straightforward manner to most other cases of temporal patterns. First, a general characterization of the problem of language learning and language processingis proposed. Then, some recent results in the study of nonlinear dynamical systems are described. These are seen as being especially relevant for an understanding of the mechanisms underlying temporal pattern recognition, especially with regard to language processing. Finally, simulations with a recurrent neural network are described, which suggest successful pattern recognition of English sentences.

The processing of symbol sequences

A paradigm for the study temporal pattern processing, especially language processing, has developed as a result of the deep relationship between formal languages and abstract automata (Chomsky 1963)[1]. Any language (or more generally, any sequence of symbols), can be described as the product of a particular automaton. By this account, learning a language is equivalent to identifying a particular automaton on the basis of a sample of the language that it generates. More formally, an automaton A is specified by the quadruple $\langle X, Y, F, G \rangle$. X and Y are sets known as the state and the output spaces, respectively. The functions $F : X \mapsto X$ and $G : X \mapsto Y$

[1]The correspondence between formal languages and abstract automata can be summarized by the so-called Chomsky hierarchy: Classes of automata that are increasingly restrictive versions of the Turing machine produce classes of languages described by increasingly restrictive generative grammars. The *regular* languages R are produced by strictly finite automata, the *context-free* languages CF are produced by pushdown stack automata, the *context-sensitive* languages CS are produced by linear bounded automata and the *recursively enumerable* languages RN are produced by unrestricted Turing machines. $R \subset CF \subset CS \subset RN$, and likewise for their corresponding automata.

are the state-transition and the output functions, respectively. Beginning at time t_0 and continuing until t_∞, the sentence-generator A constantly changes from one state in X to the next, according to its state-transition function F. At each transition, a symbol from the set Y is emitted, according to its output function G.

A langage learner attempts to identify the nature of this automaton on the basis of a sample of the language that it generates. That is to say, the language learner is exposed to a finite sequence of Y and from this must attempt to identify $A = \langle X, Y, F, G \rangle$. Having attained knowledge of A, the learner is said to have full knowledge of the structure of the language. The learner has the capability to produce all the sentences of the language, including the infinite number of sentences that were never seen. Likewise, the learner has the capability to parse the syntactic form of any sentence of the language. This ability also extends to the infinite number of never-encountered sentences. As syntactic parsing is a necessary precondition for the interpretation of language, it is said that the language has been learned once knowledge of its grammar has been attained.

While the correspondence between formal languages and automata has allowed the problem of language learning to be given an explicit characterization, these automata $A = \langle X, Y, F, G \rangle$ have always been taken to be discrete parameter systems. To continue this paradigm it is useful to demonstrate the correspondence between generative grammars and continuous as well as discrete automata. Within nonlinear dynamical systems theory, the study of *symbolic dynamics* has made apparent the relationships between formal languages, generative grammars and continuous dynamical systems. Symbolic dynamics refers to the practice of coarse-coding the ambient state-space of a dynamical system into a finite set of subspaces and assigning a symbol to each. Whenever the system enters a partition, the assigned symbol is emitted. In this way, the trajectories of the dynamical system can be represented as strings of symbols. Unless the system is entirely stochastic, only a certain subset of strings will occur. It can be shown that these strings define a language and the system producing them can be described by a generative grammar (Bai-Lin & Wei-Mou 1998).

The relationship between languages, grammars and dynamical systems has been further described by Tabor (1998). In that work, and in Tabor (2000), the computational capacities of a pushdown stack automaton were identified with those of a stochastic dynamical system, based on an *iterated function system*. This was used to demonstrate the recognition of context-free languages by a simple $2-$dimensional dynamical system. Following Tabor's approach, it is reasonable to propose that any language (or any symbol sequence) generating process may be legitimately described as a *continuous* as well as a *discrete* system. Accordingly, and by keeping a strict analogy with the automaton $A = \langle X, Y, F, G \rangle$ described above, it is possible to introduce the corresponding continuous system, A' defined by the quadruple $\langle \vec{x}, y, f, g \rangle$.

By introducing $A' = \langle \vec{x}, y, f, g \rangle$, the language generating process is being explicitly defined as a nonlinear dynamical system. For example, the system may be described by a set of coupled differential equations

$$\dot{x}_i = f(\vec{x}, \delta)$$

where $\vec{x}$ is the system's state and $\dot{x}_i$ is a vector-field defined on an m-dimensional manifold M. δ is a unspecified stochastic element in the system. The *language* being produced by this system is a result of the coarse-coding function

$$y = g(\vec{x}),$$

where y is a variable representing the *symbols* of the language. However, there are still formal similarities between the discrete automaton $A = \langle X, Y, F, G \rangle$ and its continuous counterpart $A' = \langle \vec{x}, y, f, g \rangle$. $\vec{x}$ is the state-space of A' and y is a variable representing its output. The function $f\colon \vec{x} \mapsto \vec{x}$ describes the state evolution of the system while $g\colon \vec{x} \mapsto y$ is an output function. In fact, the only essential distinction between $A = \langle X, Y, F, G \rangle$ and $\mathcal{A} = \langle \vec{x}, y, f, g \rangle$ is that in the latter case the state-space $\vec{x}$ is continuous, rather than discrete, and the evolution of the system described by f is smooth, preventing discontinuous leaps through space.

State-Space Reconstruction

A language learner can be said to be attempting to identify the process generating the language. If this generating process is described as a continuous dynamical system, the objective is to model the dynamical system $\dot{x} = f(\vec{x})$ on the basis of the language it outputs, $y_{t_0}, \ldots, y_t$. Prima facie, this problem is widely intractable. The symbols to which the learner is exposed do not identify the state of the system. They are a product of the composition of two unknown and probably non-linear functions, f and g. However, it may be fruitful to consider the analogy between this problem and a more general problem encountered in the experimental analysis of complex systems. For example, a scientist observing a sequence of individual measurements from a complex physical process (e.g. a fluid in turbulent motion) may be interested in understanding the properties of the underlying system. In the absence of prior knowledge and without loss in generality, the system can be taken to be a stochastic dynamical system, whose functional form is completely unknown. The scientist must infer its functional form on the basis of the measurement data alone. One of the more remarkable outcomes of dynamical systems theory is that in many general cases this problem is tractable. In virtue of the analogy, the manner by which this is done may also elucidate the problem of language learning.

Packard, Crutchfield, Farmer & Shaw (1980) were first to demonstrate that a dynamical system could be reconstructed entirely on the basis of its output. They proposed that *any* time-series of quantities measured from a dynamical system may be sufficient to construct a model

that preserves its essential structure. Takens (1981) developed and clarified the mathematical evidence for this proposal. This was considerably generalized by Sauer, Yorke & Casdagli (1991), and more recently Stark, Broomhead, Davies & Huke (1997) have extended these results to the more general case of stochastic dynamical systems.

Sauer et al. (1991) have suggested that the foundations of these ideas are to be found in differential topology. For example, a seminal theorem in this field (Whitney 1936) is that any m-dimensional manifold M can be mapped by a diffeomorphism[2] into Euclidean space $\mathbb{R}^d$ if $d > 2m+1$. Moreover, the subset of all possible smooth maps from M to $\mathbb{R}^{2m+1}$ that are also diffeomorphisms is both open and dense in the function space. As Sauer et al. (1991) point out a single measurement of a dynamical system is a map from the system's state to the real line. As such, the significance of Whitney's result is that *almost every*[3] set of $2m+1$ independent measurements of a dynamical taken simultaneously is sufficent to reconstruct the dynamical system in the measurement-space. The manifold M and its vector-field $\dot{x}$ are *embedded* in the measurement-space.

The more recent result by Takens (1981) may be understood in in terms of this embedding theorem. Takens considers the case of a dynamical system $f(\vec{x}, \delta) : M \mapsto M$ and the *delay-coordinate* map, $D : M \mapsto \mathbb{R}^{2m+1}$. This map D is defined as simply a time-series of scalar measurements $z = \{y_t, y_{t+1}, \ldots, y_{t+2m}\}$ obtained from this system, where $y = g(\vec{x})$. It is clear that

$$z = \{y_t, y_{t+1}, \ldots, y_{t+2m}\} = \{g(\vec{x}_t), g \circ f(\vec{x}_t), \ldots, g \circ f^{2m}(\vec{x}_t),\}$$

where f^n is the composition of f n-times. In other words, the sequence z of $2m+1$ measurements $y = g(\vec{x})$ is in fact a function of a single point or state $\vec{x}$ of the hidden dynamical system. The *delay-coordinate* map D maps each state $\vec{x}$ of the hidden system to a point in $\mathbb{R}^{2m+1}$. Takens (1981) demonstrated that with minimal assumptions about the hidden dynamical system[4] , the set of *delay-coordinate* maps D that are also diffeomorphisms is both open and dense in the space of maps D. In *almost every* case, the hidden dynamical system is *embedded* within the delay-coordinate measurement space.

Sauer et al. (1991) have considerably elaborated the Takens (1981) embedding theorem. They define both a delay coordinate map $D' : M \mapsto \mathbb{R}^s$, where s is an integer arbitrarily greater than $2m+1$, and a smooth transformation of this map, $\phi : D' \mapsto \mathbb{R}^{2m+1}$. In the spirit of Takens (1981), Sauer et al. (1991) demonstrate that the set of these composite functions $\phi \circ D' : M \mapsto \mathbb{R}^{2m+1}$ that are also diffeomorphism is open and dense in the function space.

The theorems of Takens (1981) and Sauer et al. (1991) apply to deterministic dynamical systems. These are systems whose entire future evolution can be be determined from precise knowledge of the system's state. As real world systems are inevitably coupled with sources of external noise, the generality of these theorems may seem limited. Stark et al. (1997) have shown, however, that the embedding theorems can be generalized to a much less restricted class of stochastic dynamical systems. They consider a discrete time system where at each time step one of k different discrete-time maps $f_\omega : M \mapsto M$ is chosen, where $\omega = 1, \ldots, k$. As in Takens (1981), they define the *delay-coordinate* map, $D : M \mapsto \mathbb{R}^{2m+1}$ and show that in the stochastic systems under consideration the set of maps D that are also diffeomorphism is open and dense in the function space.

State-Space reconstruction in neural systems

While these results are obviously important for the general problem of nonlinear time-series analysis, their relevance for the problem of language learning may be limited. The problem of language learning does not fit neatly into the scenarios considered by Takens (1981), Sauer et al. (1991) and Stark et al. (1997). This is primarily due to the fact that the output of the language generating dynamical system is a sequence of symbols rather than a real-valued scalar. In addition, the stochastic system considered by Stark et al. (1997) might not be general enough to describe the arbitrary stochastic dynamical system that is here taken to be the language generator. More importantly, these theorems consider and explain certain *sufficient* conditions and do not lead naturally to a general algorithmic procedure for reconstructing state-space. For example, Taken's theorem demonstrates that the coordinate space of $2m+1$ scalar measurements is sufficient to embed the generating dynamical system of dimensionality m. Practically, however, this just means that the coordinate space of a *finite* number of scalar measurements is sufficient for the embedding. It does not indicate how it can be known that an embedding has in fact occurred. What is necessary, therefore, is an *objective function* that may be optimized to produce a reconstruction of the dynamical systems from its outputs.

Crutchfield & Young (1989) introduce ε-machines as a general procedure for state-space reconstruction. They propose that the state of the ε-machine uniquely corresponds to the state of a dynamical system emiting a symbol sequence if it can be shown that its state renders the future of the symbol sequence conditionally independent of its past. In other words, if the probability distribu-

[2] A *diffeomorphism* from M to N is a one to one map, where the map and its inverse are diferentiable.

[3] The fact that the set of maps that are also diffeomorphisms is an *open* subset of the function space means that any arbitrarily small perturbation of a diffeomorphism is also a diffeomorphism. The fact that the set is *dense* means that every point in the function space is arbitrarily close to a diffeomorphism. In addition, Sauer et al. (1991) have shown that *almost every* map in the function space is a diffeomorphism, in that the complement to this subset is of measure zero. In other words, the likelihood of an arbitrary map also being a diffeomorphism is *probability one*, or infinitely likely.

[4] In particular, it is assumed that the dynamical does not contain periodic orbits that are exactly equal to (or exactly twice) the sampling rate of the measurement function $y = g(\vec{x})$.

tion over future sequences of symbols is independent of the past symbols *given* the state of the ε-machine, then the ε-machine uniquely labels the state of the dynamical system generating the symbols. The ε-machine can then be taken as a model of the unseen symbol generating dynamical system[5].

On the basis of the embedding theorems and the ε-machine of Crutchfield & Young (1989), an objective function for state-space reconstruction may be introduced. The objective is to *model* the dynamical system $f(\vec{x},\delta)\colon M \mapsto M$, and this can be defined as learning a structure-preserving map from the manifold M to a second topological *model-space* N. If the probability distribution over sequences of symbols emitted by the dynamical system defined on M is independent of its past symbols *given* the state of the *model-space* N, then N smoothly and uniquely labels the state of the dynamical system generating the symbols. The trajectory of states on N can then be taken as a model of the unseen symbol generating dynamical system N. This idea may be illustrated by means of a neural system.

A system of cortical neurons can be minimally modeled by a set of n coupled nonlinear differential equations,

$$\dot{y}_i = -y_i + \sum_{j=1}^{j=n} w_{ij}\sigma(y_i) + I_i,$$

where σ is a smooth and monotonic transfer function, y_i is the soma potential of neuron i, resulting from a weighted sum of its inhibitory and excitatory inputs. I is the external input to the system. Clearly, this system is a dynamical system defined on a n-dimensional manifold N. In addition, the state of this system $\vec{y}_t$ at a given time t is a function of both its present input I_t and, through the action of its recurrent synapses, the history of previous input, $\{I_{t_0},\ldots,I_t\}$. In other words, the system's state at any given time is a smooth function of an entire sequence of inputs. This can be represented by the correspondence $\vec{y}_t = \psi(I_{t_0},\ldots,I_t)$. If the sequence of inputs $\{I_{t_0},\ldots,I_t\}$ represents the output $I_t = g(\vec{x}_t)$ of dynamical system $f(\vec{x},\delta)$ then it is clear that

$$\vec{y}_t = \psi(I_{t_0},\ldots,I_t) = \psi\left(g(\vec{x_{t_0}}), g\circ f(\vec{x_{t_0}}),\ldots,g\circ f^t(\vec{x_{t_0}})\right),$$

where f^t is the composition of f t times. The state $\vec{y}$ of the neural system is a function of the state $\vec{x}$ of the hidden dynamical system.

The neural system $\dot{y}_i$ on N is a diffeomorphism of the dynamical system $\dot{x}$ on M, if the state $\vec{y}$ smoothly and uniquely labels the state $\vec{x}$. If the future inputs to the neural system are stochastically independent of the past inputs, *given* the state $\vec{y}$ of the system then N and M are diffeomorphically equivalent. If the probability of the future inputs to the neural system, conditioned on its state $\vec{y}$, is not further sharpened by acquiring information about the previous inputs to the system then there is a structure preserving map between the two systems.

Network simulations

In this paper, it is taken that a language (or a sequence of symbols) is produced by a continuous dynamical system. To learn this dynamical is to learn the statistical structure of the language. By hypothesis, this can be accomplished by embedding the hidden dynamical system in a second model space. To maximize prediction of future states given present ones is effectively to seek such an embedding. As such, it should be the case that if a recurrent neural network is trained on a corpus of natural language (in the now familiar style introduced initially by Elman (1990)) it should develop a state space that is a model of the generating process of the language. One manifestation of this would be that sentences, judged (by human observers) to be structurally similar, should also be clustered in the state space of the neural system.

To explore this hypothesis further, a simulation of an idealized neural system was performed by implementing the system of coupled equations,

$$\dot{y}_i = -y_i + \sum_j w_{ij}\sigma(y_i) + \theta_i + \sum_k w_{ik}I_k,$$

$$O_l = \sigma\left(\sum_i w_{li}(y_i\right),$$

$$\sigma(\zeta) = \left(1+e^{-\zeta}\right)^{-1},$$

where y_i is the state of the neuron and can be viewed as representing its mean soma potential, θ_i is a bias term and I_i is external input. O_l is the output of the system which "reads off" the recurrent network. There were 120 neurons in the recurrent network. The input was a 250 dimensional bit vector, described below. The output was likewise a 250 dimensional vector. For the purposes of computer simulation, a difference equation was used,

$$y_i^{t+\Delta t} = (1-\Delta t)\,y_i^t + \Delta t\sum_j w_{ij}\sigma(y_i) + \Delta t\,\theta_i^t + \Delta t\sum_k w_{ik}I_k^t,$$

[5] In a dynamical system, the entire evolution of the system is described by its trajectory from $t_{-\infty}$ through t_0 to t_∞. The future trajectories of the system are conditionally independent of the past, *given* the present state of the system. In the ideal case of a deterministic and autonomous system, the future trajectory of the system, $X[t_0,t_\infty)$, can in principle be determined from the present state of the system, $X(t_0)$. Absolute knowledge of the system's state X at t_0 provides absolute knowledge of the future trajectory $X[t_0,t_\infty)$. No information about the system's prior trajectory $X(t_{-\infty},t_0]$ is necessary. In a stochastic dynamical system (where, for example, at irregular points in time there is coin toss of an k-sided coin to choose between k different set of differential equations), a similar situation occurs. While the future is not entirely predictable on the basis of the present state in this system, no *increase* in information about the future is gained by knowing the past. In other words, the future trajectory of the system is stochastically independent of the past, *given* the state of the system. The case of a stochastic system can be seen to generalize to the case of a dynamical system driven by external input.

This was obtained by an approximation of its continuous counterpart. Δt was a variable parameter which could be manipulated for finer approximations of the underlying continuous system.

The data-set used for network learning was a corpus of natural language amounting to over 10 million words. The corpus comprised 14,000 documents, the average length of each document being approximately 700 words. All documents were in a plain-text and untagged format. They were obtained from publicly available electronic text archives on the internet[6]. No explicit criteria were used when selecting documents other than that cover a wide range of subject matters such as science, social science, literature, children's stories, history, law and politics.

Altogether, the entire corpus contained a vocabulary of 115,000 words. Of these, a set of 50,000 accounted for over 99% of the total number of words in the corpus. Only the members of this set were used for training the network, the infrequent words having been deleted. Each of these 50,000 words was coded by being randomly assigned to a unique bit vector of 247 zeros and 3 ones (there are over 2.5 million possible combinations to choose from). While this random coding scheme introduced some spurious correlations between words, the average correlation between words was close to zero[7].

The network was presented with the entire corpus as a sequence of words, one word at a time. The network was trained to predict its future word-input given its present word-input. The synaptic weight parameters were adapted using the continuous version of back-propagation through time due to Pearlmutter (1989). In this procedure, the minimum of the cross-entropy objective function was sought by calculating the derivatives of this function with respect to each weight parameter at each time "tick" Δt of the 50 previous time steps.

With a learning rate parameter of .01, and a Δt parameter of .25, the network was trained for 46 passes through the corpus. At this time, the learning rate parameter was annealed to .001, and the Δt parameter was lowered to .1. Training was continued for another five passes through the entire corpus. The performance of the network at predicting future words could be adequately assessed using the a method of ratios between squared errors,

$$R_i = \frac{\sum_t \left(d_i^t - y_i^t\right)^2}{\sum_t \left(d_i^t - d_i^{t-1}\right)^2},$$

where d_i^t is the target or to-be-predicted outcome for neuron i at time t. The denominator of this ratio specifies the sum squared differences between the target outcome and the target at the previous step. This ratio is useful as the best prediction a random-walk model can make would be to predict the same value for the future as is obtained at the present. Thus, if the ratio is greater than 1.0 the network is performing worse than a chance model. At values less the 1.0, the network is performing better than a chance model. A value approaching 0, would indicate perfect predictive accuracy.

On the final pass through the corpus, the mean performance ratio for the training data was .4767. Furthermore, a validation set which comprised 1000 unseen documents was prepared. The mean performance ratio on this set was .4989. These values indicate substantial predictive performance and generalization abilities by the network. They compare very favorably to mean performance ratios usually obtained in non-linear time series prediction tasks (Weigend & Gershenfeld 1993).

Discriminant function analysis

If a neural network learns the statistical structure of the language , its state space should have topological organization based on a similarity principle. For example, sentences that are similar in content should cluster in compact neighborhoods of the state space. An ideal experimental test of this would be to have reliable human judges classify a large set of sentences on the basis of their content, and then to compare this with a network's classification of the same set of sentences. To the extent that the network's classifications are close to those of human judges, the network would have met a behavioral criterion for language comprehension.

To adequately assess generalization abilities, a large set of sentences would be required. Such an experiment would be laborious to conduct. Fortunately, however, data-sets of labeled or categorized documents (rather than sentences) are readily obtainable, as these are regularly used as benchmark tests of text categorization techniques. In the experiment conducted here, sentences were extracted from labeled documents. Sentences were then assigned to the semantic class of the document from which they came. For example, sentences taken from a document assigned to the class 'motorcycling' would themselves be assigned to the semantic class 'motorcycling'. In this way, a large set of sentences could assigned a plausible, although somewhat limited, interpretation. The data-sets were the Reuters-21578 newswire data-set, the 20 newsgroups data-set[8] , and then a third set which was compiled for the purpose of this experiment from 6000 documents obtained from the Library of Congress, which had been previously classified by their Dewey Decimal categories

An appropriate test of the network's representational capacities would be to assess the probability that a sentence from a given semantic class would be assigned correctly to that class. To do this a linear discriminant function was used to divide the state space into (simply connected and convex) sub-regions based on semantic class. The discriminant function is a straightforward

[6]The main sources of the electronic texts were, Project Gutenberg, the Etext Archives, and archives.org.

[7]A more valid distributed code based the actual orthography of English words has been used by the author in previous simulations, but these will be reported here.

[8]The two data sets are available on the internet. See http://www.cs.cmu.edu/ textlearning and http://www.research.att.com/ lewis

Table 1: Accuracy of sentence classification.

Data Set	Accuracy

Reuters	75%
Newsgroups	69%
Mean	76%

linear transformation of the state space, such that the centroids of "training" sentences labeled by their class are made maximally distant from one another. The network's ability to categorize by semantic class can be assessed for a "test" set of sentences by assessing the probability that a given sentence from a certain semantic class would be correctly assigned to that class. The measure used was Mahalanobis distance. This measure is approximately proportional to an estimate of the posterior probability that a given sentence will correctly assigned to its appropriate class. 5000 sentences from each of the three data-set were used in this test. The results are illustrated in Table 1.

These accuracy rates are suitably high, and in fact compare favorably to state-of-the-art text categorization methods which use similar or identical data-sets (Nigam, Mccallum, Thrun & Mitchell 2000). It is reasonable to conclude from this that the state space of a recurrent neural network trained to predict word sequences becomes organized on basis on semantic similarity. Sentences and texts that are semantically similar are clustered into compact neighborhoods which can be discriminated by a simple linear function.

Conclusion

Temporal pattern recognition is not as theoretically sophisticated as its multidimensional and static counterpart. Here, an approach to temporal pattern learning is introduced that is based on recent results from dynamical systems theory. It is proposed that the reconstruction of system generating a language (or symbol sequence) is adequate for learning the statistical structure of temporal data. It is proposed that state-space reconstruction can be carried out in a straightforward manner in a recurrent neural network. Results showing pattern recognition of English sentences by the network are provided. These results are similar in kind to those obtained by Elman (1990) and in the many works that followed this paradigm. It is believed that the appropriate explanation of these now familar sets of results, is that the recurrent neural network has reconstructed the language generating process. Sentences that were produced by similar trajectories in the original systems are now modelled by similar trajectories in the recurrent neural network. It is clear, however, that this is not a definitive demonstration of state-space reconstruction and a more detailed analysis of temporal pattern learning using formal grammars is being currently undertaken (Andrews 2001).

Abstract

The basic idea of the present study is that it is useful to conceptualize the processes involved in action comprehension in a similar manner as the processes involved in sentence comprehension. One important question then is whether order and meaning of action sequences are processed sequentially or in parallel (analogous to syntactic and semantic processing in sentence comprehension). We conducted three experiments to address this issue. Participants were asked to detect violations of order, meaning, or both, in action sequences of the game Paper, Scissors, and Rock. The main results were that it took longer to detect single violations than double violations and that it was impossible to ignore any of the violations. This pattern of results suggests that the processes involved are highly automatic and that they are running in parallel.

Have you ever wondered why people in sports bars stare at the numerous TV-screens that are silently picturing sequences of actions like people in fancy dresses bumping forcefully into one another, or two people hitting a ball with their rackets? Obviously, in some situations observing other people's actions is more interesting than chatting. This is not only true for sports bars but also for French street cafés and many other places. But how do we understand what happens while we watch other people acting?

Whereas cognitive science has been making much progress regarding the processes involved in language comprehension (Friederici, Steinhauer, & Frisch, 1999; Garrod & Pickering, 1999; MacDonald et al., 1994; Rayner & Pollatsek, 1989), action comprehension has been hardly addressed. Although Schank and Abelson's (1977) script theory seems relevant, it mainly deals with the comprehension of extended texts and not action comprehension as in the examples above. Another well-known approach, the grammar of action (Goodnow & Levine, 1973), addresses only the construction of complex movements from simpler units in writing. Our research is guided by the idea that it might be useful to conceptualize the processes involved in action comprehension in a similar fashion as the processes involved in sentence comprehension.

Sentence and Action Comprehension

In order to understand a sentence it is necessary to parse it according to the grammatical rules that governed its formation and to understand the meaning of the words given the context of the sentence. Likewise, to understand an action sequence it is often necessary to parse the sequence according to rules that constrain the order in which one action follows another and to understand the meaning of single actions given the context of the sequence. Although there might be action sequences the order of which is hardly constrained, most of them follow rules that can be spelled out clearly.

The main question for action comprehension (as for sentence comprehension) then becomes how processing of the order of action sequences (in analogy to syntactic processing) and the processing of its meaning are related. There are essentially four possibilities: (1) The analysis of order generally precedes and influences the analysis of meaning. (2) The analysis of meaning generally precedes and influences the analysis of order. (3) The two processes run in parallel and do not affect each other. (4) They run in parallel and they do affect each other. Controversies in sentence comprehension have mainly focused on the possibilities that are analogous to 1 and 4. The garden path model (Frazier & Rainer, 1982) suggests that meaning does not influence the selection of the initial syntactic structure (syntax first). The connectionist theory of MacDonald et al. (1994) states that syntactical and semantic constraints are narrowing the possible interpretations of a sentence in parallel and interactively. However, (2) and (3) are also viable possibilities for action comprehension. For instance, in favor of (2) one could say that the meaning of a single action of a peer might be most relevant for organisms (for instance because they can be dangerous or not) and that therefore the action comprehension system analyses meaning before order. The experiments that follow focused mainly on the question of whether the order and meaning of an action sequence are analyzed in parallel or whether there is any sequential order of the two processes.

Experimental Paradigm

In our experiments, we used a simple action domain, the game Paper, Scissors, and Rock. In this game, the order of consecutive actions is well defined and only a small set of gestures is meaningful in its context. Moreover, the game is well known (at least in Germany), so that people are quite familiar with the rules. The game has a fixed sequence (see Figure 1): In the beginning, the two players hold their hands close to the chest (upper position) and form a fist. In the next step, they drop their fists to a position near their waists (lower position) synchronously, and lift them again. This pattern is repeated once. During the third downward movement both players form one of three gestures: paper, scissors, or rock. The winner is determined by the following rules: Rock dulls scissors (rock wins), scissors cut paper (scissors win), paper wraps rock (paper wins). There are three meaningful gestures, that is, paper, scissors, and rock. Other gestures produce violations of context, as for instance the thumbs up gesture. It is also easy to see what a violation of order might look like. There is only one valid structure that is defined by alternating hand positions:

Upper, lower, upper, lower, upper, lower.

Therefore violations of order can be introduced by changing the sequence in the following way:

Upper, lower, upper, lower, upper, *upper.*

Obviously, violations of context and order are independent of one another. A violation of order might occur, although a meaningful gesture is formed (e.g. paper in the upper position, see leftmost picture in Figure 2). Alternatively, a meaningless gesture can be formed without violating order (e.g. thumbs up at the lower position (see picture in the middle of Figure 2). In addition, both violations can occur at the same time as when displaying a meaningless gesture at the wrong position (e.g. thumps up at the upper position, see rightmost picture in Figure 2). By comparing reaction times for different types of violations one can determine how order and meaning are analyzed in this type of action sequence.

Experiment 1

The aim of Experiment 1 was twofold. The first aim was to determine whether it is easier to detect violations of order than violations of context. If processing the order of an action sequence is similar to syntactic processing, it might be completed before the meaning of an action is fully retrieved or it might even be a necessary condition for the analysis of meaning. Hence people might be faster in detecting violations of order than violations of context. If, on the other hand, the processing of meaning is prevalent in action comprehension, violations of context should be faster detected.

The second aim was to determine whether order and meaning are processed in parallel. Faster detection of either violation does not necessarily imply that sequence and meaning are analyzed in a serial fashion. Rather, the differences could be due to different processing times taken by two parallel processes. If order and meaning are processed in parallel it should take less time to detect double violations than either single violation. The rationale behind this assumption is that the process that is completed first will trigger the reaction indicating that the violation was detected. Alternatively, evidence accumulated by each process might converge to trigger the wrong reaction. If order and meaning of action sequences are processed sequentially, detecting a double violation should take the same time as detecting the single violation (of either order or context) that is detected fastest.

One problem with measuring RTs for the detection of order and context violations in action sequences is that the onset of the violation is not well defined. When watching a video film displaying a person playing paper, scissors, and stone, the syntactic violation may be detected as soon as the expected downward movement does not occur. The semantic error can only be detected as soon as a gesture is formed. To avoid these problems, we used still frames that displayed the upper and lower position of the hand three times, respectively. The changing frames create the impression of a movement and they are readily interpreted as action sequences (Stürmer, Aschersleben, & Prinz, 2000). With still frames, syntactic, semantic, and double violations have the same onset, that is, the onset of the frame that completes the sequence at the lower position.

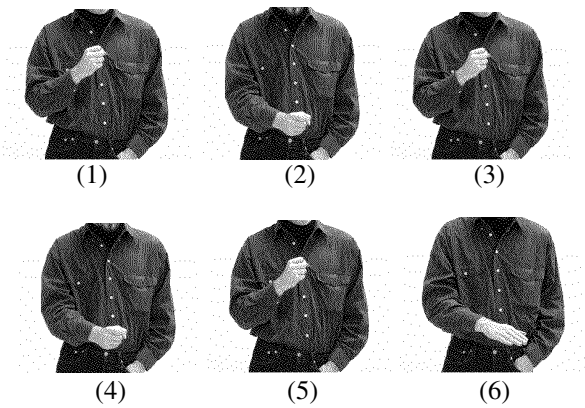

Figure 1: Sample sequence of pictures (correct).

Method

Participants. Sixteen participants, all students at the University of Munich, took part in the experiment, 9 of them male. They ranged in age from 24 to 35 years. The key assignment was counterbalanced across participants.

(a) v. of order (b) v. of context (c) double violation

Figure 2: Sample for last frame in action sequences with violation of order, meaning, or both.

Material. The material consisted of action sequences showing still frames of a person playing paper, scissors, and rock. There were six pictures displaying the actor forming legal gestures (Rock, Scissors, Paper), and six displaying him forming illegal gestures. The first five pictures of a sequence always showed a closed fist alternating between the upper and lower position. The sixth picture displayed one of the six possible gestures in the upper or lower position (see Figure 1 for a complete legal sequence). Hence, there were sequences ending with (1) a legal gesture at the lower position (correct), (2) an illegal gesture at the lower position (violation of context), (3) a legal gesture at the upper position (violation of order), and (4) an illegal gesture at the upper position. Figure 2 shows examples for the last frame in the violation conditions.

Procedure and Design. The experiment consisted of two blocks of 144 trials each. The order of action sequences was randomized in each block. To avoid response bias, correct action sequences were displayed as often as incorrect sequences. Hence there were 72 correct action sequences in each block, and 24 containing a violation of order, context, or both, respectively. The course of each trial was as follows: The first five frames were displayed for 500 ms, respectively. The sixth, critical frame was displayed for 1000 ms. The reaction time interval started with the onset of the last frame and lasted as long as the gesture was displayed (1000 ms). The participants judged whether there was a violation or not and pressed a left or a right key, accordingly. If they committed an error or did not react within the given time interval of 1000 ms, they were given error feedback.

Results and Discussion

Figure 3 displays the RTs for the detection of different types of violations during the first and second block of trials. Double violations (M = 540, S = 56) were faster detected than either violations of order (M = 569, S = *71*) or violations of context (M = 602, S = 57). Moreover, violations of order were faster detected than violation of context. These differences were present in both blocks, although RTs were generally faster in Block 2 (M = 559 ms, S = 66) than in Block 1 (M = 580 ms, S = 55). The mean RTs for responses to correct action sequences were 566 ms (S = 58). They were not included in the statistical analysis because they are hard to compare to RTs for violations because of the different base rate and the different type of response.

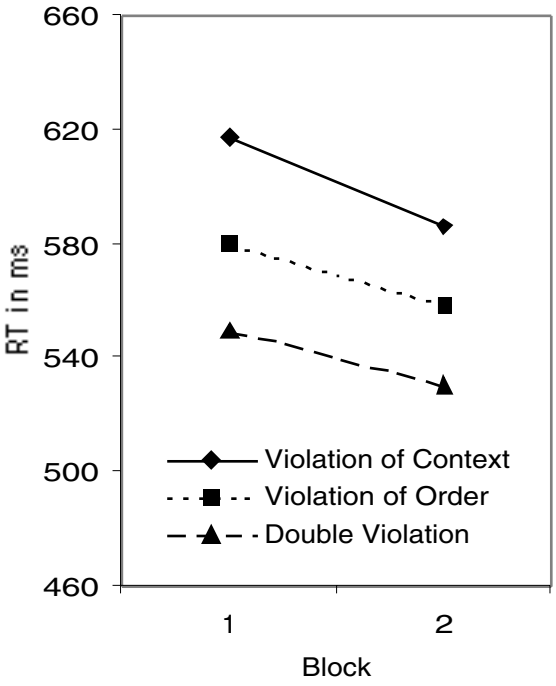

Figure 3: RTs for detecting different types of violations.

The RTs for the three error conditions were entered into a 3 x 2 repeated measurement ANOVA with the factors Type of Violation (Order, Context, vs. Double) and Block (1st vs 2nd). The analysis revealed significant main effects for Block, F (1, 15) = 9.9, p < .01, and Type of Violation, F(2, 30) = 28.4, p < .001, but no significant interaction. The RTs differed significantly for different types of violations. Duncan tests showed that double violations were detected significantly faster than either violations of order or context (both p < .001). In addition, there was also a significant difference between the two types of single violations (p < .001).

The pattern of RTs is in favor of a parallel processing explanation. Double violations were detected faster and more reliably than either violations of sequence or context. This is in favor of the claim that either of two

parallel processes being completed first can trigger the reaction indicating that a violation was detected. Order violations were faster detected than context violations right from start. Hence, it seems that analyzing the order of a sequence is completed before the meaning of an action is fully processed. An alternative explanation for the different speed with which violations of order and context can be detected is perceptual saliency. Violations of order might have been easier to detect because a wrong hand position is perceptually more salient than a hand forming a different gesture.

Experiment 2

The second experiment was conducted to rule out the perceptual saliency explanation. To do so, we replicated Experiment 1 using a set of stimuli in which the perceptual saliency of order and context violations was more comparable. The deep structure of the action sequence, five alternations of the same gesture and formation of the target gesture with the last alternation, did not change. However, the alternations were now expressed as hand turnings instead of arm movements (see Figure 4). Hence both, violations of order and context now depended on the configuration of hand and fingers. Violation of order consisted in a missing turn of the hand, violations of context consisted in invalid gestures, as in Experiment 1 (see Figure 5).

If higher perceptual saliency caused the faster detection times for violations of order in Experiment 1 the detection times should be slower or equally fast as for violations of context under the new conditions. If faster processing of sequence information caused the difference the results should be the same as in Experiment 1. It is quite likely that such a difference would not occur right from start because people have to link the new type of alternation (hand turning) to the familiar deep structure of the sequence before optimal detection of order violations becomes possible. Hence, in order to allow this link to be established we added a further block of trials. For double violations we expected the same pattern as in Experiment 1, that is, faster detection than for either single violation.

Method

Participants. Fifteen participants, all students at the University of Munich, took part in the experiment, five of them male. They ranged in age from 24 to 35 years.

Material. A different set of stimuli was used. The fixed pattern of alternations consisted of hand turnings while the hand position remained fixed. The critical manipulation occurred with the last frame. The gesture displayed could either be correct, a violation of order, context, or both (see Figure 5 for examples). There were three different valid gestures and three that violated the context. There were two versions of each gesture, one displaying the face of the hand (correct) and one displaying the backside (violation of order).

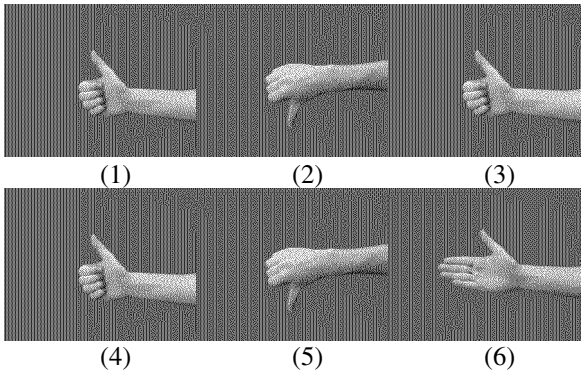

Figure 4: Sample sequence of pictures (correct).

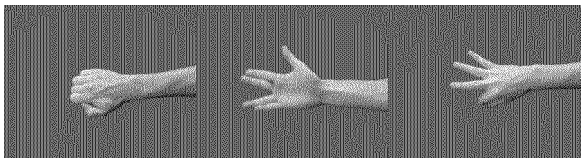

Figure 5: Examples for violation of order (left: wrong orientation), context (middle), and double violation (right) in Experiment 2.

Procedure and Design. The procedure was the same as in Experiment 1 with one exception. A third block of 144 trials was added.

Results and Discussion

Participants pressed the wrong button in about 3% of the cases and reacted too late in about 2% of the cases. Figure 3 displays the RTs for the detection of different types of violations during the first, second, and third block of trials. Overall, it took participants longer to detect violations of context (M = 615, S = 64) than violations of order (M = 596, S = 76). However, this difference occurred only after the first block. As expected, double violations were faster detected than either single violation right from start (M = 561, S = 70). Participants became faster during later blocks. Mean RTs were 617 (S = 56), 584 (S = 63), and 572 (S = 70) during Block 1, 2, and 3.

The RTs of the three error conditions were entered into a 3 x 3 repeated measurement ANOVA with the factors Type of Violation (Order, Context, vs. Double) and Block (1, 2, vs. 3). There were significant main effects for Type of Violation, $F(2, 28) = 14.7$, $p < .001$, and Block, $F(2, 28) = 20.9$, $p < .001$, the interaction between both factors was only marginally significant, $F(4, 56) = 2.0$, $p = 0.1$. Duncan-tests showed that the RTs for violation of order were significantly faster than for

violations of context in Block 2 and 3, but not in Block 1. The difference between double violations and either single violation was significant in each Block.

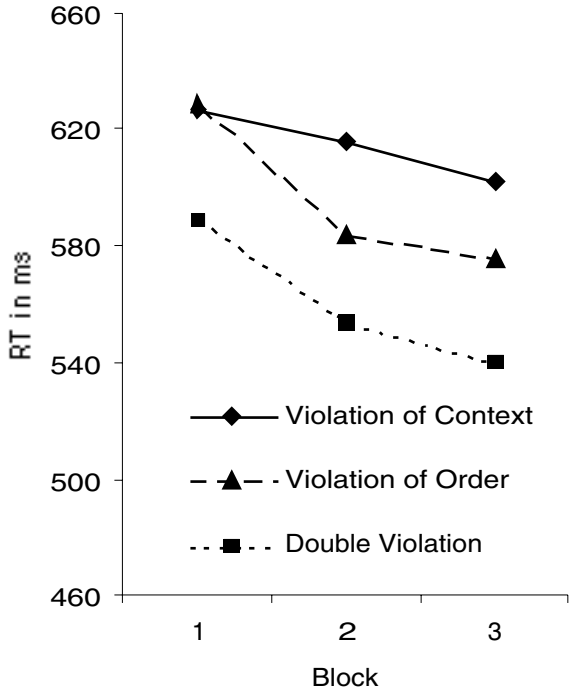

Figure 6: RTs for detecting different types of violations.

The results basically replicate Experiment 1. After Block 1, the RTs were almost numerically identical to those observed in the first experiment. This suggests that it was not perceptual saliency that created the RT differences between violations of order and context. Rather it seems that sequence information is faster processed, at least for simple sequences as in paper, scissors, and rock. The lack of difference during the first block is probably due to the necessity of establishing a link between the new perceptual cues and the familiar deep structure. The finding that double violations were faster detected right from start further supports the claim that order and meaning of action sequences are processed in parallel.

Experiment 3

It has often been claimed that parallel processes do not require attention and that they are highly automatic. Experiment 3 was conducted to determine whether this is also true for the processes involved in analyzing the order and meaning of action sequences. We used an interference paradigm to provide evidence for the automatic nature of the processes involved. The first block of Experiment 3 was identical to that of Experiment 2. In the following blocks we asked participants to ignore violations of order or context while detecting the other type of violation, respectively. In a first block, they were asked to detect violations of order and to ignore violations of context, that is, sequences containing the latter violation should be judged as correct. In the other block they were asked to detect violations of context and to ignore violations of order, that is, sequences containing a violation of order should be judged as correct.

If order and meaning of action sequences are analyzed automatically the violations to be ignored should interfere with judging a sequence as correct. If the processes are not automatic there should be no differences in RTs between action sequences containing an interfering violation and truly correct action sequences. Moreover, if sequence processing is faster than the processing of meaning a violation of order should interfere more strongly with the correct response than a violation of context.

Method

Participants. 20 participants, all students at the University of Munich, took part in the experiment, 8 of them male. They ranged in age from 24 to 35 years. The order of blocks was counterbalanced.

Material. The material used was identical to that of the second experiment.

Procedure and Design. The experiment consisted of three blocks of 144 trials each. The first block was the same as in Experiment 2. At the beginning of the second and third block participants received an instruction to attend to one of the single violations only and to ignore the other (e.g. detect violation of context/ignore violation of order). During the third block participants attended to the other type of violation and ignored the other (e.g. detect violation of order/ignore violation of context). The order of blocks 2 and 3 was counterbalanced across participants.

Results and Discussion

Participants pressed the wrong button in about 1% of the cases and reacted too late in about 3% of the cases. The RTs for different types of violations during the first block were indistinguishable from Experiment 2. Because of the space constraints, we will report only RTs for trials in which action sequences should be judged as correct. Figure 7 shows the results.

RTs were generally faster for correct sequences (M = 522, S = 59) than for sequences that contained an interfering violation (M = 580, S = 82). The difference was larger when a violation of order interfered (82 ms) than when a violation of context interfered (24 ms).

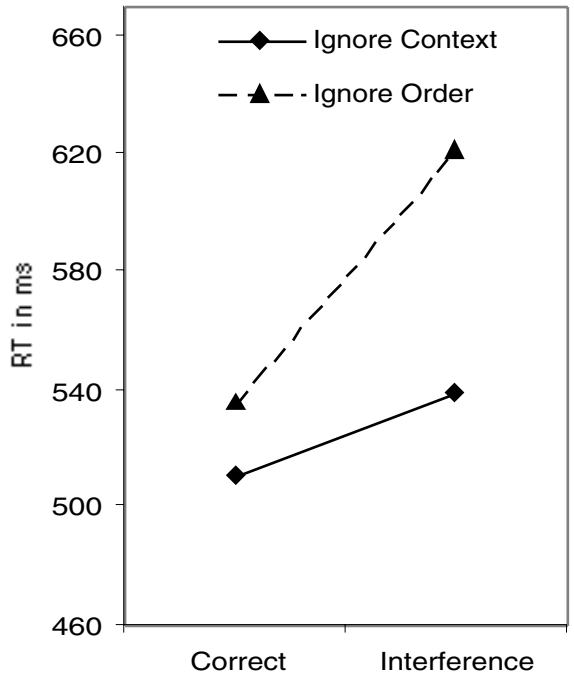

Figure 7: RTs with and without interfering violation.

The RTs were entered into a 2 x 2 repeated measurement ANOVA with the factors Type of Sequence (Correct vs. Interfering Violation) and Type of Interference (Order vs. Context). There were significant main effects for the factors Type of Sequence $F(1, 19) = 27.5$, $p < .001$ and Type of Interference $F(1, 19) = 86.6$, $p < .001$, as well as an interaction between the two factors $F(1, 19) = 23.1$, $p < .001$.

The pattern of results is consistent with the claim that the processes involved in analyzing order and meaning of action sequences are highly automatic. Otherwise one would not expect the huge interference effects that were observed in Experiment 3. It seems impossible to focus on one or the other aspect of an action sequence and to ignore the other. The stronger effect in the condition with interfering violations of order further supports the claim that analyzing the order of an action sequence takes less time than analyzing it's meaning.

General Discussion

The general pattern of results suggests that in action comprehension the analysis of order and meaning proceeds in parallel. Moreover, both processes seem to be highly automatic, that is, none of the two aspects of action sequences can be easily ignored. A further result is that analyzing the order of a sequence might be completed before its meaning is fully analyzed. However, further experiments are needed to determine whether the faster processing of order is a general phenomenon or whether it depends on the complexity of the task at hand.

The possibility to conceptualize action comprehension in an analogous manner to language comprehension does not necessarily imply that the cognitive processes involved in both domains are the same or that they are governed by the same principles. However, this strategy provides an opportunity to relate findings from both domains and to detect interesting parallels or differences. Currently, we are conducting ERP studies to determine whether violations of order and context in action sequences evoke the same ERP components as syntactic and semantic violations in spoken sentences (Friederici et al., 1999). The results of such studies might provide more conclusive answers to the question of whether there are cognitive processes which are actually contributing to both, action and language comprehension (Rizzolatti & Arbib, 1998).

Abstract

The use of graphs to represent and reason about data is of growing importance in pre-high school mathematics curricula. This study examines middle school students' skills in reasoning about three graphical representations: histograms, scatterplots and stem-and-leaf plots. Students were asked to interpret graphs, select an appropriate graph type to represent a relationship and to generate graphs. Accuracy levels varied substantially across the three tasks and three graph types. The overall pattern of results is largely explained by the varying ease of transfer of student knowledge from a simpler graph type, based on surface similarity.

Introduction

External graphical representations are of considerable importance in problem solving. Considerable research has taken place over the last two decades on the different mechanisms through which graphical representations assist their users in drawing inferences (Larkin & Simon, 1987; Stenning, Cox, and Oberlander 1989).

In this paper we take up the use of representations at a very early point – at the point when a student is just learning to generate and interpret a representation – and ask what some of the major challenges are in learning these skills. There has been growing interest in attempting to teach these skills to students as young as those in the third through eighth grades[1] (NCTM 2000), but there is considerable evidence as well that these skills have not yet been developed by many undergraduates (Tabachneck, Leonardo, and Simon 1994).

We take up this subject in the context of developing a cognitive model of how novices generate and interpret some of the simpler representations used in data analysis. This model is designed with production-rule logic, in ACT-R (Anderson 1993). In this process, we hope to follow in the footsteps of some of the successful cognitive models of novices developed in other domains such as algebra problem solving (Koedinger & MacLaren 1997).

One area which might considerably influence students' performance on these tasks is transfer of the knowledge students already have of generating and interpreting other representations. Since students are taught different sets of representations at different grade levels (NCTM 2000), it is quite plausible that an important model for learning new representations will be the representations encountered earlier. Previous research into when transfer occurs shows that transfer can happen between exercises taking place in different representations, through mechanisms such as analogy, and that transfer can occur between similar processes (Novick 1988, Novick and Holyoak 1991, Singley and Anderson 1989). Hence, we seek to find out if and how these processes extend to the very first stages of learning how to use and generate a representation.

We are interested both in positive transfer, and in overgeneralization, where knowledge is transferred inappropriately. Scanlon's (1993) research in the use of representations for physics problem-solving provides some excellent examples of overgeneralization in the interpretation of different graphical representations. Additionally, other research has shown that misconceptions in physics, arising from overgeneralization of previously learned knowledge, causes long-term difficulties in correctly learning new material. How best to deal with such misconceptions is an active question in the research literature, with some arguing for a curricular strategy which acknowledges the appropriate contexts for certain conceptions and helps students see when they are inappropriate (NRC 1999).

In this paper, we present results and analysis of a empirical study we conducted in this domain, investigating novice performance (with an eye towards transfer effects) on interpreting, generating, and selecting representations important to early data analysis.

Domain

Representations

This study focuses on three graphical representations of data: histograms, scatterplots, and stem-and-leaf plots.

A *histogram* depicts a frequency distribution, as displayed in Figure 1. A set of interval categories (as in Figure 1) are represented in the X axis, and the frequency of each category is represented by the height of the corresponding vertical bar. A *stem-and-leaf plot,* shown in Figure 2, also

[1] Between the ages of 7 and 13.

displays frequency distribution data – the frequency of occurrence in this case for values between 0 and 99. In Figure 2, a distribution of 30 values, ranging from 4 to 97, is displayed. The higher order "tens" digit of the values form 10 categories down the left side of the graph. The lower order "ones" digit of each observed value is displayed in an ordered row to the right of the associated tens digit. Finally, a *scatterplot* employs a Cartesian plane to represent the relationship between two quantitative variables, as displayed in Figure 3. Each axis represents one of the variables, and the points represent paired values of the variables.

These three representations were selected because they are featured in most middle school math curricula and to systematically vary graph characteristics. Note that histograms and stem-and-leaf plots each portray univariate frequency distributions, although their surface features are dissimilar. The stem-and-leaf plot looks more like a table, frequency is depicted horizontally rather than vertically, and the frequency count is not directly depicted. In contrast, histograms and scatterplots share some superficial similarities – each has two numerically labeled axes – but they represent very different types of information.

A fourth type of graph, which was not included in the experimental tests, will be relevant in interpreting student performance. This is a *bar graph*, as depicted in Figure 4. A bar graph displays the values of a categorical variable along its X axis, and of a related quantitative variable along its Y axis.

Teacher Predictions

In this study, students are asked to (a) interpret graphical representations, (b) select the appropriate representation for different types of data display, and (c) generate different representations. We asked the two teachers in our sample classes to predict how their students would perform. The teachers predicted that students would perform about equally well on interpretation and generation, and poorly on selection. They predicted that students would be most successful with histograms, next most successful with scatterplots (because scatterplots are more conceptually challenging) and would perform worst on stem-and-leaf plots (because they are the least familiar to students).

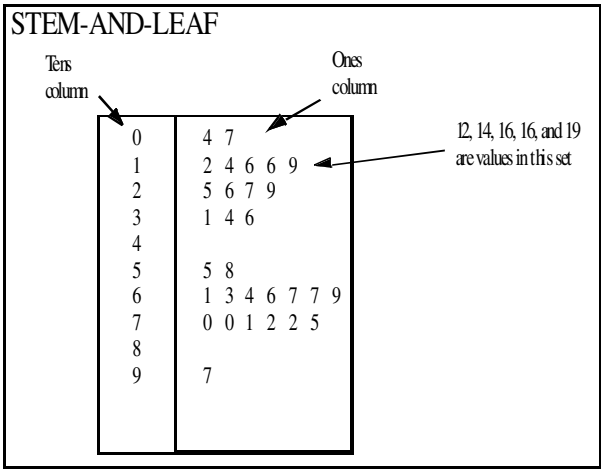

Figure 2: The drawing of a stem-and-leaf plot we used in our refresher sheet

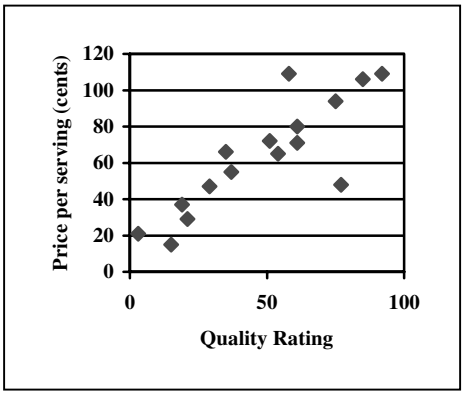

Figure 3: The scatterplot used in the interpretation exercises

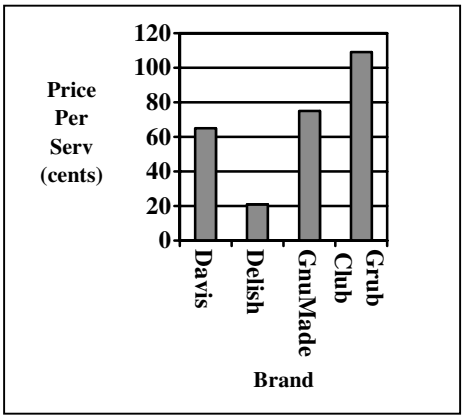

Figure 4: A Bar graph

Methods

Participants

The participants were 52 8th and 9th grade students from three mainstream pre-algebra classes in two Pittsburgh suburbs, half male and half female. The study was conducted prior to the year's data analysis unit; students had some exposure to histograms, scatterplots and stem-and-leaf plots in the last two years, and considerably greater exposure to bar graphs before that point.

Design

In the study, each of the participants completed 3-4 exercises in which they were asked to generate ("draw") a histogram, scatterplot, or stem-and-leaf plot, to answer a set of interpretation questions for one of those representations, or to select the most appropriate representation for a particular question. Four different forms were used, with questions on each form chosen such that neither the same category of task nor the same representation were assigned twice in one form. Within each form, the order of the exercises was rotated for different students to prevent order effects. These forms also included exercises involving box plots and tables, but we neither expected nor found the kind of effects we found for the representations discussed here.

The generation exercises gave the student a data set, in the form of a table, and asked them to draw the given representation of that data. The exercise statement read as follows:

> Please draw a [scatterplot, histogram, stem-and-leaf plot], showing all of the data in this table. Show all work. Feel free to use graph paper, if necessary.

The interpretation exercises gave the student a drawing of that representation and a set of questions to answer using that representation (see Figure 1and Figure 3).

The interpretation exercises had three types of questions, both multiple-choice and open-ended. The first type were straightforward questions typically asked for the target representation. These required no understanding of the representation's global properties (for the histogram, "How many brands of creamy peanut butter have between 0 and 30 mg of sodium?"). The second were also typical, but required understanding of the representation's global properties -- properties which require the student to make inferences (Stenning, Cox and Oberlander 1995, Leinhardt, Zaslovsky, and Stein 1990). "Is there a relationship between quality and price? Answer yes or no." is one such question for scatterplots. Finally, the third type were questions that are not typically asked for the target representation, but could be answered through productions more appropriate for another representation (for the scatterplot, "What is the price of the brand with a quality rating of 3?").

The representation selection questions gave the students a data set, in the form of a table, a question to answer (such as "What type of graph would be best for determining whether or not there is a relationship between price and quality?"), and four choices.

The students were also given a sheet with a picture of the four types of representations directly addressed in the exercises (histograms, scatterplots, stem-and-leaf plots, and box plots – bar graphs were not included in this sheet, nor mentioned in the study). An example from this sheet is shown in Figure 2. We did this in order to prevent the forgetting of terms from having an effect on the students' performance.

Scoring

For generation exercises, we developed rubrics for completely correct solutions (no features incorrect), and solutions that had the correct surface features (with the same general appearance as a correct solution – axes and bars or dots). For interpretation and representation choice exercises, we scored answers either completely right or wrong.

Results and Discussion

Performance accuracy in the graph interpretation, generation and interpretation tasks is displayed in Table 1. Students performed moderately well overall on graph interpretation, averaging 56% correct. However, there was large difference between performance on different representations – the 15 students interpreting histograms performed considerably better (average of 96% correct) than the 12 students interpreting scatterplots (average of 56% correct on the open-ended questions) ($t(25)=4.925, p<0.0001$). Both groups performed considerably better than the 13 students interpreting stem-and-leaf plots (average of 17% correct) (for scatterplots versus stem-and-leaf plots, $t(23)=4.109$, $p<0.001$; for histograms versus stem-and-leaf plots, $t(26)=12.191$, $p<0.0001$). In contrast, student performance on graph selection and graph generation was quite poor. Students were not better than chance accuracy (1 out of 4, 25%) in graph selection. Furthermore, they were completely unsuccessful at generating histograms and scatterplots. Performance by the 15 students who attempted to generate stem-and-leaf plots was relatively poor at 20% completely correct, but was marginally significantly better than the performance of the 12 students attempting to generate histograms (0% completely correct) and the 12 students attempting to generate scatterplots (0% completely correct), using a test of the significance of independent proportions. ($z=1.64$, $p<.11$).

The teachers accurately predicted that students would struggle with graph selection problems. Their predictions that histograms would be easiest and stem-and-leaf plots hardest corresponded with the data, but only for graph interpretation. Their expectation that students would have comparable success with generation and interpretation proved dramatically incorrect. Nathan and Koedinger (2000) report a similar result, that experienced teachers sometimes exhibit an "expert blindspot" and, in some cases,

Table 1: Average student performance in graph generation and interpretation. Percent which students would be expected to get right through guessing is placed in parentheses where appropriate.

	Histogram	Scatterplot	Stem-and -leaf plot
Generation	0%	0%	20%
Interpretation (open-ended questions)	95%	56%	17%
Selection	15% (25%)	20% (25%)	8% (25%)

consistently make inaccurate predictions about which problems will be most challenging for students.

This unanticipated decoupling between performance on graph interpretation and graph generation is striking. In addition to the large difference in overall accuracy, the relative difficulty of different representations is essentially reversed in the two tasks. Students had the most trouble in interpreting stem-and-leaf plots, but that was the only graph type they had any success in generating. A similar dissociation of interpretation and generation has been observed in other domains such as programming (Anderson, Conrad & Corbett, 1989), although not always (Pennington & Nicolich, 1991).

Histogram & Scatterplot = Bar Graph

When we examined the student graph generation solutions which were correct at least so far as having the proper surface features, we noted a characteristic error in 100% of the histograms and 28% of the scatterplots that provides strong evidence about the students' problem solving strategy. Figure 5 displays a typical histogram solution and Figure 6 displays a typical scatterplot solution. In each case the students have constructed axes that are appropriate for a bar graph. In both graphs, the x-axis represents individual values of a categorical variable (individual brands of peanut butter) and the y-axis represents values of a quantitative variable (sodium level). Each of these graphs is the informational equivalent of a bar graph. This suggests that, in this stage of learning, students are transferring existing knowledge about bar graphs, instead of using knowledge specific to the target representation. That students would already have knowledge of bar graphs is consistent with bar graphs being a simpler representation than histograms (no aggregation of data in the x-axis) and scatterplots (only one continuous variable). This hypothesis not only explains the graph generation results, but also appears to account for the overall pattern of graph interpretation and graph selection results as we discuss below.

Graph Interpretation

Figure 7 displays a set of production rules for common bar graph interpretation problems – given one of the categorical

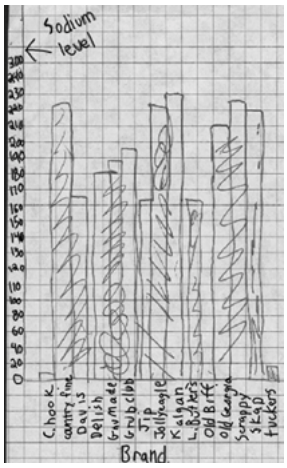

Figure 5: An example of a student-drawn "histogram". Note the axes are a categorical variable versus a quantitative variable – appropriate for a bar graph.

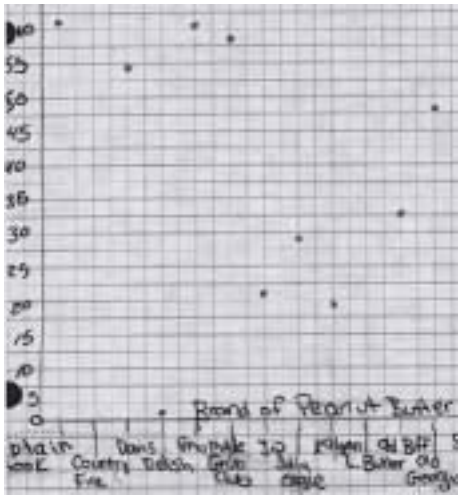

Figure 6: An example of a student-drawn "scatterplot". Note the axes are once again more appropriate for a Bar graph.

instances on the x-axis, find the associated quantitative value on the y-axis. For example, if a bar graph displays the price of several brands of peanut butter (see Figure 4) and a student is asked "What is the price of GnuMade peanut butter?", the student finds "GnuMade" on the x-axis, finds the top of the associated bar, then reads horizontally across to find GnuMade's price on the y-axis. These productions were directly applicable to all of our histogram interpretation exercises. On those exercises, the 15 students had an average accuracy rate of 95%. These productions were also applicable to several of the scatterplot questions (e.g., "What is the price of the brand with a quality rating of 3?"). Students had an average accuracy rate of 50% on these questions.

Student performance on the scatterplot questions is quite striking, when we consider the fact that these questions are not standard for scatterplots. At the same time, the students

Table 2: Average student performance in graph interpretation, for different kinds of problems. Percent which students would be expected to get right through guessing is placed in parentheses where appropriate.

	Histogram	Scatterplot	Stem-and -leaf plot
Interpret: "Bar graph Productions"/ Analogous	95%	50%	21%
Interpretation: Emergent Properties	N/A	67% (50%)	N/A
Interpretation: Overall	95%	57%	17%

had considerable difficulty with other scatterplot exercises. In fact, on the exercises where students had to interpret a scatterplot's global properties, generally considered that representation's main function, the students did not perform significantly better than chance ($p>.10$, $N=12$, using a sign test).

By contrast, the bar graph interpretation productions in Figure 7 do not transfer to stem-and-leaf plots, because the student can neither look up the given value on either axis, nor read the answer off the other axis. This is borne out by the fact that on the 4 questions which were almost word-for-word identical to the histogram interpretation questions, the 13 students performed much more poorly, averaging 21% correct. This is significantly lower than the performance on the corresponding questions for histograms ($t(26)=9.908, p<.0001$).

Hence student interpretation performance levels are more similar between histograms and scatterplots that share surface features with bar graphs, than between histograms and stem-and-leaf plots that have similar content but different surface features (cf. Chi, Feltovich, & Glaser 1981).

Graph Selection

If students are reasoning about all three representations with reference to a single familiar bar graph, they have no basis for discriminating which of the three is appropriate for representing different types of relationships and we would expect chance performance levels. This is in fact what we found, with students getting 15% on the graph selection exercises, even below the 25% accuracy choosing 1 out of 4 would predict. In the absence of understanding which representation is appropriate, an apparent bias in favor of the representation the student had drawn in another question, which by our study design was necessarily wrong, may have led to the observed below chance performance.

```
If we are trying to find a value on a graph
  And we are looking for the value
        corresponding to a value V
Then
  Set a subgoal of looking for V written on the x axis

If we are looking for V on the x axis
  And value V is written at location x* on the x axis
Then
  Set a subgoal of looking at location x*

If we are looking at location x* on the x axis
  And point P is the topmost drawn in graphic
        above location x* on the x axis
Then
  Set a subgoal of looking across from P

If we are looking across from P
  And y* is the value on the y axis horizontally
        over from P
Then
  Return y* as the value we were looking for
```

Figure 7: English-language productions for bar graph interpretation, also suitable for some histogram and scatterplot interpretation.

```
If we are trying to generate a graph G
And G's axes have not been selected
Then
  Set a subgoal for selecting G's axes

If we are attempting to select axes for graph G
  And the X axis is not selected
  And there is a variable V in our data set
  And V is a categorical variable
Then
  Select V as our X axis
```

Figure 8: An English-language production for choosing the X axis variable during generation, overgeneralized to apply inappropriately during scatterplot and histogram generation.

Conclusion and Future Work

Novice students' performance on interpretation, generation, and selection of the data representations in this study can be explained as depending upon transfer of their prior knowledge of bar graphs. Where transfer and generalization are afforded by surface similarity, they occur, whether appropriate or not. This hypothesis exposes a more integrated pattern of interpretation and generation performance than is apparent in the overall results.

Given these findings, we are working toward developing a more complete ACT-R cognitive model of learning data representations

A major subtask in developing our model will be refining our understanding of the factors which scaffold the novices in transferring their knowledge, both appropriately and inappropriately. We do not yet know which common features between representations are essential to this process – certainly it seems that surface features are more important than deeper features, a finding compatible with those in analogical transfer (cf., Novick 1988; Novick and Holyoak 1991) – but which surface features are most salient is an important question in itself. For example, stem-and-leaf plots have three large differences from histograms: flipped axes, the need to remove the tens digit, and the need to count up values. Determining which of them is most

important will have large impacts on our understanding of the generality of the productions students use.

Eventually, we hope to use the cognitive model we develop to build a Cognitive Tutor (Corbett, Koedinger, & Hadley, in press) for this domain. Already, our research has given us extensive information about some of the important difficulties novices have in learning how to generate and interpret these basic representations, including the confusion between histograms and bar graphs. Additionally, our curriculum will be strongly shaped by further research determining whether these overgeneralizations are truly misconceptions which need to be broken down, or whether they are preconceptions which can still be built upon in some way (cf., NRC 1999).

A final future direction is one that may have surprising power – rather than trying to repair misconceptions, we may get even better long-term results from addressing the possibility that we can create a curriculum where bar graphs are taught differently, and the overgeneralization never develops in the first place – where the interpretation productions still transfer, but the generation productions do not become inappropriately broad. Through research in these areas, we hope to transform students' knowledge in this domain.

Acknowledgments

We would like to thank Jay Raspat and Katy Getman for assisting us in the administration of the study discussed here. We would also like to thank Bethany Rittle-Johnson and Jack Zaientz for helpful discussions.

Referential Form, Word Duration, and Modeling the Listener in Spoken Dialogue

E. G. Bard (ellen@ling.ed.ac.uk)

Abstract

Referring expressions are thought to be tailored to the needs of the listener, even when those needs might be costly to assess, but tests of this claim seldom manipulate listener's and speaker's knowledge independently. The design of the HCRC Map Task enables us to do so. We examine two 'tailoring' changes in repeated mentions of landmark names: faster articulation and simplified referring expressions. Articulation results replicate Bard et al. (2000), depending only on what the speaker has heard. Change between mentions was no greater when it could be inferred that the listener could see the named item (Expt 1), and no less when the listener explicitly denied ability to do so (Expt 2). Word duration fell for speaker-Given listener-New items (Expt 3). Reduction was unaffected by the repeater's ability to see the mentioned landmark (Expt 4). In contrast, referential form was more sensitive to both listener- (Expt 3) and speaker-knowledge (Expt 4). The results conform most closely to a Dual Process model: fast, automatic, processes let the speaker-knowledge prime word articulation, while costly assessments of listener-knowledge influence only referential form.

Introduction

Speakers are said to design their utterances to suit the needs of their listeners, insofar as those needs can be known (Ariel, 1990; Clark & Marshall, 1981; Gundel, Hedberg, & Zacharski, 1993; Lindblom, 1990). Certainly, there is variation in form. Clarity of pronunciation varies with predictability from local context (Hunnicutt, 1985; Lieberman, 1963) and with repeated mention (Fowler & Housum, 1987). Referential forms are syntactically simpler the more readily interpreted or 'accessible' their antecedents, are (*a blacksmith's cottage* v *it*) (Ariel, 1990, Fowler, Levy, & Brown, 1997; Gundel, et al., 1993; Vonk, Hustinx, & Simmons, 1992). Yet maintaining an incrementally updated model of what the listener knows, what is established common ground, and what the listener needs to know is a considerable cognitive task. Because speaker's and listener's knowledge overlap and because it may be impossible to assess the latter accurately, speakers may default to an account of their own knowledge as a proxy for the listener's (Clark & Marshall, 1981). In fact, many studies simply assume that the two are the same: they manipulate the speaker's knowledge without independently manipulating the listener's (see Keysar, 1997).

This paper compares two versions of the hypothesis that referring expressions are genuinely tailored to the addressee. One deals with the articulation of individual words, the other with the syntactic form of referring expressions. Under current models of language production, NP structure and articulation are generated within units of different sizes, intonational or syntactic phrases on the one hand and phonological words, lexical words, or syllables on the other (Levelt & Wheeldon, 1994; Smith & Wheeldon, 1999; Wheeldon & Lahiri, 1997). Moreover, speech appears to be produced in a cascade, with a sequence of smaller units being prepared for articulation even as the succeeding larger unit is being designed. Thus, incrementally updating a listener model in order to articulate each phonological word appropriately would impose a much heavier computational burden than updating it phrase by phrase. Making both kinds of update for the processes running in parallel would be even more demanding, with the listener model operating both in the state appropriate to the most recently produced word and in the state created by the most recently planned phrase.

We will first develop existing hypotheses about how speakers model listeners while planning and producing speech. Then we will report four studies which test these hypotheses on materials from a single corpus. They follow the comparisons made by Bard et al. (2000) on a psychological measure of clarity, the intelligibility to naïve listeners (recognition rate) of a balanced sample of excised spoken words. The present paper reports a phonetic measure of clarity (word duration), and a syntactic measure of referential form for all suitable cases in a dialogue corpus. Finally, we will discuss the implications of the comparison.

Modeling Listeners while Speaking

Existing accounts of tailoring to listeners' needs make different computational demands on speakers. Where they are not designed with a view to on-line processing, we will attempt to interpret their implications.

Lindblom's *H-and-H Hypothesis* (1990) makes the heaviest computatonal demands. It posits that speakers adjust the articulation of spoken words to the knowledge which the listener can currently recruit to decoding the speech signal: speakers hyper-articulate when listeners lack such auxiliary information and hypo-articulate when redundancy is high. More redundant linguistic environments do contain word tokens articulated with greater speed and less precision (Bard & Anderson, 1983, 1994; Fowler & Housum, 1987; Hunnicutt, 1985; Lieberman, 1963; Samuel & Troicki, 1998). The question is whether this relationship depends on the speaker's consulting an up-to-date model of the listener's current knowledge each time s/he prepares the prosodic character of a phonological word or the articulation of its syllables. Though H-and-H does not preclude defaulting to speaker-knowledge, it is framed in terms of genuine listener-knowledge and implies that speakers should observe listeners continuously for signs of misunderstanding or disagreement. Wherever speaker's and listener's knowledge differ, the latter should take precedence.

In contrast, Brown and Dell (1987) propose a modular division between the initial formulation of utterances and the revision of output which does not adequately convey the intended concepts. The listener's knowledge is implicated only in revision (Dell & Brown, 1991, pp. 119-120). Called the *Monitor and Adjust Hypothesis* (Horton & Keysar, 1996), this model defaults to speaker-knowledge first and pays later – if necessary. As originally formulated, Monitor and Adjust does not explain how the hitherto speaker-driven processes assess the adequacy of an utterance from the listener's point of view. We assume that each interlocutor's knowledge includes a record of what the other has actually said. Listeners' occasional explicit feedback, a minimal listener model, could therefore influence a modular system which revises inadequate utterances. Under this Extended Monitor and Adjust Hypothesis, post-feedback utterances could reflect any listener-knowledge which the feedback has conveyed. Otherwise, listener-knowledge should be irrelevant to production.

The third proposal deals with co-presence, characteristics of listeners which affect likely overlap with speakers' own knowledge (Brennan & Clark, 1996; Fussell & Krauss, 1992; Isaacs & Clark, 1987; Schober, 1993). The manifestations of co-presence in the dialogue literature are many, but the notion was originally used to reduce the computation which a speaker must perform to determine the unknown component of mutual knowledge, i.e. what the listener knows. Under this heading, Clark & Marshall (1981) list shared community membership, physical co-presence of interlocutors and the objects under discussion, and knowledge both of the dialogue and of a suitable scenario. Since much of co-presence is long-lasting, it can reduce both the depth and the frequency of listener modeling. To exploit these economies, speakers should attend to evidence for and against co-presence, and they should maintain defaults for some undefined time after positive evidence. We will call this the *Co-presence Default Hypothesis.*

Finally, Bard et al. (2000) develop a suggestion of Brown and Dell (1987) which we will call the *Dual Process Hypothesis*. It proposes a division between fast, automatic processes, which have no computational cost, and slower, more costly processes requiring inference or attention. The former include priming. (Balota, Boland, & Shields, 1989; Mitchell & Brown, 1988), an effect of the speaker's own recent experience. The latter include the kind of complex reasoning usually implicated in constructing a model of the listener. In competition with listener-modelling are the computations which support planning a dialogue or tracking a shared task. When there is competition for time and attention, (Horton & Keysar, 1996), the inferential processes may suffer, leaving the speaker with only cost-free defaults in the form of his or her own knowledge.

Studies of Intelligibility and Referring Expression

Givenness and Referring Expressions

To test these hypotheses, we made use of two effects of Given status broadly defined. First, spoken words introducing New items are longer and clearer than those in repeated mentions (Fowler & Housum, 1987) but only when the two tokens are co-referential (Fowler, 1988; Bard et al, 1991). Initial mentions of items uttered without visible referents (Prince's (1981) 'brand new') are also longer and clearer than those with visible referents (Prince's (1981) 'situationally' Given) (Bard & Anderson, 1994). Second, referring expressions simplify with repeated mention (*a blacksmith's cottage.... it)* as their antecedents become more accessible (Ariel, 1990, Gundel, Hedberg, & Zacharski, 1993). To compare the two systems, we used a single coded corpus of spontaneous speech which made it possible to select items which were Given to one or both interlocutors on the basis of what each saw, said, or heard in the dialogue.

Method

Materials. Materials came from the HCRC Map Task Corpus (Anderson et al., 1991), 128 unscripted dialogues in which pairs of Glasgow University undergraduates ($N = 64$) communicated routes defined by labeled cartoon landmarks on schematic maps of imaginary locations. Instruction Giver's and Follower's maps for any dialogue matched only in alternate landmarks. Participants knew that their maps might differ but not where or how. Players could not see each other's maps. Familiarity of participants and ability to see the interlocutor's face were counterbalanced. Each participant served as Instruction Giver for the same route to two different Followers and as Instruction Follower for two different routes.

Channel per speaker digital recordings were word-segmented. All words of any expression referring to a landmark were coded for the landmark, tagged for part-of-speech, and parsed. Interrupted or disfluent items were excluded. All remaining expressions making repeated reference to a landmark and meeting experiments' design criteria were used. Duration was measured only if both mentions include the same words. All repeated mentions were are assessed for syntactic form.

Dependent Variables

K-reduction. Normalized duration (Campbell & Isard, 1991) assigns each word token a value, *k*, representing its position in the expected log length distribution for words of its dictionary phoneme composition and stress pattern. *K-reduction* is the difference between the *k*-durations of a read control form and of the corresponding item in running speech. Faster articulation with repeated mention would enhance *k*-reduction.

Form of referring expression. The 27 items with relative clauses in their first mentions were excluded because of a conflict in coding schemes. All other first and second mentions of landmarks (***N*** = 1136) were classed on the scale displayed in Table 1, where '0' indicates least simplified/accessible. Simplification score should increase with repeated mention.

Table 1. Simplification scale for referring expressions

Code	Definition		Example
0	numeral + indef art +	noun sequence	*one mountain* *a mountain*
1	def art + poss +	nominal	*the mountain* *my one*
2	 deictic adj+	possess pro deictic pro nominal	*mine* *that* *this mountain*
3		other pro	*it*

Experiment 1: Inferable Listener Knowledge

Design. Experiment 1 compared repeated mentions of landmarks appearing on both players' maps in two conditions, self- and other-repetition. The key to the design is the fact that a speaker who first mentions a landmark must have it on his or her own map. Thus, in an other-repetition the repeater can easily infer that the introducer can see the landmark. The second token, therefore, refers to an object which is Given both to the repeater who has heard it mentioned and can see it, and to the current listener who has also heard it mentioned, who can see it, and who has mentioned it. Self-repetitions differ in two respects: the repeater who introduced the landmark does not know if the listener can see it. Thus, the design contrasts a case where the listener can easily be concluded to have more knowledge of the referent with one where the listener's knowledge is in doubt. The inference about shared visual resource is both simple and important to the task. Since visibility can affect clarity of mention (Bard & Anderson, 1994), tailoring to the listener here should enhance change across mentions (more *k*-reduction, greater simplification of expression) where the listener has more information - in other-repetition.

Not all hypotheses make this prediction. H-and-H predicts that articulation will be sensitive to the listener's needs in this way. Dual Process predicts instead that any effect will be found in referential form, which is designed over intervals long enough to allow for completing the necessary inference. Copresence predicts effects to what the listener can see. Monitor and Adjust makes no special prediction because speakers are not obliged to model listeners cotinuously to conduct dialogues.

Table 2. Changes with self- v other-repetition:

Measure	Original speaker	
	Self	Other
Articulation: *k*-reduction	0.127	0.192
Form of referring expression	0.878	0.745

Results. Table 2 shows similar changes in articulatory clarity for self- and other-repetition. As in Bard et al. (2000), words were said faster on repeated mention (F_2 (1,691) = 63.75, $p < .0001$) but with no significant difference in reduction between the 263 other-repetitions and the 430 self-repetitions (mention x prior speaker: n.s.). Form of referring expression simplified with repeated mention (F_2 (1,269) = 177.12, $p < .0001$) but again did not distinguish the 90 other-repetitions from the 430 self-repetitions (mention x prior speaker:

n.s.). Contrary to the H-and-H predictions, the listener's experience was not critical. Repetitions of any mentions of visible objects which the repeater had heard were treated alike.

Experiment 2: Listener Feedback

Design. Experiment 2 provides a more direct test of the effects of listener knowledge. When one speaker introduces an unshared landmark, the listener, who lacks it, may provide corrective feedback indicating the discrepancy between the players' maps. Sometimes, however, the listener fails to do this. We compare repeated mentions of the names of unshared landmarks by the same speaker in these two cases. In both, the repeater has said and heard the initial mention and can see the object. When the listener denies having it, the repeater knows that the listener has heard the word but cannot see the object. Otherwise, the repeater cannot tell if s/he can see the landmark.

Cooperative behavior would yield a more restricted effect of repetition where the listener has denied ability to find the object. This comparison is important for the Extended version of Monitor and Adjust, which predicts that feedback at least could make a difference to subsequent mention design. Only Dual Process holds that pronunciation must and syntactic form may be designed without regard to the listener's comments.

Table 3. Changes for repetition with v without feedback on listener's inability to see the landmark:

Measure	Visibility to listener	
	Not denied	Denied
Articulation: *k*-reduction	0.070	0.140
Form of referring expression	0.470	0.410

Results. Table 3 shows that both articulation and form of referring expression were unaffected by feedback. The 73 repetitions with intervening denial and the 122 without abbreviated with repetition significantly and equally ($F_2(1,193) = 9.45$, $p = .0024$; mention x denial: *n.s.*). The simplification of referring expressions on second mention was similar for the 44 cases with intervening denials and the 86 without (F_2 (1,128) = 18.49, $p < .0001$; mention x denial: *n.s.*). Feedback that could block defaulting under Monitor and Adjust does not do so. Only what the repeater has seen, heard, and said seems to play a role.

Experiment 3: Listener Identity

Design. Experiment 3 examines introductory mentions of the same shared landmarks in Givers' two trials with the same map. In the first trial, the landmark is New for both players. In the second, it is Given for the speaker, an Instruction Giver who has mentioned it before, heard that mention, and seen the landmark. However, it is New to each successive listener. Adjustment to the new listener should block any tendency to utter a second introduction as a shorter, more accessible Given item.

In fact, this experiment offers the classic test of Co-presence. Mentions to new listeners should be geared to their ignorance. H-and-H posits that listener modeling will block at least articulatory change. Monitor and Adjust predicts changes in articulation and form, because the speaker's knowledge controls language production, not the listener's. Dual Process predicts a loss of clarity because articulation depends on the speaker's previous mention, not on the listener's knowledge. Only form of referring expression may reflect the listener's ignorance and remain unchanged.

Results. Table 4 shows that second introductions are significantly shorter than first for 239 pairs of words (F_2 (1,238) = 12.48; $p < .0005$). In contrast, simplification of referring expression does not significantly increase over 116 pairs of introductory mentions (F_2 (1,115) < 1). Thus, word reduction appears to reflect the Given status of the item for the speaker, while referential form reflects the fact that the freshly introduced landmark is New for each listener. Greater sensitivity in form of referring expression is predicted only by the Dual Process Hypothesis.

Table 4. Change with reintroductions to new listeners.

Measure	Introduction	
	1	2
Articulation: *k*-reduction	0.498	0.558
Form of referring expression	0.466	0.552

Experiment 4: Speaker Knowledge

Design. In Experiment 4, only other-repetitions were used, but now the landmark in question was either shared by both speakers or absent from the repeater's map. In both cases, the original introducer, who is the listener at the point of second mention, can see the item, has mentioned it, and has heard it mentioned. The repeater has also heard it mentioned, but has not mentioned it and may or may not be able to see it.

Because this experiment holds listener knowledge constant, adjustment to the listener cannot yield any differences between conditions. If the speaker's visual surroundings are important, then changes across

repeated mentions will be greater for visible, shared landmarks than for unshared.

H-and-H predicts no effect of what the speaker can see. Monitor and Adjust allows the speakers' knowledge to affect both dependent variables. Dual Process claims that auditory priming keys articulation to speaker-knowledge, but also allows for costly access to additional information, which would permit effects of speaker-knowledge on referential form.

Table 5. Changes on other-repetition of shared v unshared landmark names

Measure	Visibility to speaker	
	+	–
Articulation: *k*-reduction	0.114	0.183
Form of referring expression	0.745	0.240

Results. Table 5 shows reduction of word tokens with repeated mention (F_2 (1,224) = 12.37, $p < .0005$) but .no significant difference between the outcome for the 144 shared, visible landmarks and the 82 unshared (mention x visibility: *n.s.*). Referential form, however, is speaker-centric. Second mentions are more simplified than first overall (F_2 (1,138) = 24.67, $p < .0001$), but the change is greater for the 90 shared items than for the 50 unshared (mention x visibility: F_2 (1,138) = 6.48, $p < .02$).

This outcome is not consistent with adjustment to listeners alone or with overall use of speakers'-knowledge as a proxy for listeners'. It conforms best to the notion that referential form is sensitive to a wider range of information than articulatory clarity.

Discussion

The experiments reported here and in Bard et al. (2000) test for effects on repeated mentions of several aspects of speaker- or listener-knowledge. Experiment 1 pitted the speaker's own experience in seeing and hearing against the listener's under two conditions, when it could and could not readily be inferred that those listeners could see the landmark. Experiment 2 pitted the speaker's experience of seeing, saying, and hearing against the listener's declared inability to see the item in question. Experiment 3 pitted the speaker's experience in having seen the mentioned landmark, mentioned it, and heard it mentioned against the new listener's ignorance of the item as the landmark was introduced in a second trial. Experiment 4 kept the listener's knowledge constant as well as the speaker's experience in hearing a prior mention, but manipulated the speaker's ability to see the landmark.

In all these cases, the repeating speaker had heard the original mention. In all, clarity of articulation was sensitive only to what the speaker had heard. These are exactly the results found by Bard et al. (2000) for a balanced but restricted sample of materials and with intelligibility to naïve listeners directly measuring clarity. Thus, reduction and consequent reduction in articulatory detail with repeated mention is conditioned by the repeater's experience. There is no indication that models of the listener are consulted.

Referential form showed a different pattern. Like articulation, it was insensitive to some information which should have entered a model of the listener: an indications of what the listener could or could not see (Expts 1 and 2). Yet, it did show two effects which articulation did not. First, referential form did not simplify on re-introduction to new listeners (Expt 3)[1]. In this case, form of referring expression was tailored to the listener's needs. Second, simplification of form across repeated mentions was enhanced when the speaker could see the named landmark (Expt 4). Thus, referential form is more sensitive than articulation but to both interlocutors' knowledge.

Why should form have these characteristics? Form of referring expression does not respond on-line to aspects of co-presence delivered via feedback or inference. It shows neither the complete insensitivity to listeners that Monitor and Adjust predicts for initial design, nor the sensitivity to feedback which should guide redesign. We would argue that Map Task participants juggled competing demands on their attention, as the Dual Process Hypothesis predicts. Unlike the fast automatic processes through which speaker memory affects articulation, slower processes can compete for attention with the communicative task in hand. In this task, however, listener modeling does not take precedence. Only the listener factor most grossly related to the task -- who is participating – affects the design of referring expressions. It shares that honor with an equally basic speaker factor -- what is on the speaker's own map.

The difficulty of the communicative task may well influence the degree to which speakers appear to be modeling their listeners. Certainly direct manipulation of communicative tasks changes speakers' priorities (see Horton & Keysar, 1996). Presumably, speakers could be more sensitive to listener-knowledge if some kind of external record-keeping were to ease the computational burden. The Dual Process Hypothesis predicts that both task and memory load should influence the design of referring expressions, but that neither should affect the articulation of individual words.

[1] While Jurafsky et al. (2001) have recently reported less reduction for reintroduction to new listeners than to old, they find significant reduction to both.

The Utility of Reversed Transfers in Metaphor

John A. Barnden (J.A.Barnden@cs.bham.ac.uk)
School of Computer Science; University of Birmingham
Birmingham, B15 2TT, United Kingdom

Abstract

In metaphor research there is usually some notion of transfer of aspects of the source domain to the target domain. More rarely, transfers in the opposite direction are countenanced, affecting one's perception of source as well as target. This paper argues that, even without this aim, transfers from target to source should happen. One radical claim here is that it is often better to translate information from literal sentences into prevailing metaphorical terms than to translate the information from metaphorical sentences into literal terms. The issues have been obscured by confusion between intuitive directions of static source/target mappings, directions of individual transfer actions, and direction of main intended information flow. Relevance to an implemented AI system for metaphorical reasoning, ATT-Meta, and to Blending Theory are briefly mentioned. Asymmetry of metaphor is also addressed.

Introduction

In this paper, metaphor is thinking or communicating about some target scenario TS in a way that relies on or is motivated by seeing it as something one takes to be qualitatively different from it. Consider: *"In the far reaches of her mind, Anne knew Kyle was having an affair"* (from real discourse: Gross, 1994). TS is what is going on in Anne's mind. Her mind is being seen as a physical space that has "far reaches." The utterance relies on or is motivated by a metaphorical view of MIND AS PHYSICAL SPACE. In this view, the *source domain* is the knowledge domain concerned with physical spaces, locations, etc., and the *target domain* is concerned with minds and mental states/processes. My term *metaphorical view* means much the same as *conceptual metaphor* (Lakoff, 1993). However, I use a different term partly because Lakoff makes claims about conceptual metaphors that do not affect the present paper.

In analyses of metaphor there is usually a notion of *transfer* of aspects of the source domain to the target domain. The transfer involves copying or in some way translating the source aspects. An "aspect" is an entity, property, relationship, proposition, ... that features in source-domain knowledge. The centrality of *source-to-target* (S→T) transfer is especially evident in feature-transfer accounts (e.g., Ortony, 1979) and analogy-based accounts (e.g., Falkenhainer *et al.*, 1989; Holyoak & Thagard, 1989). In the former, understanding of metaphorical utterances is meant to proceed by finding one or more suitable features of a source entity and ascribing them to, or emphasizing them in, a target entity. In analogy-based accounts, the understander either already possesses an S→T mapping handling some aspects of the source or constructs such a mapping on the fly. The understander uses that mapping in transferring *further* aspects of the source to become potentially new target aspects, or at least target aspects that were not previously attended to or not dealt with in the original mapping. The rest of the paper will be geared ostensibly to analogy-based accounts. However, observations to be made generalize to other accounts as long as they involve notions of mapping and/or transfer.

A mapping generally maps more than one aspect of a domain. I call a part of the mapping that is concerned with one specific aspect a *mapping relationship.* Consider the Socrates-as-midwife metaphorical view in Plato's *Theaetetus*, analyzed by Holyoak & Thagard (1989). This involves, amongst others, a mapping relationship between a midwife and Socrates, one between students (even if male) and mothers, one between babies and ideas, and one between pregnancy and idea-development.

Mappings must be distinguished carefully from actions related to them. A mapping is just a set of relationships between aspects of two domains. It is to be distinguished from the act or process of creating the mapping (another possible meaning of the word "mapping"). Also, a transfer is an action. In fact, a transfer generally rests in part on acts of using the existing mapping. For instance, we might transfer the source-domain proposition that *Socrates helps Theaetetus to give birth to [a particular idea]* to become the target-domain proposition that *Socrates helps Theaetetus to produce [that idea].* Here the particular proposition transferred was not previously mapped, but its parts were. There could be more creative transfers as well, such as transferring the cleaning up of the afterbirth to eliminating useless side-effects of a produced idea. Either sort of transfer involves actions exploiting existing mapping relationships (e.g., the one from babies to ideas).

Metaphorical views are generally (and perhaps always) considered to be directed, in a natural and intuitive way. A view of midwives as teachers is clearly distinct from a view of teachers as midwives. This is the asymmetry of metaphor. In a view of A as B, the *direction*

of the metaphor is from B to A. Also, in all mapping-based accounts I have seen, the *intuitive direction of the mapping* is usually taken implicitly or explicitly to be the same as the direction of the metaphor.

But there is a further direction, namely *the direction of information flow*. In most examples in the literature, the information flow is from source to target, in that all that is discussed is informational effects on the target. However, in some accounts, notably interaction accounts (Black, 1979; Waggoner, 1990) and the blending-based account (Turner & Fauconnier, 1995), information flow from target to source (T→S) is allowed for, though much less commonly analyzed than S→T flow. Thus, in general, the direction of the metaphor may not be the same as the direction of all information flow. A major task of this paper is to expand on this point beyond where the literature has taken it so far, showing that it is of much more general importance than heretofore realized.

The plan of rest of the paper is as follows. The next section explains why the direction in which a mapping relationship is used (e.g., during a transfer) is theoretically independent of its intuitive direction. The third section shows argues for T→S as well as S→T information-flow and mapping-usage actions. The fourth section explains that it is inappropriate to think of the direction of mapping always being (wholly) the same as the direction of the metaphor. The fifth section comments on the asymmetry of metaphor. The sixth links the considerations to an implemented AI system, ATT-Meta, that performs some of the reasoning needed in metaphor understanding (Barnden *et al.*, 1996; Barnden & Lee, 1999, 2001).

Directionality: Relationship *versus* Usage

As stated above, mappings are usually described informally as going from source domain to target domain. (Some authors, e.g., Holyoak & Thagard, 1989, occasionally depart from this). Each mapping relationship can just be denoted as an ordered pair *(s,t)* where *s* is the source-domain aspect mapped and *t* is the target-domain aspect it maps to. For instance, in Socrates-as-midwife, a source-domain scenario containing a particular midwife *mw1* is assumed, and we have the mapping relationships *(mw1, Socrates)* and *(give-birth, produce-idea)*.

Now, it is normally assumed that the *use* of a mapping relationship *(s,t)* is in the direction from *s* to *t*. At one point in processing, a source-domain structure involving *s* may be being worked on; and then, typically as a result of an attempted transfer, a structure involving *t* will be considered. But, in principle, the direction of use is independent of the direction of the relationship. If for some reason it were beneficial to create source-domain structures that paralleled existing target-domain ones according to the metaphorical view at hand, a mapping relationship *(s,t)* could be used, in reverse, to go from *t* to *s*. Equally, we could just as well have mapping relationships that intuitively go from target to source without affecting their *usability* from source to target.

In much work on analogy and metaphor, mappings are required (e.g., in SME, Falkenhainer *et al.* 1989) or preferred (e.g., in ACME, Holyoak & Thagard, 1989) to be one-to-one. A one-to-one mapping does not allow there to be two different mapping relationships *(s,t1)* and *(s,t2)* or two different mapping relationships *(s1,t)* and *(s2,t)*. Clearly, if a mapping violated the former condition, some attempted S→T transfers would be faced with extra complication because of the choice between target aspects; and a mapping violating the latter condition would similarly complicate some attempted movements from target to source. These difficulties do not, however, stop a particular *(s,t)* or *(t,s)* relationship in a non-one-to-one mapping being usable in either direction.

Usefulness of Target-to-Source Transfers

Some accounts of metaphor (notably interaction accounts and Blending Theory) allow for T→S transfers. Such transfers therefore use mapping relationships in the T→S direction. However, in those accounts, attention is focused on cases where the ultimate effect is to make some relatively long-term change in the understander's appreciation of the source domain. In contrast, the present paper argues that T→S transfers can be useful even when there is no effect on the source domain that outlives the short-term purposes of the current processing (e.g., understanding a sentence), and where the original goal of the processing is purely to add information to the target domain. The general argument is that T→S transfers can create source-domain information that feeds into within-source-domain processing that in turn ultimately feeds back into some S→T transfer. We therefore have a distinction between *direction of ultimate information flow*, which is normally S→T, from *direction of individual transfers*, which can be T→S, although there must be at least one S→T if ultimate information flow is to be in this direction.

The next three subsections look at different types of T→S transfer.

T→S Transfer: Certainty Downgrading

In a teacher-as-midwife scenario, suppose that reasoning within the source domain establishes, to some level less than absolute certainty, that *Adonis [a student] gave birth to the idea J* (J viewed as a child). Let us call this proposition SP. Suppose that by ordinary S→T transfer this creates the target-domain proposition TP that *Adonis produced J.* But, finally, suppose that there is an independent argument in the target domain that Adonis did not produce J, and that this argument is deemed stronger than the metaphor-based argument. Thus the certainty level ascribed to TP must be downgraded. Now, in discussions of such conflict in the literature, it is not pointed out that *therefore* it may be desirable or perhaps even necessary (a) to downgrade correspondingly the certainty level ascribed to the source-domain proposition (here SP) from which the downgraded target-domain proposition (here TP) came, and possibly also (b) to affirm the negation of SP.

Action (a) is T→S transfer of certainty downgrading. The motivation for it is that the original source-domain proposition (SP) could have been used to support other propositions in the source domain scenario (e.g., that *Socrates has acted as a midwife for Adonis*). The downgrading of SP may therefore be needed so that those other propositions can be properly downgraded—and this may then require withdrawal of earlier S→T transfers of those propositions. Somewhat similarly, affirmation of the negation of SP in the source domain could be useful as it could lead to new inferences in the source domain and hence new S→T transfers.

Metaphorization of the Literal

There is a much stronger and more explicit type of T→S transfer. Consider the following discourse fragment:

> Socrates helped Adonis to give birth to [the idea J]. Similarly, John helped Mary to produce [some idea K].

It would surely be natural to take John's help to be metaphorically a matter of helping a birth. That is, to transfer the target-domain proposition that *John helped Mary produce K* to become the source-domain proposition that *John helped Mary give birth to K*. Then, the rich resources of the source-domain scenario are available to make further inferences. One such inference, albeit an uncertain one, could be that *John acted as a midwife for Mary*. There could then be a further inferences that John was instrumental in introducing Mary to the responsible sexual partner. This matchmaking function of (ancient Greek) midwifery is explicit in *Theaetetus*. Such further propositions could then lead by ordinary S→T transfer to new propositions in the target domain, for instance that John introduced Mary to people who stimulated her ideas.

Notice the contrast to the following method: derive target domain propositions from the first, metaphorical, sentence; then extract target-domain propositions from the second, non-metaphorical, sentence; then integrate the two sets of propositions. Most existing accounts of metaphor, in not properly dealing with the role of metaphorical utterances in *discourse* leave one with the impression that this would have to be the method. But it is highly impoverished compared to the method in the preceding paragraph, as it does not access the rich source-domain scenario. The impoverished method does allow room to infer that John is Socratic, partly because of the word "similarly"; but once the metaphor used in the first sentence has been left behind there is no strong impetus to make that inference, rather than simply interpreting the word to be pointing out that John is like Socrates purely in having helped someone produce an idea.

In any case, the argument does not depend on the word "similarly." The alternative second sentence *"Socrates also helped Theaetetus to produce [idea K]"* could again be felicitously be processed by doing a T→S transfer to get the proposition that *Socrates helped Theaetetus give birth to K*.

The argument somewhat relies on the source domain scenario not having a complete, equally rich and extensive correspondent in the target domain. That is, reasoning in the source domain uses much knowledge about midwives and their role in (ancient Greek) society, where that knowledge is not all mapped to corresponding knowledge in the target domain. That this lack of mapping is common in metaphor is argued further in (Barnden *et al.*, 1996; Barnden & Lee, 2001), but is also linked to common themes in metaphor research such as the relative unparaphrasability of many metaphorical utterances (see, e.g., Waggoner, 1990) and the relative familiarity, richness and accessibility of source domains as opposed to target domains (see, e.g., Lakoff, 1993). Indeed, even if the metaphorical mapping captured all the richness of facts in the source domain, that would still not be enough because methods of reasoning peculiar to the source domain may need to be captured as well. Also, if familiarity of subject matter can affect the facility of people's reasoning even if the pattern of reasoning is kept constant (see, e.g., Johnson-Laird, 1983:29–34), source-domain reasoning stands to have an advantage just from this factor.

Also, it is a mistake to think that if there is an extended use of a metaphor across a stretch of discourse then target-domain information has to be derived from *each* metaphorical patch in the stretch. It may only be necessary to switch to the target-domain once some source-domain *conclusion* has been obtained from within-source-domain reasoning that the stretch stimulates. Thus it may not only be fruitful but also much more economical to metaphorize intervening literal statements than to literalize the metaphorical ones.

In sum, in many cases the proper way to integrate metaphorical discourse elements with non-metaphorical ones is *not* to literalize the metaphorical ones and then do integration (that's the impoverished method above) but rather to metaphorize the literal ones and then integrate. This technique is a radical departure from other research on metaphor, even when discourse-sensitive as in Hobbs (1990). Hobbs does not preclude metaphorization, but he does not appear to have argued for it.

T→S Transfer: Reasoning Queries

One sense in which T→S transfers can occur is through query-directed reasoning (goal-directed reasoning). This is a powerful and important technique in AI generally. In particular, it can be used to focus metaphorical processing fruitfully, and this is especially important given the notorious indeterminacy of the process of extracting information from metaphorical utterances. The ATT-Meta approach places great stress on the technique. In query-directed reasoning, the process starts with a query—a question as to whether something holds. Queries are compared to known propositions and/or used to generate further queries, which, if eventually established, could help provide an answer to the original query; and the in-

vestigation of these queries results in turn from recursive application of the same principle, or by a match to given information. Suppose the discourse at hand is using the Socrates/midwife metaphor, and one reasoning query that has been posted in the target domain (as a result of processing of surrounding discourse) is whether a student *produced a particular idea J.* By virtue of suitable mapping relationships, this query could give rise to the query as to whether the student *gave birth to J.* We can say therefore that the target-domain query has been transferred to become a source-domain query.

Query-directed reasoning of this sort in metaphor or analogy has been advocated by others (e.g., Markman, 1997), and for the particular purposes of the present paper it involves a relatively uninteresting sort of T→S transfer, as it is only useful if it eventually leads to a proposition transfer from source to target. In the student-producing-idea example, the task is to find support for the *student-gives-birth* proposition in the source. This supportedness in the source must be transferred to turn the *student-produces-idea* query in the target into a proposition. Thus, the proposition transfer is S→T even though the query transfer is T→S.

Directionality: Mapping *vs* Metaphor

Given that the intuitive direction of a metaphor of A-as-B is from B to A, it seems obvious that the intuitive direction of the *mapping* involved in the metaphor should be the same. However, this is simplistic—there are exceptions. They may be quite common, and different mapping relationships in a given metaphorical view may intuitively and theoretically be best viewed as going in different directions.

Metaphorical views of IDEAS AS PHYSICAL OBJECTS and MIND AS PHYSICAL SPACE are used in the sentence *"The idea was hidden behind a door in Mary's mind."* Note that whereas the mentioned idea is being viewed as a physical object, so there is indeed a physical object in the source-domain scenario that is mapped to the idea, other implied physical objects in the source-domain scenario, such as the door, should presumably *not* be mapped to ideas. If, therefore, one takes the *property* of being a physical object to map to the property of being an idea, one would have to say that not all applications of *being-physical-object* in the source-domain scenario map to *being-idea* in the target domain. This is an unfortunate gap between the property and its applications, and brings into question the idea that the *being-physical-object* property maps to *being-idea* after all.

One could, of course, say that the *being-physical-object* property does not map at all, and that it is only particular physical objects that map. But that is surely less intuitively appealing than having some sort of mapping of a property. In fact, it is better to take the following, reversed, stance: the property *being-idea* maps to the property *being-physical-object*. This is a natural mapping relationship because it is a reasonable assumption that if one idea in the specific target-domain scenario at hand is being viewed as a physical object then others are too. Consider for instance the following hypothetical discourse segment:

> Many ideas were whizzing around inside Mary's mind. John's question made her think up even more.

This again uses both IDEAS AS PHYSICAL OBJECTS and MIND AS PHYSICAL SPACE. It would be natural to assume that the further ideas implied by the second sentence are also physical objects inside Mary's mind-space (and indeed whizzing around in it). This is another example of metaphorization. Thus, it is plausible that the mapping of *being-idea* to *being-physical-object* has uniform application to all ideas mentioned in the local discourse context.

As for MIND AS PHYSICAL SPACE, the point is yet starker. Consider *"The idea was in the recesses of their minds."* The minds of all the people concerned are being viewed as physical regions. However, *not* all physical regions in the source-domain scenario are being viewed as minds: in particular, the recesses are not. It is therefore much more natural to think in terms of a mind-to-region mapping relationship rather than the other way round.

We can always restrict a not-uniformly-applicable property (or relationship) in such a way that the resulting property (or relationship) does apply uniformly. However, the restriction may be highly unnatural. For instance, in IDEAS AS PHYSICAL OBJECTS the property *being-physical-object*, restricted to apply only to a physical object *that happens to correspond to a particular mentioned idea* trivially coheres with its applications, with respect to to the metaphorical mapping. Of course, the italicized restriction is not itself a restriction framed in terms of the source domain.

Given that a metaphorical mapping typically involves several mapping relationships (e.g., applying to different properties), the possibility arises of having its component relationships go in different directions. Also, a given mapping relationship together with its inverse may both be intuitively part of the mapping. To accommodate these possibilities we can either broaden the notion of mapping to allow relationships to go in different directions, or we can replace the single mapping by two mappings, one consisting of S→T relationships and the other of T→S ones.

Asymmetry of Metaphor

It is frequently pointed out (e.g., Way, 1991) that metaphor is asymmetric (see Introduction above). The present paper might be thought to conflict with this, as it claims that the direction of the metaphor does not completely determine the direction of transfers or even the intuitive direction of mapping relationships. However, there is no conflict, because of the following points.

There must still be some information flow from source to target, i.e. in the direction of the metaphor: it is the *target* domain that contains the topic being attended to. Even if teachers-as-midwives and midwives-as-teachers

both happened to use exactly the same mapping relationships (up to inversion), it is very different to conclude, say, that in reality certain teachers help certain students from concluding, say, that in reality certain midwives help certain pregnant mothers.

But, in any case, the present paper in no way implies that A-as-B would indeed involve exactly the same mapping relationships as B-as-A, even though in practice there may well be considerable overlap, especially as a structural isomorphism between parts of two domains is an inherently symmetric thing. The isomorphism that is appropriate for one direction of metaphor may be slightly or greatly different from the one appropriate to the other direction. (For one thing, even with a fixed direction there can be competing possibilities for partial isomorphism. Such competition is an important aspect of SME and ACME.) Whereas in some particular discourse a use of teachers-as-midwives might involve an isomorphism between the process of giving birth and the process of producing an idea, a use of midwives-as-teachers in another discourse might rest on an isomorphism between the process of a mother coming to bond with her already-born baby and the process of a person producing an idea.

Finally, mapping relationships for A-as-B and B-as-A could be intuitively similar but be different in detail. We saw that for IDEAS AS PHYSICAL OBJECTS, not all physical objects in the source-domain scenario are mapped to ideas, whereas all ideas in the target-domain scenario are likely to be mapped to physical objects. If a metaphorical view of PHYSICAL OBJECTS AS IDEAS were to be used in discourse, it could similarly be that not all ideas in the source-domain scenario were mapped to physical objects but that all physical-objects in the target-domain scenario were mapped to ideas. Asymmetry is addressed again at the end of the next section.

The ATT-Meta System

The ATT-Meta system is too complex to be described at any length here. It is described in Barnden & Lee (1999, 2001). The present section summarizes how the system is related to the issues in previous sections.

The system is aimed at performing the reasoning needed for understanding a broad class of metaphorical utterances that we call *map-transcending utterances based on familiar metaphors.* Here the understander already knows the metaphorical views used, and therefore possesses source/target mappings underlying those views; however, the utterance uses aspects of the source domains(s) that are not mapped by the known mappings. The system is designed on the principle that there should by default be no attempt to create new mapping relationships to handle those aspects; rather, the system should try to do reasoning that links those aspects to source aspects that are already mapped. For example, consider again the sentence *" In the far reaches of her mind, Anne knew Kyle was having an affair."* ATT-Meta handles this as follows, given knowledge of MIND AS PHYSICAL SPACE and IDEAS AS PHYSICAL OBJECTS, and most importantly the knowledge that (in)ability to operate physically on an idea, in the source domain of IDEAS AS PHYSICAL OBJECTS, maps to (in)ability to operate mentally on the idea, in the target domain. Assume that ATT-Meta's mappings do not map the far-reaches location within a space to anything, so that the utterance transcends the system's mappings in this respect. ATT-Meta can reason, using (mainly) commonsense knowledge about physical spaces and objects, that Anne has only a very low ability to operate physically on the idea that Kyle was having an affair. (This is because the far reaches of a physical region are very distant from the main part of the region, and Anne, or rather her conscious self, is taken to be in that main part.) Then, using the known mapping, ATT-Meta can infer that Anne has only a very low ability to operate mentally on the idea. This example is treated in much more detail in Barnden & Lee (2001). A variety of other examples are also treated in that report and in other reports cited in it.

ATT-Meta's long-term domain knowledge and its knowledge of metaphorical views is couched in terms of IF-THEN rules. A given metaphorical mapping relationship takes the form of a rule, such as (roughly)

> *IF J is in reality an idea AND J is being viewed as a physical object AND person X is being viewed as being able to operate physically on J to at least degree D*
> *THEN in reality X can operate mentally on J to degree at least D.*

ATT-Meta's reasoning is entirely query-directed. So, for instance, in the Anne/Kyle example the reasoning steps mentioned arise from a backwards-going process of query construction, proceeding backwards through rules. In particular, a query about the degree of ability of Anne to operate mentally on the Kyle-affair idea in reality leads to the creation also of a query about the degree of ability of Anne to operate physically on the idea, under the metaphorical view. Thus, the system exhibits T-to-S transfer of queries.

The system's metaphor-based reasoning is thoroughly integrated into a general-purpose framework for qualitatively uncertain reasoning. Reasoning in source-domain terms and in target-domain terms is generally uncertain. Rules and propositions are annotated with qualitative certainty levels, and there is a heuristic conflict-resolution mechanism that attempts to adjudicate between conflicting arguments. As a result of conflict-resolution, the certainty of one or more propositions is downgraded. Reasoning leaves behind a record of dependency links between propositions, so certainty downgrade of a proposition leads to downgrading also of propositions dependent on it. Now, for a given S→T mapping relationship there is often a converse mapping relationship, e.g. (to continue the above example),

> *IF J is in reality an idea AND J is being viewed as a physical object AND in reality person X can operate mentally on J to at least degree D*

THEN X is being viewed as being able to operate physically on J to degree at least D.

Consequently, ATT- Meta performs T→S transfer of certainty downgrades when suitable target-domain propositions are downgraded. Because of the extensive within-source reasoning that ATT-Meta often performs, downgrade within the source domain can lead to other downgrades there by propagation along dependency links.

Because of the T→S mapping relationships, ATT-Meta can metaphorize literally-stated information, and such metaphorization steps are seamlessly mixed in with other reasoning steps. However, only limited experimentation on this has been done so far using ATT-Meta.

As for asymmetry of metaphor, it is instructive to look at the following situation that could hold in ATT-Meta. Recall the T→S rule mentioned above for IDEAS AS PHYSICAL OBJECTS. It can be reworded to have the overall form:

IF J is in reality an idea AND J is being viewed as a physical object AND ... THEN ... .

Now consider S→T rules for a view of PHYSICAL OBJECTS AS IDEAS. These will have the overall form:

IF O is in reality a physical object AND O is being viewed as an idea AND ... THEN ... .

The rule-forms differ crucially in their first two conditions. Thus, T→S rules for A-as-B will be act very differently from S→T rules for B-as-A, even when the source and target aspects mapped are the same or similar.

Conclusions

The main conclusions are that (a) target-to-source transfers of several distinctly different types are desirable in metaphorical discourse understanding; (b) in particular, metaphorization of within-target-domain utterances can be desirable; and (c) the directions of mapping relationships are sometimes intuitively the wrong way round in accounts of metaphor.

The ATT-Meta system is one that routinely allows target-to-source transfers of the sorts mentioned above. Blending theory (cited earlier) allows transfers into and out of the blended space, including transfers from the blended space back into a source domain. Also, the LISA model for analogy (Hummel & Holyoak, 1997) allows mapping to go from target to source, though the relationship to the considerations in the present paper is unclear. Thus, a small number of approaches are beginning to allow effects such as those in this paper. However, the topic appears to have seen little psychological experimentation or computational realization, and would be a fertile ground for future empirical investigation.

A Model Theory of Deontic Reasoning About Social Norms

Sieghard Beller (beller@psychologie.uni-freiburg.de)
Department of Psychology, University of Freiburg
D-79085 Freiburg, Germany

Abstract

This paper outlines a model theory of deontic reasoning. It proposes that social norms form the basic concept on which deontic inferences operate. The theory unifies and extends current deontic approaches. Empirical findings from the deontic selection task will be presented which support the theory.

Introduction

Deontic reasoning is thinking about which action a person *may* or *must* perform with respect to a social rule. Imagine an officer who has to administer the admission to an event. The promoter has given him the rule "If a person has a ticket, then this person *may* enter." Lisa has *no* ticket. *May* she enter? The officer answers: "No, Lisa *must not* enter. She does not fulfill the entry condition." Although intuitively plausible, this answer is in conflict with standard conditional logic. The antecedent of a conditional '*If* P *then* Q' denotes a sufficient but not necessary condition. If 'P' does not hold then one can *not* decide whether 'Q' holds. Thus, the officer should rather ask his promoter what to do with Lisa instead of refusing the entry. Why is it, that his answer nevertheless seems right? The goal of this paper is to introduce a new theory of deontic reasoning which explains such phenomena. It will be compared to alternative approaches and backed up with findings from the deontic "micro-laboratory" of the selection task (Wason, 1966).

The Deontic Mental Models Theory (DMM)

The model theory assumes that reasoning requires the construction of mental models which represent the meaning of, for example, verbal premises or a person's background knowledge (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991). Their structure and content capture semantic relations of the situations they refer to. To make an inference, reasoners first extract a putative conclusion from an initial model and then validate it or, if necessary, revise it by fleshing out alternative models. Of which structure and content are the models that underlie deontic reasoning? In this article, it is proposed that the underlying models represent social norms.

Normative Models and Deontic Inferences

Social norms constitute constraints on actions but they do not really restrict a person's freedom of action. A person may follow a norm or violate it. Consequently, two types of models must be distinguished: factual models and normative models.

Factual models describe which conditions hold or which actions are taken. A condition (`C`) is viewed as a state of affairs that can be fulfilled or not (symbolized as `C` vs. ¬`C`). Actions are taken by a person on a certain occasion; not performing an action is notated by negation (`Action` vs. ¬`Action`); a more detailed analysis is given by von Wright (1963). The fact, for example, that a person with a ticket is entering an event can be represented by the following factual model:

(1) Normative	Factual
	[entering] [ticket]

Normative models cannot describe which actions persons really take. They describe constraints on actions, that is, under which conditions actions are forbidden or obligatory. In a consistent system of norms an action cannot be forbidden and obligatory at the same time, otherwise the person is trapped in a dilemma. In the following, 'bans' are taken as the basic normative concept and represented as `forbidden(Action)`. In accordance with the axiom of definitional equivalence in modal logics '*must* X ≡ *must-not* ¬X' (e.g., Chellas, 1980), an obligation can also be represented as a ban: the obligation to take an action means that the omission of the action is forbidden (`forbidden(`¬`Action)`).

With regard to the relation between a ban and its conditions, two assumptions are made: First, people represent *each* ban together with *all* conditions that put the ban into force (*closed world assumption*). Second, people treat the relation between a banned action and the conditions as an *equivalence* (which is justified under the closed world assumption): If the conditions are met, then the action is forbidden, otherwise it is allowed. Taking both assumptions together, the basic schema of a norm (concerning one action) takes the following explicit standard form:

(2) Normative		Factual
[forbidden(Action)]	[Conditions]	
[¬forbidden(Action)]	[¬Conditions]	

Each line denotes a separate model. Since all conditions concerning this action are considered (closed world assumption), the representation is exhaustive (indicated by square brackets). In the simplest case, there is one norm with one condition. Having a ticket, e.g., is often the only condition to be admitted to an event:

(3) Normative		Factual
[forbidden(entering)]	[¬ticket]	
[¬forbidden(entering)]	[ticket]	

Sometimes, however, several conditions have to be considered in combination. Necessary conditions may be treated by a conjunctive model, alternative conditions by a disjunction of models. Spectators of German soccer matches, for example, are often examined not only for their tickets but additionally for weapons. The normative models then contain two disjunctive conditions: A person is not allowed to enter, if (and only if) he or she has no ticket *or* has a weapon:

(4) Normative		
[forbidden(entering)]	[¬ticket]	[weapon]
[forbidden(entering)]	[¬ticket]	[¬weapon]
[forbidden(entering)]	[ticket]	[weapon]
[¬forbidden(entering)]	[ticket]	[¬weapon]

Of course, there may be additional norms concerning other actions as well. Their representation, however, follows the same schema. *Deontic inferences* connect normative and factual models. If a person fulfills the conditions (Cs) associated with a forbidden action then one can assert "the action *must not* be taken" and – according to the axiom of definitional equivalence – "the action *must* be omitted". Thus, two inferences can be drawn from the corresponding set of models[1]:

(5) Normative		Factual
[forbidden(Action)]	Cs	[Cs]
...		∴ must-not Action
		∴ must ¬Action

If an action is taken which is potentially forbidden, then it follows that the conditions Cs *must not* be fulfilled or else the norm would be violated. Equivalently, it *must* be the case that the conditions are *not* fulfilled:

(6) Normative		Factual
[forbidden(Action)]	[Cs]	[Action]
		∴ must-not Cs
		∴ must ¬Cs

While the modals *must not* and *must* correspond to the notions of *ban* and *obligation*, the modals *may* and *need not* are related to the concepts of *permission* and *release* from obligation. Both pairs, ban and permission as well as obligation and release, are *contradictories*. In a consistent system of norms, exactly one of each pair is true: an action is either forbidden or allowed; it is either obligatory or not. One can infer that something *may* be the case if it is not forbidden, and that something *need not* be the case if it is not obligatory. Finally, a norm is *violated* if a person takes an action while fulfilling at least one condition under which the action is banned:

(7) Normative		Factual	
[forbidden(Action)]	[Cs]	[Action]	[Cs]
		∴ violation	

To illustrate the application of the theory, let's reconsider the introductory example. An officer was given the rule: If a person has a ticket, then this person *may* enter. It mentions one condition for the action of entering. Since norms constitute constraints on actions, the officer can map the rule to norm (3) which expresses that entering is not forbidden with a ticket, but it is forbidden without one. For Lisa who has no ticket, model (5) applies which allows the officer to answer: "She *must not* enter".

"Why a New Theory of Deontic Reasoning?"

... one may ask since a number of well-established proposals already exist. While each of the current approaches emphasizes a different aspect, the proposed DMM theory tries to unify their main characteristics.

DMM theory takes up two previous ideas: (1) Modal terms gain their deontic meaning by referring to deontic norms (Johnson-Laird, 1978) which represent (2) permissible and impermissible situations (Johnson-Laird & Byrne, 1992). DMM theory goes beyond these ideas by proposing a concrete representation of norms and relating deontic modals to it. Manktelow and Over (1991; 1995) claimed that social roles and utilities need to be incorporated. These factors are indeed important since social roles distinguish between the parties affected by a social rule and utilities influence its negotiation. They seem not necessary, however, for deontic inferences (Johnson-Laird & Byrne, 1992). Once a social rule has been established, it defines the normative constraints on each parties' actions, and the corresponding normative models determine the possible deontic inferences.

Thompson (2000) argued that a theory of reasoning should not only specify the inferential procedures that operate on a given representation; it must also specify the interpretative processes that set up this representation. As her experiments show, the interpretation of conditional reasoning tasks is affected by two factors: by the perceived necessity and sufficiency relations and by the pragmatic relation (deontic vs. factual). DMM theory integrates necessity and sufficiency relations on the condition-side of norms and it considers the characteristics of the deontic domain she condensed from her studies: the normative character of the models which gives relevance (Sperber, Cara & Girotto, 1995) to the notion of norm-violation. In addition, DMM theory may be used to analyze the interpretation of normative statements by exploring how they are related to norms.

The theory of *pragmatic reasoning schemas* (PRS;

[1] For reasons of simplicity, the action side of the norm is represented exhaustively: all banning conditions are subsumed under Cs. The condition side in model (5) is not represented exhaustively because there may be other bans under the same conditions.

Cheng & Holyoak, 1985; Holyoak & Cheng, 1995) proposed two deontic inference schemas – one for permission and one for obligation – each consisting of four rules which are applicable when their appropriate content is present. The rules of the permission schema are:

P1: If the action is to be taken, then the precondition *must* be satisfied.
P2: If the action is not to be taken, then the precondition *need not* be satisfied.
P3: If the precondition is satisfied, then the action *may* be taken.
P4: If the precondition is not satisfied, then the action *must not* be taken.

The two deontic schemas are sufficient to explain many findings with deontic reasoning tasks (see, e.g., Holyoak & Cheng, 1995). As a theory of deontic reasoning, however, the PRS approach is faced with two problems. First, with regard to terminology the two schemas are not clearly distinguishable – both include a permission rule (e.g., P3) and an obligation rule (e.g., P1) – and the modal terms defining the schemas are themselves undefined (Manktelow & Over, 1995). The idea of a domain-specific representation of norms is adopted by DMM theory but it uses a single normative concept (bans) instead of different schemas and defines the modals by reference to norms, actions, and conditions. This approach encompasses both PRS schemas (Beller, 1997). Second, the scope of PRS theory is quite restricted: It does not cover some deontic inferences that people easily draw. For example, from the entry-rule "If a man has no ticket, then he *must not* enter" people easily infer that without a ticket "he *must* stay out". A corresponding inference rule is available in neither schema; the inference is supported, however, by DMM theory (model 5 applied to norm 3). By considering relations of modal logics the range of covered deontic inferences is extended beyond the PRS schemas.

"What is the *origin* of domain-specificity in reasoning?" is the question posed by evolutionary approaches. Are domain-specific concepts learned as assumed, for example, by PRS theory or do they reflect innate evolutionary adaptations (e.g., Cosmides, 1989; Cummins, 1996)? DMM theory stresses which information persons represent in their models and how these affect reasoning. It is open with respect to the origin question.

Having justified the theoretical relevance of the new theory, it is now applied to Wason's (1966) selection task. Since the discovery of content effects in the 1970s, this prominent paradigm has developed into a micro-laboratory of deontic reasoning with findings that each deontic theory must be able to explain.

Touchstone "Deontic Selection Task"

How does DMM theory fit the basic findings with deontic task versions? For reviews of the vast selection task literature see, for example, Beller (1997), Evans, Newstead and Byrne (1993), or Newstead and Evans (1995).

The Deontic Task: In the original, non-deontic task (Wason, 1966) persons are shown four cards with a letter on one side and a number on the other side. One side is visible: "A", "K", "5", and "8". A rule is given: "If there is an 'A' on one side, then there is a '5' on the other." The task is to select all cards which need to be turned over to find out whether the rule is true or false. Since a conditional '*If* P, *then* Q' is false only if the antecedent 'P' holds and the consequence 'Q' is false, exactly two cards can prove the rule: the 'P'-card ("A") and the '*not* Q'-card ("8"). This answer is usually given by less than 10 % of the participants (e.g., Evans, Newstead & Byrne, 1993). Now, consider the following deontic version (adapted from Griggs & Cox, 1982):

> *Imagine that you are a police officer on duty. It is your job to ensure that people conform with certain rules. The cards in front of you have information about four people. On one side of a card is a person's age and on the other side is what the person is drinking. Here is a rule: If a person is drinking beer, then he or she must be over 19. Select the card(s) that you need to turn over to determine whether people are violating the rule.*

The cards show: "drinking beer", "drinking Coke", "22 years", and "16 years" ('P', '*not* P', 'Q', and '*not* Q' with respect to the rule '*If* P, *then must* Q'). As in the abstract task, 'P'/'*not* Q' should be selected because these cards indicate a rule violation: a person under 19 drinking beer. Deontic tasks often yield solution rates of about 70-90 % (Dominowski, 1995). Different from the abstract task, people need not to evaluate the truth of the conditional. According to DMM theory they can construct normative models that tell them which persons (cards) they have to check. With the closed world assumption and the equivalence assumption, the drinking age rule can be mapped to norm (8):

```
(8) Normative
 [forbidden(drinking_beer)]      [¬over_19]
[¬forbidden(drinking_beer)]       [over_19]
```

The norm is violated (model 7 applied to 8) by a person under 19 ('*not* Q') who is drinking beer ('P') which can be checked for by selecting the cards 'P'/'*not* Q'.

It was this "facilitation effect" that necessitated a deontic theory. Subsequent experiments revealed several factors that are of particular relevance for the deontic solution. Besides the use of the deontic term *must* (e.g., Platt & Griggs, 1993) and a "detective" scenario (van Duyne, 1974) – both strengthening the deontic interpretation – three factors received particular attention: the instruction, the type of negation used, and the rule form.

Instruction: While the abstract version asks for testing the truth of the conditional, the deontic task requires to detect cases of rule violation thereby making clear that each card has to be examined independently from the others (Stenning & van Lambalgen, in press). The high rate of 'P'/'*not* Q' in deontic tasks decreases when the testing instruction is used (e.g., Noveck & O'Brien, 1996; Yachanin, 1986). This is exactly what one would expect from the perspective of a deontic theory, because the testing instruction is not applicable in the deontic

case. Different from indicative conditionals, the truth of a deontic rule is independent from individuals who may conform to the rule or not. Its truth cannot be determined by simply observing persons' behavior – little astonishing that the solution rate decreases.

Negation: The use of explicit negation turned out to be crucial for the solution of tasks with abstract deontic rules like "If one is to take action 'A', then one must first satisfy precondition 'P' " (e.g., Cheng & Holyoak, 1985). An explicit negation of the fact that a person "has taken action 'A' " would be "has not taken action 'A' " while the statement "has taken action 'B' " can be regarded as an implicit negation. Typically, the proportion of 'P'/'*not* Q' decreases when implicit negation is used on the cards (e.g., Jackson & Griggs, 1990; Noveck & O'Brien, 1996). But again, this is consistent with a deontic theory as Holyoak and Cheng (1995) pointed out. Two actions need not exclude each other; they can take place at the same time. If a reasoner does not know whether taking action 'B' and action 'A' are mutually exclusive there is no basis to interpret the two "implicitly negated" cards '*not* P' and '*not* Q' as really negated.

Rule Form: Persons' apparent insensitivity to syntactic modifications of the conditional rule used in the tasks has been taken as an argument against a purely "syntactic" view of reasoning. Cosmides (1989), for example, reversed conditionals from '*If* P *then must* Q' in the 'standard' form to '*If* Q *then* (*may*) P'. From a syntactic point of view, one may expect that the cards to be selected should switch correspondingly from 'P'/'*not* Q' to '*not* P'/'Q'. From a deontic point of view, the reversed rule cannot be violated at all (in the sense of doing something forbidden) because the consequence (by using the modal *may*) does not express a behavioral constraint a person could offend. Consequently, none of the cards should be selected. In either case the predominant selection should change. Empirically, the opposite has been found: 60-70 % keep choosing 'P'/'*not* Q' (e.g., Cosmides, 1989). What is the reason for that? Consider two drinking-age rules: The standard form "If a person is drinking beer (P), then he or she *must* be over 19 (Q)" and the reversed one "If a person is over 19 (Q), then he or she *may* drink beer (P)". According to DMM theory, both rules can be mapped to the same norm (8) although they describe different aspects. The norm is violated by a person drinking beer who is not over 19 ('P *and not* Q'). By assuming that people derive their answer from this norm and not from the conditionals, DMM theory accounts for the insensitivity to their form. The related effect of perspective change (e.g., Gigerenzer & Hug, 1992; Manktelow & Over, 1991) can be explained in a similar way (Beller & Spada, 2000).

Deontic Tasks Without Deontic Solution? The previous results can all be brought in line with DMM theory. Cosmides (1989), however, reported findings that seem to rule out a deontic explanation categorically. She demonstrated that non social contract (non-SC) versions of deontic standard rules produce significantly less facilitation than equivalent social contract (SC) versions although both are said to trigger the same deontic solution. One of her examples is the 'school problem' about assigning students to either Grover High or Hanover High. Both versions mention the deontic conditional: "If a student is to be assigned to Grover High School, then that student *must* live in Grover City". However, while the SC problem (task 9) specifies that the cards should be checked for *cheating*, the non-SC version (task 10) leaves the subjects with an incomplete deontic interpretation. In this latter task it is said that "There are *rules* to determine which school a student is to be assigned to, the most important of these rules is …". Rule violations are attributed to an "… old lady … who often made mistakes when categorizing student documents" (p. 270). The first quotation implies that several normative rules have to be applied in the categorization process but not all of them are known (the closed world assumption is violated). The term "mistakes" leaves open whether the old lady incorrectly assigned students to Grover High *or* Hanover High. – Experimental manipulations that weaken the deontic interpretation or end up with an inconsistent or incomplete interpretation may result in a decrease of the deontic solution but they cannot be taken as an argument against a deontic explanation.

Rule-Change Revisited

The DMM explanation of the deontic selection task assumes that persons do not rely on the conditional rule itself but on normative models that tell them which cards to check. The finding with switched rules corroborates this hypothesis. Nevertheless, persons could also have derived their solution from the conditional rule since there is a rule available in both the standard and the switched version. A stronger argument in favour of the "normative-models hypothesis" would be, if (1) people kept choosing the same cards in a "rule-free" selection task – like those that have been used recently to back up the effect of knowledge about causal relationships (Beller & Spada, 2000) and about promises (Beller & Spada, 2000; Fiddick, Cosmides & Tooby, 2000). The rule-change effect seems to show subjects' insensitivity to the form of deontic conditionals. Although both the standard and the switched form are consistent with one and the same norm, the switched rule cannot be violated deontically as argued above. Thus, if (2) a task does not allow persons to construct a normative model but requires to evaluate the conditional itself, then they should state correctly which conditional can be violated. Both hypotheses are examined in the following experiment (Beller, 1997).

Materials: The materials comprised six tasks: five versions of selection tasks and one rule evaluation task. Four deontic conditionals were used:

R1: If a child is drinking Coke,
then he or she *must* be over 12 years of age.

R2: If a child is over 12 years of age,
then he or she *may* drink Coke.

R3: If a child is over 12 years of age,
then he or she *need not* drink juice.

R4: If a child is drinking Coke,
then he or she *must not* be under 12 years of age.

R1 denotes a standard rule ('*If* P *then must* Q' with "drinking Coke" symbolized as 'P' and "over 12 years" as 'Q') while R2 is reversed ('*If* Q *then may* P'). R3 and R4 are corresponding rules using the other two deontic operators. All rules are derived from norm (9) that forbids drinking Coke if a child is younger than 12 years:

(9) Normative	
[forbidden(drinking_coke)]	[¬over_12]
[¬forbidden(drinking_coke)]	[over_12]

The *selection tasks* started with an introductory part:

> *In a particular country there are two beverages popular with children: Coke containing caffeine and a particular sort of juice. A scientific study has shown that the circulatory system of children younger than 12 years is often affected by drinking Coke. Therefore, the government passed a rule permitting to drink Coke dependent on age. A dispenser offers both beverages, the juice and Coke. The children of a school class are standing in front of the dispenser together with their teacher. Some of the children are already over 12 years of age, some are under 12 years. The teacher reminds her pupils of the correct behavior. [She mentions the following beverage rule].*

The five versions differed in the rule following right after this part: Four tasks mentioned one of R1-R4; the fifth task comprised no conditional (and omitted the sentence in square brackets). The instruction continued:

> *The cards below represent four children who took a beverage from the dispenser. On one side of each card it is written whether the child is drinking Coke or juice, the other side shows whether he or she is over 12 years. Your task: Please indicate all the cards that you would have to turn over (i.e., all of which you need to know the information on the back) in order to find out whether the child has violated the beverage rule.*

The cards read: "is drinking Coke", "is drinking juice", "is over 12", and "is under 12" ('P', '*not* P', 'Q', and '*not* Q'). Since all tasks can be mapped to one and the same norm (9), the model theory predicts that people choose the same cards 'P'/'*not* Q' that may indicate a violation of this norm (model 7 applied to 9) by children under 12 ('*not* Q') who are drinking Coke ('P').

The instruction of the *rule evaluation task* required to evaluate the deontic conditionals (R1-R4) without reference to an underlying norm:

> *Please read carefully through the following if-then-statements. Check for each statement whether it expresses a behavioral rule that can be violated by a child.*

Only the obligation and the ban (R1 and R4) can be violated by doing something forbidden: drinking Coke under 12 years of age. R2 and R3 do not express a behavioral restriction and hence cannot be violated.

Participants: 168 students from various disciplines (excluding psychology, mathematics, and philosophy) of the University of Freiburg volunteered for the study and were paid for participating. They were untrained in logic and had no prior experience with selection tasks.

Table 1: (a) *Selection tasks*: Frequency of 'P'/'*not*-Q' responses depending on rule version (n each 28). (b) *Rule evaluation tasks*: Frequency of selecting a rule as one that can be violated ($n = 28$, multiple selections possible).

Rule	(a)	(b)
R1 '*If* P, *then must* Q.'	27	24
R2 '*If* Q, *then may* P.'	27	9
R3 '*If* Q, *then need-not not*-P.'	22	3
R4 '*If* P, *then must-not not*-Q.'	26	25
R5 None	26	

Design and Procedure: The participants were randomly assigned to one of six groups ($n = 28$). Each received one of the six tasks together with other tasks analyzed elsewhere (Beller & Spada, 2000). The treatment was administered in small groups. Each participant received a booklet with a general instruction on the first page and the various tasks each on a new page. Each booklet presented the tasks in a new random order. The order of the conditionals in the rule evaluation task and of the "cards" in the selection tasks was also determined randomly for each participant.

Results: The results of the *selection tasks* are shown in Table 1(a). As predicted, changing the conditional had only a marginal effect ($\chi^2_{(4,\, n\,=\,140)} = 7.84$; $p = 0.10$). Most participants ($m = 91.4$ %) selected the predicted cards 'P'/'*not* Q', even in the task without an explicit conditional. Table 1(b) shows the frequency of selecting each conditional as a rule that can be violated (*rule evaluation task*). Summed up over individual combinations, the predicted conditionals R1 and R4 were selected 49 times while R2 and R3 were selected 12 times (80.3 % vs. 19.7 %; $p < 0.01$, based on the binomial distribution with $n = 61$ and $r = 1/2$). The combination of R1 and R4 was selected by 16 participants.

Summary and Discussion

The experimental results show how violation checking is affected task-specifically by the possibility of constructing normative models. (1) Given the possibility to construct a norm, as in the selection tasks, persons rely on this *norm* and appear to be insensitive to the *form* of the conditional rule describing the norm. This replicates the effect of changing the rule from 'standard' to 'switched' and extends it to other rules. The rule-free version demonstrates that an enriched deontic context (as it is used in many other deontic selection tasks as well) is sufficient to elicit this effect. Since the participants do not regard the conditional rules as relevant premises, their insensitivity to the syntactic form of the rules should not be attributed to illogical reasoning. In fact, persons' answers are in accordance with the logic of social norms. (2) If a task does not allow persons to construct normative models but requires to evaluate deontic conditionals directly, then their answers are indeed quite sensitive to the deontic form. Together,

these findings strongly support the dual source argument (Beller, 1997; Beller & Spada, 2000): in order to understand human deductive reasoning it is necessary to integrate inferences from two sources, namely from the syntactic form of an argument and from conceptual knowledge associated with its content or context.

A mental models notation was used to describe the representation and inferential use of norms (although it is assumed that the deontic principles may be adapted to a mental logic framework as well). The course overview of selection task findings demonstrated how a fine-grained analysis of the domain can guide the interpretation of experimental results. The next step will be to apply DMM theory to findings from other tasks, for example, reformulation tasks or conditional syllogism tasks (e.g., Thompson, 1995), in order to assess its full potential. Two assumptions characterize the proposed representation of norms: the closed world assumption (all norms are known to the reasoner) and the equivalence assumption (concerning the relation between a ban and its conditions). The selection task data are consistent with both. However, they only provide indirect evidence. Reformulation tasks or sufficiency and necessity ratings could prove both assumptions more directly.

Acknowledgements I am grateful to Keith Stenning (University of Edinburgh) as well as to Andrea Bender, Gregory Kuhnmünch, Nikol Rummel, and Hans Spada (Freiburg) for encouraging discussions and helpful comments. This work was supported by a grant from the German Research Foundation (DFG) within the graduate program GK MMI at the University of Freiburg.

Cue Preference in a Multidimensional Categorization Task

Patricia M. Berretty (berretty@fordham.edu)
Department of Psychology,
Bronx, NY 10458-5198 USA

Abstract

Many natural categories vary along multiple dimensions. The present studies address two main questions underlying categorization with multiple dimensions. First, how well can humans perform in a categorization task consisting of five categories varying along nine continuously valued dimensions? Second, what are the properties of the cues preferred by humans if not all the available cues are used? Remarkably, participants not only learned to distinguish among the five categories, but they also learned to do so using only the relevant dimensions. A satisficing model of categorization was best able to account for participants' responses. In addition, in a cue preference task, the results showed that nearly all participants preferred to use the dimension with the greatest variance when the number of dimensions available was restricted, in accord with predictions made by the satisficing model.

Introduction

Categorization has been studied by many disciplines including psychology and machine learning. In the area of psychology, the psychological processes underlying human categorization have been investigated. One common approach to determining these processes has been to teach humans to learn novel categories based on very simple stimuli that vary along only a few dimensions. In such simple situations, the complex calculations involved in some of the popular models of categorization (e.g., Nosofsky's (1986) generalized context model; Ashby's (Ashby & Gott, 1988; Ashby & Perrin, 1988) decision bound theory) may be psychologically plausible. However, the results of these experiments are then assumed to be generalizable to categories whose members vary along many dimensions. It seems unreasonable to assume that humans are capable of the even more complex calculations required with an increase in category dimensionality. For example, Nosofsky, Palmeri, and McKinley (1994) "question the plausibility of exemplar storage processes and the vast memory resources that they seem to require" (p.53).

Machine learning, on the other hand, has been primarily concerned with developing algorithms based on experts in specific domains (Quinlan, 1986) – although the algorithms themselves tend to be general-purpose algorithms (i.e., the algorithms are intended to apply to any categorization task). These algorithms have been developed using large data sets that vary along many dimensions. Therefore, an important step in such algorithms is determining which dimensions from the set of possible dimensions should be used. However, the different methods used to model this step usually involve complex computations and thus are also not psychologically plausible.

What follows is a brief review of two popular categorization models (exemplar models and decision bound theory), as well as a review of a satisficing model of categorization (categorization by elimination). Next, a multi-dimension, multi-category task is described, including a discussion of how well the above three models can account for human responses in such a task. The paper concludes with a brief discussion on the learning of relevant cues in the multi-dimension, multi-category task.

Review of Models

Exemplar Models

Exemplar models (Brooks, 1978; Estes, 1986; Medin & Schaffer, 1978; Nosofsky, 1986) assume that when presented with a novel object, humans compute the similarity between that object and all exemplars of every category in which the novel object could be placed. In theory, the object is placed into the category with which it is most similar, however most exemplar models assume probability matching. Nosofsky's (1986) generalized context model (GCM) allows for variation in the amount of attention given to different features during categorization (see also Medin & Schaffer, 1978). Therefore, it is possible that different cues will be used in different tasks. However, this attention weight remains the same for the entire stimulus set for each particular categorization task, rather than varying across different objects belonging to the same category. GCM uses a probabilistic response rule based on the Luce-Shepard choice model. The probability of placing stimulus i into category j is computed by summing the similarity between stimulus i and all objects in category j along every dimension and then weighting the summed similarity by the bias to respond with category j. The weighted summed similarity is divided by the sum of the weighted summed similarity of stimulus i to each category. Similarity is usually either an exponential (for separable stimuli) or gaussian (for integral stimuli) function of psychological distance (Shepard, 1964). Psychological

distance is computed by the Minkowski r-metric with the addition of two parameters, c and w_k, where c is the discriminability parameter which takes into account that stimuli will look more distinct as experience is gained and w_k is the attention weight for the kth dimension.

Decision Bound Theory

Decision Bound Theory (or DBT—see Ashby & Gott, 1988) assumes that there is a multidimensional region associated with each category, and therefore, that categories are separated by bounds. DBT uses a deterministic response rule. An object is categorized according to the region of perceptual space in which it lies. The perceptual space is divided into regions by decision bounds. For two categories (A and B) each composed of two dimensions (x and y), an object will be placed into category A if the estimated likelihood ratio is greater than some bias, where the likelihood ratio refers to the ratio between the likelihood that stimulus i comes from category A and the likelihood that stimulus i comes from category B. The parameters of this model are b, a response bias; a mean and variance for each dimension (which are usually absorbed into the bound parameters); correlations between pairs of dimensions; as well as parameters to define the decision bound.

Both of these psychological models categorize by integrating cues and using all the cues available (except in exemplar models if a cue has an attention weight of zero). But the memory requirements of these models do differ. GCM assumes that all exemplars ever encountered are stored and used when categorizing a novel object, while DBT only needs to store the bound-determining parameters of each category. In comparison, the Categorization by Elimination algorithm (described below) typically requires as little memory as DBT but it does not integrate all available cues.

Categorization by Elimination

Categorization by Elimination (CBE) was originally developed to describe people's categorization judgments in an animate motion task (see Blythe, Miller, & Todd, 1996). CBE is closely related to Tversky's (1972) Elimination by Aspects model of choice. CBE is a noncompensatory model of categorization, in that it uses cues in a particular order, and categorization decisions made by earlier cues cannot be altered (or compensated for) by later cues. In CBE, cues are ordered and used according to their probability of success. For the present purpose probability of success is defined as a measure of how accurately a single cue categorizes some set of stimuli (i.e., percent correct). This is calculated by running CBE only using the single cue in question, and seeing how many correct categorizations the algorithm is able to make. (If using the single cue results in CBE being unable to decide between multiple categories for a particular stimulus, as will often be the case, the algorithm chooses one of those categories at random—in this case, probability of success will be related to a cue's discriminatory power.)

CBE assumes that cue values are divided up into bins (either nominal or continuous) which correspond to certain categories. To build up the appropriate bin structures, the relevant cue dimensions to use must be determined ahead of time. At present, complete bin structures are constructed before testing CBE's categorization performance. Bins can be constructed in a variety of ways from the training examples by determining low and high cue value boundaries for each category on each dimension. These boundaries are then used to divide up each dimension into the cue-value ranges that form the bins. Thus, CBE only needs to store two values per category per cue dimension, independent of the number of objects encountered.

Categorization with Multiple Dimensions

The majority of psychological studies of categorization have used simple artificial stimuli (e.g., semicircles in two-dimensional space—Nosofsky, 1986) that vary on only a few (two to four) dimensions[1]. This is in contrast to the more natural high-dimensionality machine learning applications, such as wine tasting (Aeberhard, Coomans, & Devel, 1994) or handwriting recognition (Martin & Pittman, 1991). It remains to be demonstrated how optimal humans can be when categorizing objects using many continuously valued dimensions. In addition, the predominant psychological models of categorization have not addressed the issue of how people can categorize a multidimensional object when they are constrained by limited information.

Berretty and her colleagues (Berretty, Todd, & Martignon, 1999; Berretty, Todd, & Blythe, 1997) have illustrated that it is possible for a satisficing model that does not use all the available cues to categorize objects, to perform comparably to integrative models on natural data sets. The purpose of the first experiment in this paper is to investigate whether such a satisficing model is able to account for human categorization data from a multi-dimensional, multi-category task. In Experiment 1a, humans are trained to learn categories that vary along nine dimensions. The generalized context model, categorization by elimination, and a form of decision bound theory will be tested to determine how well each model fits the participants' responses. The purpose of the second experiment is to determine how well humans

[1] Posner and Keele (1968) have used random dot stimuli to test human classification, however, the number of dimensions is indeterminable.

are able to categorize when information is limited. In addition, Experiment 1b investigates the properties of the dimensions people prefer to use when information is limited.

Participants

Four graduate students from the University of California, Santa Barbara participated in Experiment 1a and 1b. All participants had normal or corrected vision. Each participant was paid $8 per hour.

Method

Design The design consisted of five different categories that vary along nine dimensions, where only three of the dimensions are necessary for accurate categorization. The values for each category were generated from a multivariate normal distribution where variance(dim 1) > variance(dim 3) > variance(dim 2), with the variance for the remaining 6 dimensions equal to the variance along dimension 3. All uni-dimensional rules that best separate two categories with the same mean on the other two relevant dimensions have an accuracy of 90% (i.e., category overlap along each pair of dimensions was set to 10%).

Procedure Participants were told that they were to learn five different categories that were equally represented during each learning session. Participants were instructed that they may or may not need to use all the dimensions available to them. Participants were run over consecutive days until learning curves leveled off. Each day consisted of 20 blocks with 50 trials per block (for a total of 1000 trials per day). Stimulus display was response terminated and corrective feedback was given after every trial. Thus, if a subject responded 'A' to an exemplar from category B, a low tone sounded followed by a 'B' appearing on the screen. In addition, overall percent correct was given after every learning block.

A cue preference task (Experiment 1b) was administered to participants the day after learning ended. The cue preference day began with a practice block in which participants simply categorized 50 stimuli as they had done on previous days. The practice block was followed by twelve blocks, each consisting of 50 trials. Each trial began with the presentation of one of the three relevant dimensions. Participants then made a categorization judgment based on only that one dimension. After making a judgment, participants chose another dimension and then made another categorization judgment. Thus, two judgments were made for the same stimulus. The first judgment was based on only one experimenter-chosen dimension, while the second judgment was based on two dimensions. No feedback was given during the last twelve blocks of the test day.

Stimuli and Materials Stimuli were generated using the GRT Toolbox (Alfonso-Reese, 1995). Values along every dimension were transformed from number of dots per square into actual screen coordinates. Each dimension was represented as a texture in one of nine possible squares on a computer screen. The location of the three relevant dimensions was different for each subject with the constraint that the center square (in a 3x3 grid) will never be one of the relevant dimensions. Stimuli were presented on a SuperMac Technology 17T ColorDisplay driven by a PowerMacintosh G3 running a Psychophysics Toolbox (Brainard, 1997) and low-level VideoToolbox (Pelli, 1997) within MATLAB (The MathWorks, Inc., 1998). Each participant sat 18 inches from the monitor. The height of the center square of the stimuli was constrained such that visual angle was less than 2°.

Results and Discussion

Experiment 1A Learning for three of the four participants reached asymptote after five days, while the fourth participant required six days. Participants 1, 2, and 3 achieved an overall accuracy of approximately 70% by the last day, while Participant 4 only achieved an overall accuracy of approximately 60% on the last day. The optimal percent correct was 81.9%. Participants' responses for the last day (without the first block) were randomly split into two halves (training and testing sets) five times. Each split was constrained to contain approximately the same number of stimuli from each category.

The Categorization by Elimination algorithm, the Deterministic Generalized Context Model (see Ashby & Maddox, 1993), and six versions of Decision Bound Theory were fit to each participant's training set responses. For CBE, low and high values of each bin along each dimension, as well as the cue order, were estimated from the responses in the training set. The parameters estimated for GCM were the sensitivity parameter, an attention weight for each dimension, the bias towards each category, and the gamma parameter (which is a measure of response selection). For fitting the GCM, a Euclidean-Gaussian distance-similarity metric was used (see Maddox & Ashby, 1998).

The six versions of DBT were all Independent Decisions Classifiers, which is a special case of Decision Bound Theory in which each dimension is assumed to be independent of the other dimensions (see Ashby & Gott, 1988; Ashby & Maddox, 1990). This version of DBT was used since the best fitting bound (to separate the categories) is perpendicular to each of the three relevant dimensions. In the versions of the Independent Decisions Classifier tested here, one criterion is placed along one dimension. Two criteria are then placed along a second dimension and four criteria are placed along the third dimension. All

Table 1: AIC Scores for Experiment 1A

	P1 Train	P1 Test	P2 Train	P2 Test	P3 Train	P3 Test	P4 Train	P4 Test
GCM	585.4	633.6	739.42	823.08	647.33	687.14	814.4	835.24
DBT	594.74	638.16	742.63	780.87	645.32	665.22	809.55	824.54
CBE	646.28	643.59	638.32	640.36	624.5	634.86	656.04	646.85

possible combinations of the three relevant dimensions were tested.

As mentioned earlier, all three models were fit to part of the data set (the training set) and the best fitting parameters estimates were obtained. These parameters were then used to determine the models' accuracy on the remaining data (the testing set). A potential problem with multi-parameter models is that these models may be prone to overfit the data. That is, they actually fit the noise present in the data in order to achieve high accuracy. Training the model on a subset of the data and testing the model on the rest of the data may assess a model's "true" performance.

The AIC goodness-of-fit statistic was used to compare the fits of the three models.

$$AIC(M_i) = -2\ln L_i + 2v_i$$

Where $\ln L_I$ refers to the negative log likelihood value for model M_i obtained through maximum likelihood estimation and v_i refers to the number of free parameters in model M_i. The smaller the AIC score, the closer the model is to the "true" model (Ashby, 1992).

Goodness-of-fit values for each participant (averaged over the five training and five testing sets) are shown in Table 1. Each row corresponds to one of the three models while each column refers to each participant's training and testing sets. The generalized context model was best able to account for Participant 1's training and testing data. Categorization by elimination was best able to account for Participant 2, Participant 3, and Participant 4's training and testing data.

Experiment 1B Experiment 1b was designed to answer two questions. First, how well can humans perform in a categorization task when dimensionality is reduced? Second, what are the properties of the dimensions preferred by humans? Obviously, one of the most important features of a cue is how accurate that cue is in categorizing objects when used alone. Another property of cues is the range of values possible, that is, the variance of a cue. It seems reasonable to assume that humans are able to learn the accuracy of various cues and would use those cues that are more accurate. Given this assumption, all three of the relevant dimensions are equally accurate when used alone. However, the question of whether humans prefer to use cues with more or less variance is addressed by having different variances for the three relevant dimensions.

In Experiment 1b (conducted after performance asymptotes) participants were given one dimension and asked for a categorization judgment.[2] Participants then chose a second dimension (from the remaining eight dimensions) and made a categorization judgment based on only those two dimensions. Only the three relevant dimensions for the categorization task were used in Experiment 1b as the first cue presented to the participant. Both high and low values of these dimensions were given to the participants. Dimension values were selected from the categories such that the values were always less than (or greater than) the best fitting criteria values for that dimension (i.e., only dimensional values from nonoverlapping category regions were presented).

The first major result to notice from this experiment is the overall percent correct participants achieved, which is shown in Table 2. The optimal percent correct possible with only two categories is 51.6%. Participant 3 was very close to optimal, while Participants 2 and 4 actually performed better than would be expected. In addition, Participant 4 actually performed better in Experiment 1b than in Experiment 1a!

Table 2: Overall Percent Correct in Experiment 1B

	Participant			
	1	2	3	4
Percent Correct	42.67	55.23	49.83	64.5

The results from Experiment 1b indicate that participants did indeed learn which of the cues in Experiment 1a were relevant. All four participants chose (nearly always, if not always) one of the three relevant dimensions as their second cue in Experiment 1b (see Table 3). This indicates that participants were not using any of the other dimensions during Experiment 1a[3].

[2] Participants were given the first cue to insure that all three of the relevant dimensions would be chosen. If participants were allowed to choose the first cue to use, it is possible that the same cue would be used first for each trial.

[3] This does not rule out the possibility that participants were using other dimensions in Experiment 1a, but preferred to use one of the three relevant dimensions when limited in the number of dimensions available to them. However, verbal

Table 3: Dimension Preference for Participants 1-4

Dimension Presented	Dimension Chosen by Participant 1			
	1	2	3	4-9
1	23	150	25	0
2	188	9	2	0
3	186	11	0	0
	Dimension Chosen by Participant 2			
	1	2	3	4-9
1	9	80	103	1
2	86	3	100	5
3	91	88	7	7
	Dimension Chosen by Participant 3			
	1	2	3	4-9
1	16	162	22	0
2	162	5	27	0
3	186	9	4	0
	Dimension Chosen by Participant 4			
	1	2	3	4-9
1	15	45	134	0
2	113	0	87	0
3	133	59	8	0

According to CBE when dimension 1 is presented, dimension 3 should be chosen and when dimension 2 or 3 is presented, dimension 1 should be chosen. When dimension 1 was presented first two of the participants preferred the dimension with the highest probability of success (dimension 3). When dimension 2 was presented first, three of the participants preferred the dimension with the highest probability of success (dimension1). All four participants preferred the dimension with the highest probability of success (dimension 1) when dimension 3 was presented first.

Overall, the participants generally chose the second dimension in accord with predictions made by CBE.

Learning Relevant Cues

Given the difficulty of the task in Experiment 1a, it is remarkable that the participants were able to learn the relevant cues. As shown above, all four participants chose (nearly always, if not always) the three relevant dimensions as their second cue in Experiment 1b. But how did cue use progress as the participants learned the different categories in Experiment 1a? To answer this question three different versions of MDS were fit to the participants' category confusion matrices from each half of each day in order to determine how many cues were used by each participant for a particular data set. MDS_1 uses only one dimension, MDS_2 uses two dimensions, and MDS_3 uses three dimensions to account for the participants' confusions. A χ^2 analysis was performed on the differences between the fit values for models differing in one dimension. These results are reported in Table 4.

For participant 1, an MDS choice model using two dimensions did fit the responses better than an MDS choice model using only one dimension for day 2. By day 4, an MDS choice model using three dimensions did obtain a significantly higher fit value than an MDS choice model using only two dimensions. These results indicate that participant 1 used only one dimension on day 1, two dimensions on days 2 and 3, and three dimensions on days 4 and 5.[4] Similarly, the MDS analysis indicates that participants 2 and 3 used only one dimension on the first half of day 1, two dimensions on the second half of day 1, and three dimensions after day 1. Participant 4 appeared to use only one dimension on the first half of day 1, two dimensions on days 2 and 3, and three dimensions on days 4 through 6. Taken with the results from Experiment 1b, it appears that participants not only increased over days the number of cues used when categorizing, but also learned the correct (or relevant) cues to use to accurately categorize.

Given a task consisting of many dimensions, it is clear that participants begin by using only one dimension. Additional dimensions are then learned in a sequential fashion. What is remarkable from these data, is that participants learned to use all three dimensions. Dimension 1 had more variance than any of the other eight dimensions while dimension 2 had less variance than any of the other eight dimensions. Therefore, it is not surprising that participants were able to learn these two dimensions (i.e., the two dimensions out of nine that had differing variances). Dimension 3 on the other hand, had the same amount of variance as the six irrelevant dimensions, yet participants learned by the end of the experiment that this dimension was necessary for accurate categorization.

Conclusion

In conclusion, the studies reported here show that humans are able to learn artificial multidimensional categories. It was also shown that people are able to distinguish relevant from irrelevant dimensions in multidimensional categorization tasks. Results from such a task indicate that a satisficing model is best able to account for the participants' responses. In addition, the predictions made by the satisficing model regarding cue preference were shown to be in accord with the cue

protocol collected at the end of the experiment indicated that participants were only using three dimensions during Experiment 1a.

[4] Note, that on the last half of day 5, the increase in parameters used by and MDS choice model with three dimensions did not fit the data significantly better than an MDS choice model with less parameters (i.e., less dimensions).

A Perceptually Driven Dynamical Model of Rhythmic Limb Movement and Bimanual Coordination

Geoffrey P. Bingham (gbingham@indiana.edu)
Department of Psychology and Cognitive Science Program, 1101 E. 10th St.
Indiana University
Bloomington, IN 47405-7007 USA

Abstract

We review the properties of coordinated rhythmic bimanual movements and previous models of those movements. Those models capture the phenomena but they fail to show how the behaviors arise from known components of the perception/ action system and in particular, they do not explicitly represent the known perceptual coupling of the limb movements. We review our own studies on the perception of relative phase and use the results to motivate a new perceptually driven model of bimanual coordination. The new model and its behaviors are described. The model captures both the phenomena of bimanual coordination found in motor studies and the pattern of judgments of mean relative phase and of phase variability found in perception studies.

Introduction

In coordination of rhythmic bimanual movements, relative phase is the relative position of two oscillating limbs within an oscillatory cycle. For people without special skills (e.g. jazz drumming), only two relative phases can be stably produced in free voluntary movement at preferred frequency (Kelso, 1995). They are at 0° and 180°. Other relative phases can be produced on average when people follow metronomes, but the movements exhibit large amounts of phase variability (Tuller & Kelso, 1989). They are unstable. Preferred frequency is near 1 Hz. As frequency is increased beyond preferred frequency, the phase variability increases strongly for movement at 180° relative phase, but not at 0° (Kelso, 1990). If people are given an instruction not to correct if switching occurs, then movement at 180° will switch to movement at 0° when frequency reaches about 3-4 Hz (Kelso, 1984; Kelso, Scholz & Schöner, 1986; Kelso, Schöner, Scholz & Haken,1987). With the switch, the level of phase variability drops. There is no tendency to switch from 0° to 180° under any changes of frequency.

These phenomena have been captured by a dynamical model formulated by Haken, Kelso and Bunz (1985). The HKB model is a first order dynamic written in terms of the relative phase, ϕ, as the state variable.

The equation of motion, which describes the temporal rate of change in ϕ, that is, $\dot{\phi}$, is derived from a potential function, $V(\phi)$, which captures the two stable relative phases as attractors as show in Figure 1. The attractors are wells or local minima in the potential layout. As the dynamic evolves, relative phase is attracted to the bottom of the wells at 0° and 180°. A noise term in the model causes the relative phase to depart stocastically from the bottom of a well. The effect of an increase in frequency is represented by changes in the potential. The well at 180° becomes progressively more shallow so that the stochastic variations in relative phase produce increasingly large departures in relative phase away from 180°. These departures eventually take the relative phase into the well around 0° at which point, the relative phase moves rapidly to 0° with small variation.

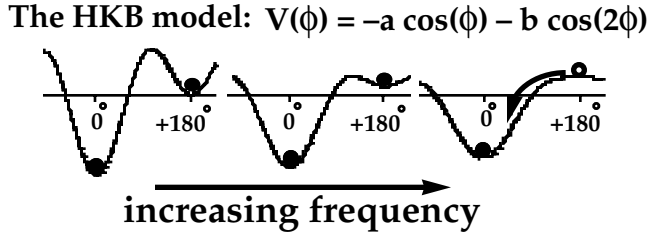

Figure 1. The HKB model. The parameters a and b are varied to model changes in the potential as a function of increases in frequency of movement.

Investigating Phase Perception

We wondered: what is the ultimate origin of the potential function in this model? Why are 0° and 180° the only stable modes and why is 180° less stable than 0° at higher frequencies? To answer these questions, we investigated the perception of relative phase because the bimanual movements are coupled perceptually, not mechanically (Kelso, 1984; 1995). The coupling is haptic when the two limbs are those of a single person. Schmidt, Carello and Turvey (1990) found the same behaviors in a visual coupling of limb movements performed by two different people. Similar results were obtained by Wimmers, Beek, and van Wieringen (1992). To perform these tasks, people must be able to perceive relative phase, if for no other reason, than to comply with the instruction to oscillate at 0° or 180° relative phase.

For reasons discussed at length by Bingham, Zaal, Shull, and Collins (2001), we investigated the visual perception of mean relative phase and of phase variability using both actual human movements (Bingham, Schmidt & Zaal, 1998) and simulations (Bingham, et al., 2001; Zaal, Bingham & Schmidt, 2000) to generate displays of two oscillating balls viewed side on or in depth. Observers judged mean phase or phase variability on a 10 point scale. We found that judgments of phase variability (or of the stability of

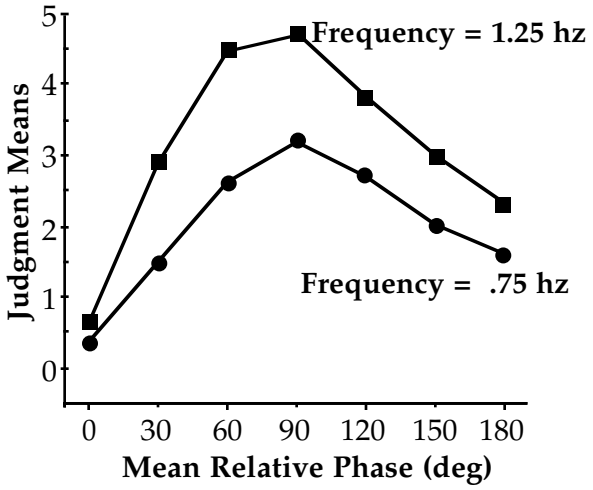

Figure 2. Judgments of phase variability. Mean judgments of phase variability for movements with 0° phase SD (Standard Deviation) and at 7 mean phases from 0° to 180° relative phase. Filled circles: Movement at a freequency of .75 hz. Filled squares: Movement at 1.25 hz.

movement) followed an asymmetric inverted-U function of mean relative phase, even with no phase variability in the movement as shown in Figure 2. Movement at 0° relative phase was judged to be most stable. At 180°, movement was judged to be less stable. At intervening relative phases, movement was judged to be relatively unstable and maximally so at 90°. Levels of phase variability (0°, 5°, 10°, and 15° phase SD) were not discriminated at relative phases other than 0° and 180° because those movements were already judged to be highly variable even with no phase variability. The standard deviations of judgments followed this same asymmetric inverted-U pattern. We found that judgments of mean relative phase varied linearly with actual mean relative phase. However, as phase variability increased, 0° mean phase was increasingly confused with 30° mean phase and likewise, 180° was increasingly confused with 150°. Also, the standard deviations of judgments of mean relative phase followed the same asymmetric inverted-U function found for the means and standard deviations of judgments of phase variability.

Finally, we investigated whether phase perception would vary in a way consistent with the finding in bimanual coordination studies of mode switching from 180° to 0° relative phase when the frequency was sufficiently increased. In addition to mode switching, increases in the frequency of movement yielded increases in phase variability at 180° relative phase but not at 0° relative phase. As shown in Figure 2, Bingham, et al. (in press) found that as frequency increased (even a small amount), movements at all mean relative phases other than 0° were judged to be more variable. This was true in particular at 180° relative phase. Frequency had no effect on judged levels of phase variability at 0° mean phase.

Results from our phase perception studies are all consistent with the findings of the studies on bimanual coordination. The asymmetric inverted-U pattern of the judgments is essentially the same as the potential function of the HKB model. The potential represents the relative stability of coordination or the relative effort of maintaining a given relative phase. The two functions match not only in the inverted-U shape centered around 90° relative phase, but also in the asymmetry between 0° and 180°. 180° is less stable than 0°. This congruence of the movement and perception results supports the hypothesis that the relative stability of bimanual coordination is a function of the stability of phase perception. So, we developed a new model of bimanual coordination in which the role of phase perception is explicit.

Modelling the single oscillator

The HKB model is a first order dynamical model in which relative phase is the state variable. That is, the model describes relative phase behavior directly without reference to the behavior of the individual oscillators. The model was derived from a model formulated by Kay, Kelso, Saltzman and Schöner (1987) that does describe the oscillation of the limbs explicitly. In this latter model, the state variables are the positions and velocities of the two oscillators. To develop this model, Kay, et al. (1987) first modelled the rhythmic behavior of a single limb. In this and a subsequent study (Kay, Saltzman & Kelso, 1991), they showed that human rhythmic limb movments exhibit limit cycle stability, phase resetting, an inverse frequency-amplitude relation, a direct frequency-peak velocity relation, and, in response to perturbation, a rapid return to the limit cycle in a time that was independent of frequency. A dimensionality analysis showed that a second-order dynamic with small amplitude noise is an appropriate model. The presence of a limit cycle meant the model should be nonlinear and a capability for phase resetting entailed an autonomous dynamic. (Note: Phase resetting means that the phase of the oscillator was different after a perturbation than it would have been if not perturbed. An externally driven or non-autonomous oscillator will not phase reset because the external driver enforces its phase which is unaffected by perturbation of the oscillator.) Kay, et al. (1987) captured these properties in a 'hybrid' model that consisted of a linear damped mass-spring with two nonlinear damping (or escapment) terms, one taken from the van der Pol oscillator and the other taken from the Rayleigh oscillator (hence the 'hybrid') yielding:

$$\ddot{x} + b\,\dot{x} + \alpha\,\dot{x}^3 + \gamma\,x^2\,\dot{x} + k\,x = 0 \quad (1)$$

This model was important because it captured the principle dynamical properties exhibited by human rhythmical movements. However, the relation between terms of the model and known components of the human movement system was unclear. The damped mass-spring was suggestive of Feldman's λ-model of limb movement (also known as the equilibrium point or mass-spring model). The λ-model represents a functional combination of known muscle properties and reflexes. Nevertheless, in the hybrid model, the functional realization of the nonlinear damping terms was unknown.

Following a strategy described by Bingham (1988),

Bingham (1995) developed an alternative model to the hybrid model. All of the components of the new model explicitly represented functional components of the perception/action system. The model also incorporated the λ-model, that is, a linear damped mass-spring. However, in this case, the mass-spring was driven by a perceptual term. Limb movements are known to exhibit organizations that are both energetically optimal and stable (e.g. Diedrich & Warren, 1995; Margaria, 1976; McMahon, 1984). Both energy optimality and stability are achieved by driving a damped mass-spring at resonance, that is, with the driver leading the oscillator by 90°. Accordingly, Hatsopoulos and Warren (1996) suggested that this strategy might be used in driving the Feldman mass-spring organization to produce rhythmic limb movements. However, a driver that is explicitly a function of time would yield a nonautonomous dynamic, that is, a dynamic that would not exhibit phase resetting. Bingham (1995) solved this problem by replacing time in the driver by the perceived phase of the oscillator. That is, instead of Fsin(t), the driver is Fsin(ϕ), where ϕ is the phase. Because ϕ (= f[x, dx/dt]) is a (nonlinear) function of the state variables, that is, the position and velocity of the oscillator, the resulting dynamic is autonomous. The perceptually driven model is:

$$\ddot{x} + b\,\dot{x} + k\,x = c\,\sin[\phi] \qquad (2)$$

where

$$\phi = \arctan\left[\frac{\dot{x}_n}{x}\right], \quad \dot{x}_n = \dot{x}/\sqrt{k} \text{ and } c = c(k).$$

The amplitude of the driver is a function of the stiffness. Bingham (1995) showed that this oscillator yields a limit cycle. This is also shown in Figure 3 by rapid return to the limit cycle after a brief perturbing pulse. As also shown, the model exhibits the inverse frequency-amplitude and direct frequency-peak velocity relations as frequency was increased from 1 hz to 6 hz. Finally, the model exhibits a pattern of phase resetting that is similar to that exhibited by the hybrid oscillator. Goldfield, Kay and Warren (1993) found that human infants were able to drive a damped mass-spring at resonance. The system consisted of the infant itself suspended from the spring of a "jolly bouncer" which the infant drove by kicking. This instantiates the model and shows that even infants can use perceived phase to drive such an oscillator at resonance. We hypothesize that all rhythmic limb movements are organized in this way.

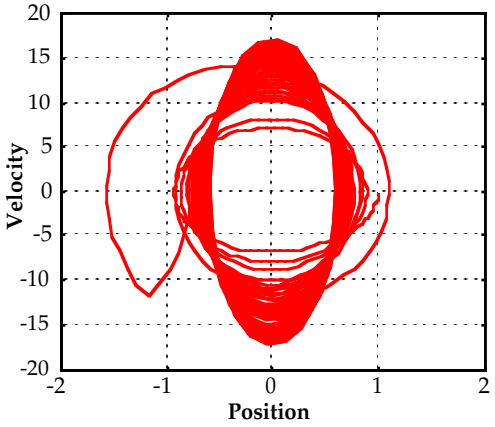

Figure 3. Phase portrait of the single perceptually driven oscillator. Movement starts at 1 hz and increases gradually to 6 hz. Early in the movement while still at 1 hz, the movement was perturbed by a 50ms pulse. Rapid return to the limit cycle within about 1 cycle is shown. Also shown is the decrease in amplitude and the increase in peak velocity that accompanies the increase in frequency.

Once again, the components are the Feldman mass-spring (composed of muscle and reflex properties) and a driver that is a function of the perceived phase of the oscillator.

Modeling Coupled Oscillators

With this model of a single oscillating limb, we were ready to model the coupled system. Kay, et al. (1987) had modeled the coupled system by combining two hybrid oscillators via a nonlinear coupling:

$$\ddot{x}_1 + b\,\dot{x}_1 + \alpha\,\dot{x}_1^3 + \gamma\,x_1^2\,\dot{x}_1 + k\,x_1 = (\dot{x}_1 - \dot{x}_2)[a + b\,(x_1 - x_2)^2]$$

$$\ddot{x}_2 + b\,\dot{x}_2 + \alpha\,\dot{x}_2^3 + \gamma\,x_2^2\,\dot{x}_2 + k\,x_2 = (\dot{x}_2 - \dot{x}_1)[a + b\,(x_2 - x_1)^2] \qquad (3)$$

This model required that people simultaneously perceive the instantaneous velocity difference between the oscillators as well as the instantaneous position differences so that both could be used in the coupling function. This model did yield the two stable modes (namely, 0° and 180° relative phase) at frequencies near 1 hz, and mode switching from 180° to 0° relative phase at frequencies between 3 hz and 4 hz.

We propose an alternative model in which two phase driven oscillators are coupled by driving each oscillator using the perceived phase of the other oscillator multiplied by the sign of the product of the two drivers (P). This sign simply indicates at each instant whether the two oscillators are moving in the same direction (sign = +1) or in opposite directions (sign = –1). The model is:

$$\ddot{x}_1 + b\,\dot{x}_1 + k\,x_1 = c\,\sin(\phi_2)\,P_{ij}$$

$$\ddot{x}_2 + b\,\dot{x}_2 + k\,x_2 = c\,\sin(\phi_1)\,P_{ji} \qquad (4)$$

where

$$P = \mathrm{sgn}(\sin(\phi_1)\,\sin(\phi_2) + \alpha(\dot{x}_i - \dot{x}_j)\,N_t) \qquad (5)$$

P represents the perceived relative phase. As shown in equation (5), the product of the two drivers is incremented by a gaussian noise term with a time constant of 50 ms and a

variance that is proportional to the velocity difference between the oscillators. This noise term reflects known sensitivities to the directions of optical velocities (De Bruyn & Orban, 1988; Snowden & Braddick, 1991) and is motivated by results from phase perception experiments (Collins & Bingham, 2000). This model also yields only two stable modes (at 0° and 180° relative phase) at frequencies near 1 hz, and, as shown in Figure 4, yields mode switching from 180° to 0° relative phase at frequencies between 3 hz and 4 hz. Furthermore, the model predicts our

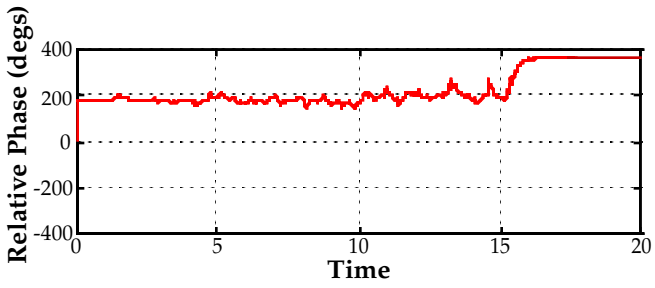

Figure 4. Continuous relative phase from a run of the perceptually coupled model starting at 1 hz and 180° relative phase. Frequency was increased progressively to over 4 hz. Relative phaase became progressively more variable and switched to 360° = 0° at 4 hz. (Note: Frequecy = sqrt(Time+1).)

results for judgments of mean relative phase and of phase variability. (See e.g. Figure 5.) Judged mean phase is produced by integrating P over a moving window of width σ (= 2 s) to yield $\mathbf{P_{JM}}$:

$$\mathbf{P_{JM}} = \frac{\int_{t-\sigma}^{t} P\,dt}{\sigma} \quad (6)$$

Judged phase variability is predicted by integrating $(P - \mathbf{P_{JM}})^2$ over the same window to yield $\mathbf{P_{JV}}$:

$$\mathbf{P_{JV}} = \frac{\int_{t-\sigma}^{t} [P - \mathbf{P_{JM}}]^2 dt}{\sigma} \quad (7)$$

$\mathbf{P_{JM}}$ varies linearly with actual mean phase and $\mathbf{P_{JV}}$ yields an asymmetric inverted-U as a function of actual mean phase.

There are two aspects of the perceptual portions of the model that should be emphasized. First, there are actually two perceptible properties entailed in the model. The two are very closely related, but they are distinct. The first is the phase of a single oscillator. The perception thereof is entailed in the single oscillator model. This is, of course, incorporated into the coupled oscillator model. The second perceptible property is relative phase. This latter property brings us to the second aspect of the model to be noted. This is especially important.

This model is being used to model performance in two different tasks, one is a coordinated movement task and the other is a judgment task. Equation (5) represents the way the perception of relative phase plays a role in the coordinated movement task. This is in terms of the momentary value of P, that is, whether the oscillators are perceived to be moving in the same or in opposite directions at a given moment in time. Equations (6) and (7) represent the way the perception of relative phase plays a role in the judgment tasks. In this case, the behavior of P is assessed (that is, integrated) over some window of time that is large enough to span one or two cycles of movement. So, the two tasks are connected by a single perceptible property, but the way the property is evaluated and used is task-specific.

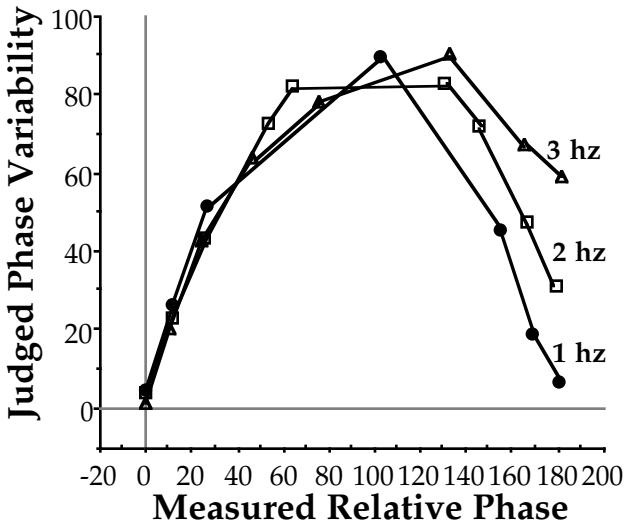

Figure 5. Model predictions of judgments of phase variability at a number of different mean relative phases and at three different frequencies of movement. The model was forced to relative phases other than 0° and 180° to obtain these results.

Conclusions

The model captures both the movement and the perception results. It exhibits the fundamental properties of human rhythmic movements. It builds on the previous task-dynamic modeling results of Kay et al. (1987) and Kay et al. (1991) which revealed fundamental dynamic properties of human movement. Those properties are captured by the new model as they were by previous models. However, unlike the previous models, the new model's components are interpretable in terms of known components of the perception/action system. It explicitly represents the perceptual coupling that is well recognized to be fundamental to the coordination task and the resulting bimanual behaviors. This is important because we can now proceed to investigate the perception component (no less important than the properties of muscle in the Feldman component) to discover the origin of some of the dynamic properties of these perception/action systems. This is an explicit perception/action model.

Finally, although its behaviors are extremely complex,

the model itself is relatively simple and elegant. Two relatively simple equations (4) capture limit cycle stability, phase resetting, inverse frequency-amplitude and direct frequency-peak velocity relationships, the stable modes and mode transitions and the increasing patterns of instability leading up to mode transition. With the addition of two more simple equations (6) and (7) computing a mean and a variance, the model accounts for the results for perceptual judgments of mean relative phase and of phase variability and the ways these vary with the frequency of movement. All this from a model with 5 parameters (k, b, c, α, and σ), four of which are fixed and one, k, is varied to generate variations in frequency of movement. (Note: because c=f(k), c varies with k but once the scaling of c is fixed, this does not represent an extra degree of freedom.) The model is representative of nonlinear dynamics: complex behavior emergent from simple dynamic organization.

Acknowledgments

This research was supported in part by NEI grant # EY11741-01A1 and by NIMH grant # 5T32MH19879-07. The author is grateful for assistance provided by David R. Collins in performing simulations and some of the phase perception studies that have constrained the model. The studies reported herein were reviewed and approved by the Human Subjects Committee at Indiana University. All participants gave their informed consent prior to participation in the experiments.

Abstract

We investigate the features people use in making inferences about continuity of individual persons. Using a transformation paradigm, we show that people weigh both continuity of the brain and continuity of mental content. Across experiments, we document instances in which participants are more likely to assert individual continuity than continuity of personhood. We discuss these results in terms of a hierarchical view of concepts and philosophical work on personal identity.

Introduction

People are sensitive to the effects that transformations have on membership in basic-level categories (e.g., Gelman & Wellman, 1991; Keil, 1989; Rips, 1989). For example, Rips (1989) asked participants to read stories about creatures of one category (e.g., birds) that came to resemble those of another (e.g., insects). If the transformation was due to accidental factors, participants believed that the creature remained a member of the original category. If the transformation was part of normal maturation, however, participants judged the creature a member of the second category. In general, transformations that alter an object's core properties also tend to change the object's category, while transformations that alter an object's surface or incidental properties tend to preserve its category.

Despite the relatively large number of studies that address questions of category membership continuity, there have been few studies addressing reasoning about individual continuity (see Hall, 1998, Johnson, 1990 and Liittschwager, 1994, for exceptions in the developmental literature). The central question is how we decide that a particular individual – for example, my dog Fido – is the same individual (still Fido) across transformations. This question is potentially different from the one about membership – whether this individual is still a dog.

We investigate here two issues concerning reasoning about individuals. First, we explore the kinds of features people use in judging continuity of identity. Second, we contrast the ways in which people reason about class membership and about identity continuity.

Features of Person Identity

What properties does a person at time t_1 need to share with one at time t_2 in order for that individual to be *the same* at both temporal markers? In making such judgments, people may be *phenomenalists*, relying on continuity of appearance.

In a preliminary experiment, we created stories that varied the type of transformation that a hypothetical target person undergoes. One set of participants -- the Plastic Surgery group -- read a scenario about Jim, a male accountant, who receives plastic surgery to alter his appearance cosmetically to resemble that of Marsha, a female actress. Another set of participants -- the Brain Transplant group -- read a similar story in which Jim's brain is replaced with that of Marsha. After reading the story, both groups supplied judgments of Jim's *identity change* – whether the individual was still Jim or had become Marsha after surgery. Results indicated that a greater proportion of participants in the Brain Transplant group believed Jim's identity had changed than in the Plastic Surgery group (45% and 15%, respectively, $\chi^2(1, 39) = 4.29$, $p < .05$).

These results suggest that changes in appearance are ordinarily not enough to warrant change in identity. The finding parallels earlier studies of natural kinds that show that people tend to reject mere appearance as evidence for category membership when appearance conflicts with deeper properties of the category in question. It has often been suggested that natural kinds' hidden, causally central properties are used for categorization and induction (Ahn, 1998; Gelman & Hirschfeld, 1999), while surface features such as appearance are used for similarity judgments (Keil, 1989; Rips, 1989). But although our results hint that our participants are not folk-phenomenalists, they leave open the question of what criteria they do use to assess personal identity.

The question of criteria for identity is one of the oldest in metaphysics. Writers on the *physicalist* side (e.g., Aristotle, Wiggins) argue that continuity of the body, or, more importantly, the brain, is critical to identity. According to this view, a person P_2 at time t_2 is the same person as P_1 at t_1 if

P_2 has the brain of P_1[1]. Philosophers arguing from a *functionalist* position (e.g., Locke) propose that what matters for identity is not the physical brain, but rather the mental content – the person's unique memories, habits, and personality.

If people are folk-physicalists, then a brain transplant that does not preserve the mental content of the original person should be judged to be as person-preserving as a transplant that retains the original memories. We test this hypothesis in Experiment 1. In Experiment 2 we test the alternative hypothesis that people are folk-functionalists.

Individuals and Hierarchies

A prevalent assumption in the cognitive-psychology literature on categories is that individuals inherit properties of the categories to which they belong. For example, if Fido is a dog, then properties of dogs are true of Fido. (However, see Sloman, 1998, for some exceptions.)

A number of philosophical positions also imply that judgments of identity (Fido vs. Rover) and category membership (dog vs. cat) are related. According to these accounts, criteria of identity for an object (whether phenomenal, physical, or functional) are given by membership in a category to which the object belongs (e.g., Geach, 1962; Gupta, 1980; Wiggins, 1980). If a dog, Fido, is somehow transformed so that it is no longer a dog, it must be true that it is no longer the same individual. In some of these theories (Geach, 1962), different categories to which Fido belongs (e.g., dog vs. pet) yield different criteria of identity, whereas in others (Wiggins, 1980) there can be only one set of criteria. In the experiments that follow, we show that people's reasoning about continuity of identity need not follow *any* obvious category. Instead, participants sometimes rely on distinct sets of features when reasoning about continuity of identity and continuity of category membership.

Experiment 1: Memories and Causality

One goal of Experiment 1 was to determine whether participants perceive continuity of memories as necessary for identity. For the purposes of this paper, we consider "memories" to be unique sets of personal mental representations.

We presented stories that manipulate whether a target person undergoing a brain transplant retains or loses memories in the process. If what matters for identity is continuity of physical parts, such as the brain, then participants should perceive brain transplants that retain memories and those that lose memories as equally conducive to sameness of identity. By contrast, if continuity of memories is essential to continuity of identity, then a brain transplant that retains memories should be more likely to elicit perceptions of sameness than a transplant that does not retain memories.

We also varied whether the memories in question could affect the person's behavior. Because the more essential features of concepts may be those that are causally central (Ahn, 1998), we expected memories that have causal efficacy to be more individual-preserving than memories that could not cause behavior.

One methodological limitation of the preliminary study discussed in the introduction is that participants were never queried about whether the target person was still a member of the same category after the transformation (e.g., whether he was still a person, as opposed to still being Jim). We were therefore not able to determine whether participants' judgments of identity change correlated with their judgments of change in category membership – a correlation that we would expect given the philosophical theories cited earlier. We address this question in Experiment 1 by asking participants to judge the extent to which the post-transformation individual is still a member of his original categories. The category most likely to confer identity on our target individual is the category PERSON itself. However, to determine whether PERSON has special status in this regard, we contrast it with other possible categories, in this case occupation (ACCOUNTANT) and gender (MALE).

Method

Thirty-eight Northwestern University undergraduates read a science fiction story about Jim, a male accountant undergoing a lifesaving brain transplant. Specifically, Jim's brain was transplanted into a robot body. In a between-groups design, we varied whether Jim's memories were the same or different after the transformation. In addition, half the participants in each group answered questions about a situation in which the memories could cause behavior in the robot, and half answered questions about a situation in which the memories could not cause behavior. The full story appears in Figure 1.

The Preserved Memory group read a version of the scenario in which the robot received an *unaltered* version of Jim's brain. The Altered Memory group read a version of the story in which the memories were significantly *altered* during the transformation process.

After reading the story, participants rated their confidence in a number of statements relating to Jim's continuity. Causal efficacy -- whether the memories were able to affect behavior -- was manipulated by varying whether the questions that followed related to events on Monday (when the robot was off) or Wednesday (when the robot was functional). For example, in the Low Causal Efficacy condition, a probe statement read:

On Monday, before the scientists switch it on, the robot is Jim.

0—1—2—3—4—5—6—7—8—9

strongly disagree *strongly agree*

[1] A qualified physicalist position need not require strict sameness of matter, just that there be an unbroken chain of intermediate states between the matter that makes up the body now and the matter that made it up in the past.

The Transplant

Jim is an accountant living in Chicago. One day, he is severely injured in a tragic car accident. His only chance for survival is participation in an advanced medical experiment. Jim agrees.

A team of scientists remove his brain and carefully place it in a highly sophisticated cybernetic body (robot). The robot is powered by electricity. The scientists connect the brain to the robot controls. Though all the right connections between the robot and the brain have been made, the scientists cannot "plug" the robot in because they are waiting for a power adapter they have ordered.

On Monday, the scientists come in to work and the power adapter still has not arrived. While they wait, the scientists scan the brain inside the robot and note that **[THE MEMORIES / NO MEMORIES]** in it are the same as those that were in the brain before the operation.

Finally, on Wednesday, the power adapter arrives and the scientists turn on the robot. The robot appears human-like in its behavior. The robot has senses and can move and talk. Again, the scientists scan the brain inside the robot and find that **[THE MEMORIES / NO MEMORIES]** in it are the same as those that were in the brain before the operation.

Figure 1: Stimulus story for Experiment 1 showing the memory manipulation.

By contrast, in the High Causal Efficacy condition, participants evaluated the statement:

On Wednesday, after the scientists switch it on, the robot is Jim.

0—1—2—3—4—5—6—7—8—9

strongly disagree *strongly agree*

Each participant provided judgments about four kinds of continuity: **individual continuity** ("*… the robot is Jim")*, **personhood continuity** ("*… the robot is a person"*), **gender continuity** ("*… the robot is a male"*), and **occupational continuity** ("*… the robot is an accountant"*). Question order was fully counterbalanced across participants.

Results

Individual Continuity Table 1 summarizes the results of this experiment. As expected, continuity of memory was important for identity. Participants gave higher ratings when the transplanted brain retained the old memories than when it did not (mean ratings on a 0-9 scale were 5.28 and 1.70, respectively; $F(1, 34) = 21.21$, $p < .001$). The capacity of memories to cause behavior also had an effect on continuity. When the robot was described as being "off," continuity judgments were lower than when the robot was "on" (M = 2.15 and 4.83, respectively; $F(1, 34) = 11.83$, $p < .001$). The interaction between Memory and Causal Efficacy was reliable, $F(1, 34) = 5.82$, $p < .05$. Causal efficacy had a larger effect when Jim's memories were retained rather than altered, suggesting that when Jim's old memories were no longer present, it did not matter for identity per se whether the altered memories were able to cause behavior.

	Memories			
	Altered		Preserved	
Continuity	Low CE	High CE	Low CE	High CE
Individual	1.30	2.10	3.00	7.56
Personhood	1.90	3.60	2.00	4.56
Gender	3.80	4.20	2.56	7.00
Occupation	1.30	1.60	2.78	6.78

Table 1: Mean continuity ratings (Experiment 1) as a function of memory continuity and causal efficacy (CE).

Personhood Continuity A similar analysis of personhood ratings showed that, in contrast to identity findings, there was no main effect of Memory, suggesting that continuity of memory was not important for continuity of personhood, $F(1, 34) < 1$. However, there was a main effect of Causal Efficacy, $F(1, 34) = 5.45$, $p < .05$. Participants answering questions about a post-transformation robot in the "on" state were more likely to judge the robot as being a person than those who responded to queries about an "off" robot (M = 4.08 and 1.95, respectively). The interaction between Memory and Causal Efficacy was not reliable, $F(1, 34) < 1$.

Responses to the personhood question were predictive of identity judgments, but the magnitude of the effect was secondary to that of memory continuity. When memory continuity, causal efficacy and personhood were simultaneously regressed onto identity judgments, the standardized regression coefficient for personhood ($\beta = 0.30$) was relatively small compared to that for memory ($\beta = 0.51$). Adjusted R^2 for the overall model was .56.

Gender and Occupation Continuity Gender continuity ("Still a male?") did not fit the pattern of identity judgments. In contrast to identity results, there was no main effect of memories, $F(1,34) < 1$. People's continuity ratings in altered and preserved memory conditions tended towards the middle of the scale (M = 4.00 and 4.7, respectively), indicating that people were not confident about the right way to think about gender continuity. Causal efficacy, however, did play a role in these judgments. When the brain was able to cause behaviors, the object was rated more likely to retain gender than when the brain was unable to cause action (M = 5.60 and 3.18, respectively; $F(1, 34) = 6.62$, $p < .05$). Also, the effect of causal efficacy was greater when memories were retained, as suggested by a reliable interaction between memory and causal efficacy, $F(1, 34) = 4.62$, $p < .05$.

By contrast, occupation ratings ("Still an accountant?") did appear to follow the pattern of the identity ratings. An analysis of variance similar to the one performed on identity continuity judgments revealed parallel effects. We found a main effect of memory continuity such that a brain transplant that preserved memories was also more likely to pre-

serve occupation, $F(1, 34) = 22.35$, $p < .001$. Also, when the brain had an effect on behavior, occupation was more likely to be preserved than if the brain had no effect, $F(1, 34) = 9.33$, $p < .01$. Furthermore, as in the case of the identity ratings, there was an interaction between memory continuity and causal efficacy such that causal efficacy was more important for occupation continuity when memories were preserved, $F(1, 34) = 6.91$, $p < .05$.

Discussion

This experiment provided evidence for the role of memory continuity in perceived identity. Participants who read about a memory-preserving transplant gave higher individual continuity ratings than did participants who read about a transplant that did not preserve memories. This supports the widely held view in the philosophical literature that personal mental representations are central to individual identity. Moreover, our participants granted the highest level of identity continuity to a transplant if these memories had the capacity to cause behavior.

Perhaps the most striking finding is the relative independence between judgments of identity continuity and personhood continuity. People's reasoning about continuity of identity does not appear tightly bound to sameness of membership in normal categories. In fact, participants in some conditions were more likely to agree that the individual was still Jim after the transformation than that he/it was still a person. Specifically, in the condition judged optimal for individual continuity (Preserved Memories, High Causal Efficacy), participants gave a high mean rating of 7.56 when asked if the individual was the same, but a much lower rating of 4.56 when asked if it was still a person, $t(8) = 2.63$, $p < .05$.

We used gender and occupation categories as foils for personhood. As expected, we found only a poor fit between gender continuity and identity. Occupational continuity fared better in terms of reflecting identity judgments, though it seems likely that individual identity was driving occupation identity rather than the reverse. On intuitive grounds, occupational categories are hardly viable as granting identity to individuals. I can cease being a student, without any significant loss of identity. We revisit the issue of individual and occupation identity in Experiment 2.

In general, it seems possible that our participants used different criteria to judge identity, gender, and occupation. Most importantly, people decided about identity and personhood using different criteria. While the critical property of identity appears to be continuity of memories, personhood may depend more heavily on typical properties of persons, such as having a human body and engaging in human behaviors.

Experiment 2 pursues this issue, asking whether perceived identity continuity can be maintained through a transformation that does not preserve any of the physical parts of the original person.

Experiment 2: Necessary Features of Identity

Experiment 1 showed that a brain without the right memories does not guarantee identity of individuals. It is still possible, however, that the brain may be a necessary but not sufficient property of individuals. In this case, memories would have to be transmitted in the physical stuff in which they arose. By contrast, if memories are the "software" that is merely running on the brain "hardware," then it is conceivable that physical brains are not even necessary for identity – any computationally adequate device would do. This is the issue that separates physicalists and functionalists. Will people infer individual continuity even if the original person's memories are "implemented" on a machine that is not the original physical brain?

If the answer is "yes," then we may conclude that people's beliefs about identity are relatively unconstrained, allowing for identity to be preserved through a wide range of fairly extreme transformations. Such a folk-functionalist position is at least intuitively sensible. For example, body cells die and regenerate multiple times throughout the lifespan. It seems odd to consider such physical changes as threatening to personal identity. The competing folk physicalist theory sees brain tissue as at least necessary for identity.

Method

To address the question of physicalism versus functionalism, we modified the brain-transplant scenario from Experiment 1 to include a condition in which the memories in Jim's brain are copied onto a computer designed to control the robot (Computer Copy condition). The story for this condition appears in Figure 2. We also ran a replication of the Brain Transplant scenario from Experiment 1 (Brain Transplant condition) without the passages relating to causal efficacy.

The second factor in the design was whether the memories in the brain (computer) were altered or preserved. This design thus generated four scenarios, which we gave to separate groups of participants. After reading the scenario, participants answered the same set of questions as in Experiment 1. Judgments of individual, personhood, gender, and occupational continuity were made on a 10-point scale.

> Jim is an accountant living in Chicago. One day, he is severely injured in a tragic car accident. His only chance for survival is participation in an advanced medical experiment. Jim agrees.
>
> A team of scientists copy the memories in his brain onto a state-of-the-art computer. The computer is placed in a highly sophisticated cybernetic body (robot). All the right connections between the robot and the computer have been made, and the computer is able to control the robot. The scientists scan the computer and note that [***NONE OF***] the memories in it are the same as those that were in the brain before the operation.
>
> When the scientists turn on the robot, the robot appears to be human-like in its behavior. It has senses and can move and talk.

Figure 2: Stimulus story for the computer copy condition in Experiment 2.

	Memories			
	Altered		Preserved	
Continuity	Computer Copy	Brain Transplant	Computer Copy	Brain Transplant
Individual	0.89	1.53	1.97	5.27
Personhood	1.11	2.83	2.08	2.69
Gender	2.23	4.77	4.34	4.58
Occupation	3.17	0.91	5.78	4.16

Table 2. Mean continuity ratings (Experiment 2) as a function of memory continuity and transplant type.

Questions were presented in two different random orders across participants. Sixty-four Northwestern University undergraduate students took part in the study.

Results

Table 2 presents a summary of the results, which appear to favor a folk-physicalist over a folk-functionalist position.

Individual Continuity Participants in this experiment were more likely to think that the post-transplant individual was still Jim if the transplant included Jim's brain than if it merely included Jim's memories. A Brain Transplant elicited higher continuity ratings than a Computer Copy, $F(1, 56) = 17.95$, $p < .001$. As in Experiment 1, there was also an effect of the memories themselves. Participants who read about a transformation that preserved memories gave higher continuity ratings than those reading about a transformation that altered memories, $F(1, 56) = 26.81$, $p < .001$. Most importantly, however, there was also an interaction between transformation type and memory factors: Preserved memories facilitated continuity to a greater extent when the transformation was a Brain Transplant than when it was a Computer Copy, $F(1, 56) = 8.17$, $p < .01$. There were no reliable effects of question order.

Personhood Continuity As in the case of individual continuity, participants who read the Brain Transplant scenario viewed the robot as more likely to be a person than people who read about a Computer Copy, $F(1, 56) = 4.13$, $p < .05$. However, there was no reliable effect of memory continuity on personhood judgments: Participants were about as likely to think that the robot was a person whether or not the memories were the same as Jim's, $F(1, 56) < 1$.

As this result suggests, personhood continuity ratings did not fully predict judgments of identity continuity. That is, participants were not simply basing their identity judgments (Still Jim?) on whether they believed the object in question is still a person. We tested this claim as we did in the previous study, by running a simultaneous regression with personhood ratings, transplant type, memory continuity, and the interaction between them as predictors of identity responses. The pattern of regression weights closely resembled those in Experiment 1. Memory continuity ($\beta = .46$) was a better predictor of identity judgments than personhood ($\beta = .32$). Adjusted R^2 for the overall model was .54.

Gender and Occupation Continuity A similar analysis of variance on gender continuity ratings revealed no reliable effects. There was a trend for readers of the Brain Transplant story to assert a higher level of gender continuity than participants reading a Computer Copy story ($M = 4.67$ and 3.29, respectively; $F(1, 56) = 3.33$, $p = .07$, n.s.)

Occupational continuity revealed a main effect of transformation type, $F(1, 56) = 8.25$, $p < .01$. It is important to note, however, that the direction of the effect was reversed relative to the identity findings. A Computer Copy was more convincing than a Brain Transplant in allowing Jim to retain the status of an accountant ($M = 4.48$ and 2.53, respectively). As in the previous study, there was also a main effect of memory continuity, $F(1, 56) = 18.71$, $p < .001$. Continuity of memory positively predicted retention of an occupation.

Discussion

These data support the hypothesis that people's naïve construal of individual identity is roughly compatible with folk-physicalism. Continuity of the physical brain had an effect on continuity that went beyond that of functionally equivalent brain content. As in the previous experiment, our data speak against the possibility that this was due entirely to people's beliefs about personhood. While our participants did indicate that a computer copy was less of a person than a Brain Transplant, a regression analysis showed that personhood ratings were not as good a predictor of identity judgments as memory continuity.

We have also replicated the results of Experiment 1 showing that when continuity conditions were optimal (Brain Transplant, Preserved Memories), identity ratings were higher than personhood judgments ($M = 5.27$ and 2.69, respectively; $t(15) = 4.22$, $p < .01$).

Gender and occupation continuity were not good candidates for granting identity to individuals. Both gender and occupation ratings exhibited a poor fit with identity judgments. Occupation continuity actually exhibited a reverse pattern on the criteria people used for continuity judgments. In a number of conditions people were more certain about the continuity of an occupation than they were about individual continuity. For example, in the Computer Copy -- Preserved Memories condition, participants were more likely to say that the object in question is still an accountant than they were to assert that Jim is still in existence (M = 5.78, 1.97, respectively; $t(15) = 3.81$, $p < .01$).

One potential limitation of the current study is that the Computer Copy story was ambiguous as to the fate of Jim's original brain. If our participants assigned identity status to whichever object inherits the original brain, and they believed that Jim's brain survived the accident (even if damaged), then we would expect low continuity ratings in the

Computer Copy condition because Jim's brain is a better candidate for being Jim than the computer containing his memories. This kind of view is proposed by Williams (1973; see Nozick, 1985 for a reply).

While the data can not rule out this possibility, a free response questionnaire administered after the experiment showed that none of our participants explicitly considered Jim's original brain as a factor in their continuity judgments. Furthermore, a related study (in preparation), addressing the question of two possible continuers, showed that people are relatively insensitive to the existence of an identity competitor, preferring to base their judgments on sameness of substance.

Summary and Conclusions

In these studies, we explored the set of features people consider important to personal identity. We showed that when people reason about identity continuity, they take into account continuity of the physical brain and its causally efficacious mental content.[2] People are not phenomenalists, in that appearance is not a necessary feature of an individual's continuity. People are also not unconstrained functionalists, in that they do not assign full continuity if an object only implements a person's unique mental content.

What can a description of a folk theory tell us about the way people form and use concepts? A common assumption is that an individual's identity conditions are given by one or more of the categories to which it belongs. While this provides a convenient way to link categories and individuals, our data show that people do not always use the same sets of characteristics in deciding continuity of an individual and continuity of membership in even its most obvious superordinate category. We have documented instances in which an individual who is viewed as having ceased to be a person is still seen as the same individual.

This finding presents a challenge to the theory that identity conditions are dictated by the superordinate category (or sortal concept) to which that individual belongs. This theory incorrectly predicts that any doubt about proper membership in the category should be reflected in doubt about the individual's survival.

Whether this finding is restricted to reasoning about persons or can be generalized to a wider range of objects remains to be seen. Although relatively minor changes to objects can often cause them to change basic category membership, their individual continuity appears to be much more rigid. Keil (1989) used the example of a coffee pot that was reshaped as a birdfeeder to show that changes in intended function cause shifts in basic-level categorization for artifacts. Despite this change at the category level, however, the object is likely to be judged as the same individual as the one before the transformation.

Finally, reasoning about individuals may turn out to be fundamentally different than reasoning about categories. Individuation often takes into account the history of an object in a way that category membership does not. Whether Jim is still a person after a transformation may depend on whether the causal forces responsible for personhood are still intact. Whether Jim is still Jim, however, may depend on the trajectory of his parts across time.

[2] A strict physicalist position may be question-begging. If being the same individual depends on having the same physical material, how do we decide about whether physical material is the same? As philosophical theories, both the physicalist and functionalist approaches have some important deficiencies, particularly with respect to possible circularity. However, our purpose here is simply to see whether either theory approximates the reasoning of untrained participants. We leave to further research the question of what would happen if our lay-physicalists were confronted with difficulties for their view.

Graded lexical activation by pseudowords in cross-modal semantic priming: Spreading of activation, backward priming, or repair?

Jens Bölte (boelte@psy.uni-muenster.de)
Institute of Psychology II, WWU Münster, Fliedner Str. 21

Abstract

Spoken word recognition models treat mismatching sensory information differently. Mismatching information deactivates lexical entries according to one type of models. In another type of models, lexical entries are activated reflecting their degree of match with the input. This issue is mainly investigated with cross-modal semantic priming and lexical decision. This paradigm has been suspected of backward priming. I report three cross-modal priming experiments using naming and lexical decision to explore the sensitivity of word recognition to different degrees of match and to investigate the contribution of backward priming. Primes were pseudowords minimally (**baprika*) or maximally (**zaprika*) deviating from a word (*paprika*). A contribution of backward priming processes is likely. A repair of the mispronounced item as suggested by Marslen-Wilson (1993) seems untenable.

Introduction

The tolerance of spoken word recognition to a wide variety of distortions, e.g. misarticulation, phonological processes, or masking by environmental noise poses a serious problem for spoken word recognition models. This problem is tied to the question of what constitutes a match or a mismatch. Certain distortions might not form a mismatch at a lexical level. A system intolerant even to minor mismatches seems unlikely given highly prevalent variation in articulation.

Effects of Match and Mismatch

An account of mismatch effects has been formulated in Cohort (Gaskell & Marslen-Wilson, 1996; Marslen-Wilson, 1993). Gaskell and Marslen-Wilson (1996) found that primes with a legally place assimilated phoneme, e.g. **leam*[1], are as effective as unaltered primes, e.g. *lean*, in cross-modal repetition priming. They suggest that only non-redundant, distinctive, and marked phonological information is coded in the lexicon. For instance, place of articulation is unspecified for coronals: [t],[d],[n],[s],[z]. Therefore, they can assimilate to different places of articulation and still do not form a mismatch at a lexical level (see Coenen, Zwitserlood, & Bölte (in press) for different observations).

Ignoring phonological underspecification, Connine, Blasko, and Titone (1993) found that minimally mismatching primes, e.g. **zervice*, accelerated lexical decision to visual targets, e.g. *tennis*. Maximally deviating primes (e.g. **gervice*, > one phonemic feature) primed if they were made from rare words. Priming effects were graded by degree of mismatch. Connine et al. (1993) concluded that the word recognition system reflects the degree of featural overlap with the input thereby compensating for deviations. These findings are in conflict with observations by Marslen-Wilson (1993; Marslen-Wilson & Zwitserlood, 1989).

McClelland and Elman (1986) claim that Trace can compensate mismatching information. In Trace, activation spreads from a feature level to a phoneme level, and from there to a word level. Activation also spreads back from a word node to its constituent phonemes at the phoneme level. McClelland and Elman (1986) report that minimal mismatches are recognised, e.g. **bleasant* as *pleasant*. But simulations using the whole Trace lexicon showed that Trace does not recover easily from initial mismatches (Goldman, Frauenfelder, & Content, 1997 cited after Frauenfelder & Peters, 1998).

The pattern of results by Connine et al. (1993) can partly be captured by the Shortlist model (Norris, 1994). Input to this model consists of a string of phonemes. A list of words candidates, the Shortlist, is formed on the basis of bottom-up information. Mismatching information lowers the bottom-up support for lexical candidates, similar to the Cohort model. But Shortlist can overcome this reduction and activate the target to "a relatively high level of activation" (Norris, 1994, pp. 214). Bottom-up inhibition prevents activating the target if the mismatch is too large. Systematic simulations investigating the role of mismatching information are not yet available.

Mismatch Repair

Marslen-Wilson (1993, Marslen-Wilson, Moss, & van Halen, 1996) interpreted the findings obtained by Connine et al. (1993) as a reflection of a repair process. According to this view, items like **zervice* are identified as mispronunciations of *service*. **zervice* activates *service* but to a degree insufficient for word recognition. The best fitting lexical entry is determined in a second pass. The target, e.g. *tennis*, might operate as a cue to the identity of the pseudoword. The repair mechanism is a subperceptual process that does not form a new perceptual experience. Marslen-Wilson et al. (1996) suggest that the influence of the repair mechanism is more evident at long interstimulus intervals (ISI) or long reaction-times (RT > 650 ms) because

[1] Pseudowords are marked by an asterix.

processing time available for repair is increased.

Contribution of Backward Priming

Cross-modal priming that is the presentation of an auditory prime accompanied or followed by a visual target was used in all studies mentioned above. This paradigm supposedly reflects backward and forward priming effects in lexical decision (Koriat, 1981; Tabossi, 1996). Backward priming refers to the observation that an association from target to prime in absence of an association from prime to target facilitates reactions.

The most unlikely mechanism for backward priming is expectancy generation. In expectancy generation, the prime is used to generate a set of potential targets. It is unlikely, that the pseudoword primes are used to generate the appropriate targets. One has to assume that the participants recognised the word the pseudoword had been made of and then they used this word to generate the appropriate target set.

At first, spreading of activation also seems to be an unlikely candidate because it is often assumed that the prime influences target processing before the target has been presented. Activation spreads from the prime to the target. Koriat (1981; Kiger & Glass, 1983) proposed that activation also spreads back from the target to the prime. This reactivation of the prime supports target processing. This mechanism requires that the pseudoword activated a lexical entry. Otherwise, there is no entry which could be reactivated by the target. Spreading of activation is restricted to short time frames and therefore predicts a reduction in priming at longer ISIs.

Backward priming is a post-lexical relatedness-checking mechanism according to Seidenberg, Waters, Sanders and Langer (1984). Only forward priming reflects spreading of activation. Lexical decision is especially prone to backward priming processes because of its sensitivity to post-lexical processes (Balota & Lorch, 1986; Neely, 1991). Participants check whether prime and target are related. If the check confirms this, a word answer is given. Chwilla, Hagoort, and Brown (1998) suggest that backward priming reflects post-lexical integration by a fast semantic matching mechanism.[2]

Peterson and Simpson (1989) found backward priming effects also for naming, but they were reduced relative to effects in lexical decision. The introduction of an 300 ms ISI reduced backward priming effects in naming even further while lexical decision was unaffected (Peterson & Simpson, 1989). The differential sensitivity of naming and lexical decision suggests that (backward) priming effects have a different origin in these tasks. Peterson and Simpson propose that backward priming effects reflect mainly lexical retrieval processes in naming but post-lexical bias in lexical decision.

In sum, naming is less influenced by backward priming than lexical decision. If backward priming effects are operative in naming, they reflect lexical retrieval processes. It is possible that research investigating mismatch effects registered backward priming effects because lexical decision has been used. The contribution of a repair mechanism is unclear.

Experimental Issues

The research reported examines backward priming effects in cross-modal priming situations while manipulating the degree of mismatch. I was interested whether pseudowords mismatching lexical entries to different extents produce priming effects and how processes other than forward spreading of activation contribute to these effects. Similar to experiments mentioned above, degree of mismatch was manipulated in broad phonemic classes (voice, place, or manner) ignoring assumptions proposed by phonological underspecification. The contribution of backward priming or a repair mechanism was determined by manipulating the ISI of prime and target and by using lexical decision and naming as tasks. The latter manipulations make this study different from that of Connine et al. (1993).

Naming was used in Experiment 1 and 2. The target followed immediately at prime offset in Experiment 1. In Experiment 2 the ISI was 300 ms. A lexical decision task (LDT) was employed in Experiment 3. The ISI was 0 ms, 250 ms, or 750 ms.

Materials and Pre-tests

The first two experiments employed the same materials and design. A subset of these materials were used in Experiment 3. A target was combined with five different spoken primes. For instance, the visual target *tomato* was either preceded by an semantically related prime, *paprika*, a pseudoword, **baprika,* that minimally deviates from the semantically related prime, or a pseudoword, **zaprika,* that maximally deviates from the semantically related prime. An unrelated word, *library*, or a pseudoword derived from the unrelated word, **nibrary*, served as controls. Minimal deviation means that the pseudoword's first phoneme differed in voice or place from the corresponding phoneme of the base word. A maximally deviating pseudoword differed in at least two phonemic classes from the base word. There were two within-factors: Prime-Target Relatedness (related vs. unrelated) and Prime Type (word, minimal, or maximal). ISI was varied between Experiment 1 and Experiment 2. In Experiment 3, ISI was a between factor for participants but a within factor for items. The experiments required evaluation of the semantic relatedness of prime and target (see Pre-test 1) and the determination that pseudowords were unequivocally perceived as pseudowords (see Pre-test 2).

Pre-test 1 Potential targets (285 in total) were used

[2] Compound cue mechanisms of semantic priming come to similar predictions (Ratcliff & McKoon, 1988). They will not be considered here.

in a cross-modal priming experiment with a LDT. Primes were either semantically related or unrelated to the target. Targets were distributed over lists such that each target appeared only once per list. On list 1 a target *n* was preceded by its semantically related prime while target *m* was preceded by its control prime. Prime conditions of target *n* and *m* were exchanged on list 2. Pseudowords were added to have no-answers for the LDT. Targets were presented at offset of the auditory prime for 250 ms. RTs were measured from target onset for 1500 ms. All prime-target pairs, 197 in total, which attracted less than 50% errors and showed a priming effect larger than 0 ms were selected for Pre-test 2. Mean error percentage for word targets was 8.8%, 5.4% for the semantically related pairs and 12.0% for the unrelated pairs. The average priming effect was 78 ms ($t1(52) = 13.76$, $p < .001$; $t2(196) = 18.81$, $p < .001$).

Pre-test 2 The goal was to investigate whether a minimal pseudoword was unequivocally perceived as a pseudoword. In case a minimal pseudoword is missed, it is equal to its base word and priming might be amplified (Bölte, 1997). Minimal and unrelated control pseudowords were tested in an auditory LDT experiment along with 197 words serving as fillers. RT was measured as before. It was 941 ms for pseudowords and 865 ms for words. Twenty-one pseudowords attracting more than 20% errors were discarded as items for the following experiments. Further 26 pseudowords exhibiting the next highest error rates were excluded. There were 3% errors for minimal pseudowords and 2.6% errors for control pseudowords in the final item set of 75 prime-target pairs.

Experiment 1: Cross-modal Priming Naming with an ISI of 0 ms

This cross-modal priming experiment aimed at investigating the role of mismatching information on lexical activation. There were 75 word targets (see Table 1). Each word target was combined with either a semantically related word, a minimally deviating pseudoword, a maximally deviating pseudoword, an unrelated word, or an unrelated pseudoword. Unrelated pseudowords were always maximally different. Fillers were added such that each prime-target combination was counterbalanced.

On each trial, the visual target was presented in capital letters for 360 ms at prime offset. Participants (63 in total) were instructed to name the target as fast and as accurately as possible.

Table 2 summarises the results of this experiment. Two participants were excluded because of technical failures. Latencies slower than 250 ms or faster than 1500 ms were discarded from the analyses.

Data were analysed using planned comparisons in form of one-sided paired t-tests. Priming effects were evaluated by comparing RTs of the related conditions with RTs of the unrelated conditions. This comparison of RTs provides a measure of priming. Its magnitude can indicate the degree of lexical activation. Word primes facilitated naming responses by 19 ms ($t1(60) = 3.68$, $p < .001$; $t2(74) = 18.97$, $p < .001$). Minimal (11 ms, $t1(60) = 2.73$, $p = .004$; $t2(74) = 2.43$, $p = .009$) and maximal pseudowords (7 ms $t1(60) = 1.94$; $p = .03$; $t2(74) = 1.72$, $p = .04$) were also effective primes.

Table 1: Primes of the target *tomato* as a function of conditions

		minimal	maximal
prime type	word	pseudoword	
related	paprika	*baprika	*zaprika
unrelated	library	*nibrary	

Word primes were more effective than minimal (7 ms, $t1(60) = 7.27$, $p = .017$; $t2(74) = 6.91$, $p = .048$) or maximal pseudoword primes (10 ms, $t1(60) = 2.69$, $p = .005$; $t2(74) = 2.48$, $p = .008$). There was no significant difference between minimal and maximal pseudoword primes (3 ms, both $t < 1$). Thus, there is no gradation in lexical activation between minimal and maximal pseudoword as one observes with lexical decision. The overall smaller priming effect might prevent to distinguish between minimal and maximal pseudowords.

Table 2: Experiment 1. Mean RTs in ms, sd (in parentheses), and error percentages as a function of conditions.

		minimal	maximal
prime type	word	pseudoword	
related	489 (61)	496 (65)	499 (62)
	1.7%	2.6%	2.5%
unrelated	507 (69)	507 (61)	
	2.8%	2.1%	

Still, this finding replicates the one obtained by Connine et al. (1993). Minimal pseudowords and semantically related words prime naming responses. Similar to Connine et al. (1993), maximal pseudowords also show a priming effect. They are able to bring about semantic priming effects if made from rare words which was also the case in this study. The average base word frequency was 23/1 million (Celex, 1995).

There was a graded effectiveness with word primes being most effective. Minimal and maximal pseudowords were less effective than word primes. No further differentiation was possible.

Experiment 2: Cross-modal Priming Naming with an ISI of 300 ms

This experiment used the same materials, design, and task as was used in Experiment 1. The ISI was 300 ms, however. The intention was to examine the effect of the ISI on semantic priming. It was shown previously that backward priming is reduced with such ISI in naming (Peterson & Simpson, 1989). In contrast, a longer ISI provides the repair process with more time available to

repair the deviating input. If it is operative, priming should increase, or, at least, it should not decrease.

There were 53 participants. One participant with more than 15% errors was excluded from the analyses. Data treatment was the same as before. Table 3 displays RTs, sd (in parentheses) and error percentages.

Table 3: Experiment 2. Mean RTs in ms, sd (in parentheses), and error percentages as a function of conditions.

		minimal	maximal
prime type	word	pseudoword	
related	437 (63)	440 (68)	444 (66)
	3.5%	3.5%	4.4%
unrelated	448 (75)	449 (71)	
	4.7%	2.1%	

There was significant priming with word primes (11 ms, $t1(51) = 1.944$, p = .029, $t2(74) = 1.656$, $p = .051$) and with minimal pseudoword primes in *t1* (9 ms, $t1(51) = 1.744$, $p = .044$; $t2 = 1.391$, $p = .084$). There was no priming for maximal pseudoword primes (both $t < 1$). The conditions did not differ statistically from each other (word – min pw: 3 ms, $t < 1$; word – max pw: 7 ms $t1(51) = 1.519$, $p = .068$, $t2(74) = 1.162$, $p = .125$; min pw – max pw: 4 ms, both $t < 1$).

Semantic priming was reduced relative to Experiment 1 and only word and minimal pseudoword primes (in *t1*) accelerated RTs. This finding does not support the repair mechanism suggested by Marslen-Wilson et al. (1996). If such process was operative, an increase in priming should have been obtained.

The activation the target received via spreading of activation by the prime might have been reduced by "normal" decay when finally the target appeared. This resulted in the reduction of priming effects. The same argument also holds for backward priming via spreading of activation. When the target started to "reactivate" the prime, the prime's activation was already decayed.

The following lexical decision experiment served to determine the contribution of specific backward priming accounts. Backward priming processes other than spreading of activation are less affected by long ISIs in lexical decision than in naming. Spreading of activation suffers in lexical decision from the same reduction as in naming (Neily, 1991; Seidenberg, et al. 1984).

Experiment 3: Cross-modal priming with lexical decision

The rational of this experiment was to investigate the influence of the ISI on semantic priming in a cross-modal lexical decision experiment. The ISI was 0 ms, 250 ms, or 750 ms. There were no maximal pseudoword primes here because semantic priming effects are most reliably obtained with minimal pseudowords (see Connine et al., (1993) or Experiment 2).

If there is no or only minor contribution of backward priming processes other than spreading of activation, then priming should be reduced at longer ISIs. If the priming effects of pseudoword primes are due to a repair mechanism, priming should increase with longer ISIs.

The same targets and primes (words and minimal pseudowords) as before were used. In order to have no answers, pseudoword targets were added. Prime-target pairs were added such that Prime Type and Lexical Status of primes and targets were completely counterbalanced.

ISI was varied between participants. The visual target on which the participants had to perform a typical lexical decision task followed an auditory prime. Thirty-five participants were tested per ISI.

Two participants and two items were excluded because of high error rates (> 15%). See Table 4 for mean RTs, sd (in parentheses), and error percentages.

Table 4: Experiment 3. Mean RTs in ms, sd (in parentheses), and error percentages as a function of conditions.

		lexical status	
ISI	prime type	word	min pw
0	related	598 (84)	591 (70)
		3.2%	.8%
	unrelated	626 (76)	614 (77)
		4.7%	3.0%
250	related	610 (70)	605 (96)
		3.6%	4.2%
	unrelated	652 (96)	625 (88)
		4.7%	4.0%
750	related	607 (105)	614 (108)
		4.1%	1.6%
	unrelated	641 (108)	631 (108)
		6.9%	3.5%

ISI was a between factor in the participant analyses but a within factor in the item analyses. All other factors were within factors. The ANOVA yielded a significant result for the main effect Prime Type ($F1(1,100) = 83.409$, $p < .001$; $F2(1,57) = 26.598$, $p < .001$). Lexical decisions were faster for related prime-target pairs (605 ms) than for unrelated prime-target pairs (632 ms). The main effect Lexical status was also significant $F1(1,100) = 7.437$, $p = .008$; $F2(1,57) = 4.265$, $p = .043$). Word pairs (622 ms) were responded to slower than pseudoword pairs (613 ms). ISI was not significant in F1 ($F < 1$) but in F2 ($F2(2,57) = 17.267$, $p < .001$). RTs were faster when the target followed the prime (608 ms) immediately. The ISI of 250 ms or 750 ms delayed the RT by 15 ms or 16 ms, respectively. There was no significant interaction of ISI with any other factor. Only the interaction of Prime Type (related – unrelated) and Lexical Status (word – pw) ($F1(1,100) = 7.446$, $p = .008$; $F2(1,57) = 4.003$; $p = .050$) was significant. The RT obtained in the control conditions differed from each other (word: 639 ms, pw: 623 ms), while the RT in the related conditions did not differ

from each other (word: 605 ms, pw: 603 ms). The related conditions differed from the control conditions (Tukey HSD = 9.145, p = .05). Put differently, the priming effect of the pw condition (20 ms) was smaller than that of the word condition (34 ms).

There is no reduction or any increase in priming across the three ISIs. Thus, no evidence was obtained for a repair mechanism as suggested by Marslen-Wilson et al. (1996). Rather, the stable priming pattern suggests that backward priming processes other than spreading of activation affect the semantic priming effect with pseudoword primes in LDT.

Discussion

Semantic priming effects for words were obtained at all ISIs in all experiments independent of the task. They probably reflect a combination of forward spreading of activation and fast backward priming mechanism such as semantic matching (Chwilla, et al. 1998). Pseudoword primes behaved differently than word primes. They produced (1) smaller semantic priming effects than word primes, (2) they were sensitive to ISIs manipulations in naming but not in LDT.

Our results confirm the finding by Connine et al. (1993) that lexical entries are activated reflecting their degree of match with the input. Even maximal pseudowords are able to activate lexical entries if they are made from rare words. This supports the assumption that a perfect match is not required under certain conditions, e.g. low frequency (or low neighbourhood density?). The flexibility of the word recognition system towards deviations is greater than suggested in Cohort. It fits better to the assumptions formulated in Trace or Shortlist. This flexibility is astonishing because listeners often have to distinguish between minimal pairs. But the employed pseudowords are different from minimal pairs. They were "unique" by fitting best to one specific word, e.g. *paprika*, and not to several words. A word of a minimal pair also fits best to a specific lexical entry but it partly also fits to the other half of the minimal pair. This activation of two lexical entries might be sufficient to cancel out the flexibility observed for pseudowords. The better fitting lexical entry might inhibit the less well fitting one. It is also conceivable that the difference in activation is sufficient to discriminate between the two entries.

The consequences for the repair mechanism are described next. Then the priming mechanisms for naming and lexical decision are introduced and finally some adaptations for the models are outlined.

Marslen-Wilson and colleagues argued that the pseudoword prime activates a lexical entry to a low degree, but not sufficient for normal word recognition. That is, without the target *tomato* one would never recognise *paprika* given **baprika*. Supposedly, this recovery process takes time and is more evident in longer RTs (> 650 ms) or longer ISIs. ISI did not influence the size of the priming effect in lexical decision and RTs were below this "critical" barrier. Thus, it is unlikely that the repair mechanism as suggested by Marslen-Wilson et al (1996) brought about the priming effects. Especially, the assumption that this process "kicks in" later in time does not fit to the data pattern.

The priming effects observed in naming can be a combination of forward spreading of activation and backward priming. They are reduced at longer ISIs because both, forward spreading of activation and backward priming, require a close temporal vicinity of prime and target (Kiger & Glass, 1983). A target presented before prime processing is complete, guides further processing of the prime and thereby influences the final representation according to this view. Notice, that a guidance of prime processing by a target requires that a pseudoword had activated a lexical entry. The smaller temporal overlap of prime-target processing results in a reduction in priming.

Priming effects were unaffected by ISI in the LDT experiment. Priming processes other than spreading of activation influences lexical decisions. Chwilla et al. (1998) showed that semantic matching contributes to priming effects over a range of ISI (0 ms – 500 ms). De Groot (1984, 1985) also postulates a fact-acting post-lexical meaning integration process. The word recognition system searches for a meaningful relationship whenever encountering words. A meaningful relationship between prime and target results in faster lexical decisions because a meaningful relation biases the participants to respond yes in LDT. Such process possibly hinders decisions to unrelated pairs because a failure to find a relation with the prime might bias a no response. That was exactly obtained. But semantic matching can only "form" a meaningful relationship if a prime activates lexical entries. Their degree of activation depend on the amount of phonological overlap with the prime. A semantic relation does not help to name a target more quickly, however. Apparently, semantic matching influences lexical decision more than naming.

To summarise, the present experiments show that pseudowords are able to bring about semantic priming effects. The priming effects are either a consequences of spreading of activation and fast-acting post lexical integration processes. The proposed backward priming mechanism requires the activation of a lexical entry by the prime. Also, pseudowords activate lexical entries according to their degree of overlap.

The models introduced above rely on spreading of activation for explaining semantic priming effects. Post-lexical integration is not implemented in any of the models. I present three reasons for this shortcoming. First, these models were not intended to cover situations in which a meaningful relationship between two words is formed. However, humans look for meaning most of the time. Second, the models miss capabilities to explain flexible task dependent behaviour. Lexical decision and naming as tasks are treated alike by the models. Task dependent capabilities are needed for

covering the findings. Third, post-lexical processes are often understood as task dependent processes in form of a "strategic" adaptation. As such, these processes do not inform about word recognition but rather about "strategic" adaptations. This conception is adequate if the "strategic" processes are under conscious control. But semantic integration is a fast unconscious process (Chwilla et al., 1998, De Groot, 1984, 1985).

Trace, Shortlist, or Cohort describe how semantically related entries influence word recognition in a spreading of activation manner. A situation in which two semantically lexical entries are activated at the same time and form a meaningful relationship, is not taken care of. Two lexical entries are mostly treated as competitors for word recognition. But word recognition can benefit of two simultaneously activated entries, especially given an imperfect input.

Acknowledgements

Part of this research was supported by a grant, BO 1479 / 3-1, of the German research foundation (DFG, Bonn) awarded to Jens Bölte. Thanks go to Pienie Zwitserlood for her support. Heidrun Bien, Gregor Weldert, and Vanessa Mense were so kind to test the participants.

Abstract

We propose an approach that allows a rigorous understanding of the visual categorization and recognition process without asking direct questions about unobservable memory representations. Our approach builds on the selective use of information and a new method (Gosselin & Schyns, 2000, *Bubbles*) to depict and measure what this information is. We examine three face recognition tasks (identity, gender, expressive or not) and establish the information responsible for recognition performance. We compare the human use of information to ideal observers confronted to similar tasks. We finally derive a gradient of probability for the allocation of attention to the different regions of the face.

Introduction

In recent years, most face, object and scene recognition researchers have gathered around a common agenda: to understand the structure of representations in memory. A number of fundamental issues have been articulated, and researchers typically ask questions such as: "Are face, object and scene representations viewpoint-dependent? " (Hill, Schyns & Akamatsu, 1997; Perrett, Oram & Ashbridge, 1998; Troje & Bülthoff, 1996; Tarr & Pinker, 1989; Bülthoff & Edelman, 1992; Simons & Wang, 1998, among many others); "Are these representations holistic (e.g, view-based, Poggio & Edelman, 1990; Tarr & Pinker, 1991; Ullman, 1998), or made of smaller components? (e.g,, geons, Biederman, 1987; Biederman & Cooper, 1991)"; "Are internal representations complete (e.g., Cutzu & Edelman, 1996), or sparse? (Archambault, O'Donnell & Schyns, 1999; Rensink, O'Regan & Clark, 1997), "two- or three-dimensional?" (Liu, Knill & Kersten, 1995), "colored or not?" (Biederman & Ju, 1988; Oliva & Schyns, 2000; Tanaka & Presnell, 1999), "Are they hierarchically organized in memory?" (Jolicoeur, Gluck & Kosslyn, 1984; Rosch, Mervis, Gray, Johnson & Boyes-Braem, 1976), "Is there a fixed entry point into the hierarchy?" (Gosselin & Schyns, in press; Tanaka & Taylor, 1991) "Does expertise modify memory representations?" (Biederman & Shiffrar, 1987; Tanaka & Gauthier, 1998; Schyns & Rodet, 1997) and the entry point to recognition?" (Tanaka & Taylor, 1991); "What is the format of memory representations, and does it change uniformly across the levels of a hierarchy?" (Biederman & Gerhardstein, 1995; Jolicoeur, 1990; Tarr & Bülthoff, 1995).

To address these complex issues, recognition researchers should be equipped with methodologies of a commensurate power; methodologies that can assign the credit of behavioral performance (e.g., viewpoint-dependence, configural effects, color, speed of categorization, point of entry, expertise and so forth) to specific properties of the representations of visual events in memory. However, the relationship between behavior and representations is tenuous, making representational issues the most difficult to approach experimentally.

In this paper, we propose an alternative approach that allows a rigorous understanding of the recognition process, without directly asking questions about unobservable memory representations. Our analysis builds on the *selective use of diagnostic information*, an important but neglected stage of the recognition process. To recognize an object, people selectively use information from its projection on the retina. This information is not available to conscious experience, but the visual system knows what it is, and how to extract it from the visual array. Our approach interrogates the visual system to determine and to depict the information the system uses to recognize stimuli.

The aim of this paper is twofold. At an empirical level, we will use Gosselin and Schyns (2000) *Bubbles* technique to visualize the information used in three face categorization tasks (identity, gender and expressive or not). Faces are a good stimulus for our demonstrations: their compactness enables a tight control of presentation which limits the spatial extent of useful cues; the familiarity of their categorizations simplifies the experimental procedure which does not require prior learning of multiple categories--most people are "natural" face experts (Bruce, 1994). However, the principles developed with faces also apply to the more general cases of objects and scenes.

At a more theoretical level, we will reveal the information used in recognition tasks without asking questions (or even making assumptions) about memory representations. This is nonetheless a powerful approach because the information used encompasses all the visual features that mediate the recognition task at

hand. These features therefore reflect the information required from memory to recognize the stimulus; their extraction from the visual array specifies the job of low-level vision. Shortly put, the features involved in a recognition task bridge between memory and the visual array. Now, show me the features!

Experiment

This experiment was cast as a standard face categorization and recognition experiment. In a between-subjects design, a different subject group resolved one of three possible categorizations (identity, gender, expressive or not) on the same set of ten faces (5 males, 5 females), each displaying two possible expressions (neutral vs. happy). Prior to the experiment, all subjects learned the identity of the ten faces, in order to normalize exposure to the stimuli.

To determine the specific use of face information in each task, we applied Gosselin and Schyns' (2000) *Bubbles* technique. *Bubbles* samples an input space to present as stimuli sparse versions of the faces. Subjects categorize the sparse stimuli and *Bubbles* keeps track of the samples of information that lead to correct and incorrect categorization responses. From this information, we can derive the usage of each region of the input space for the categorization task at hand (see Figure 1). In a nutshell, *Bubbles* performs an exhaustive search in a specified image generation space (here, the image plane x spatial scales), using human recognition responses to determine the diagnostic information.

Methods

Participants.

Participants were forty-five paid University of Glasgow students, with normal, or corrected to normal vision. Each participant was randomly assigned to one of three possible experimental groups (IDENTITY; male vs. female, GENDER; expressive or not, EXNEX) with the constraint that the number of participants be equal in each group.

Stimuli.

All experiments reported in this paper ran on a Macintosh G4 using a program written with the Psychophysics Toolbox for Matlab (Brainard, 1997; Pelli, 1997). Stimuli were computed from the greyscale faces of Schyns and Oliva (1999) (5 males, 5 females each of whom displayed two different expressions, neutral and happy, with normalized hairstyle, global orientation and lighting).

To search for diagnostic information, we used Gosselin and Schyns' (2000) *Bubbles* technique applied to an image generation space composed of three dimensions (the standard X and Y axes of the image plane, plus a third Z axis representing 6 bands of spatial frequencies of one octave each). Figure 1 illustrates the stimulus generation process.

To compute each stimulus, we first decomposed an original face into 6 bands of spatial frequencies of one octave each—at 2.81, 5.62, 11.25, 22.5, 45 and 90 cycles per face, from coarse to fine, respectively (computations were made with the Matlab Pyramid Toolbox, Simoncelli, 1997). The coarsest band served as a constant background, as a prior study revealed that it does not contain face identification information.

The face represented at each band was then partly revealed by a mid-grey mask punctured by a number of randomly located Gaussian windows (henceforth called "bubbles"). The size of the Gaussian differed for each frequency band, to normalize to 3 the number of cycles per face that any bubble could reveal (standard deviations of bubbles were 2.15, 1.08, .54, .27, and .13 cycles/deg of visual angle, from coarse to fine scales). Since the size of the bubbles decreases from coarse to fine scales, we multiplied the number of bubbles at each scale to normalize the average area of the face revealed at each scale.

To generate an experimental stimulus, we simply added the information revealed at each scale. The total subspace revealed by the bubbles (and therefore the number of bubbles per scale) was adjusted to maintain categorization of the sparse faces at a 75% correct criterion.

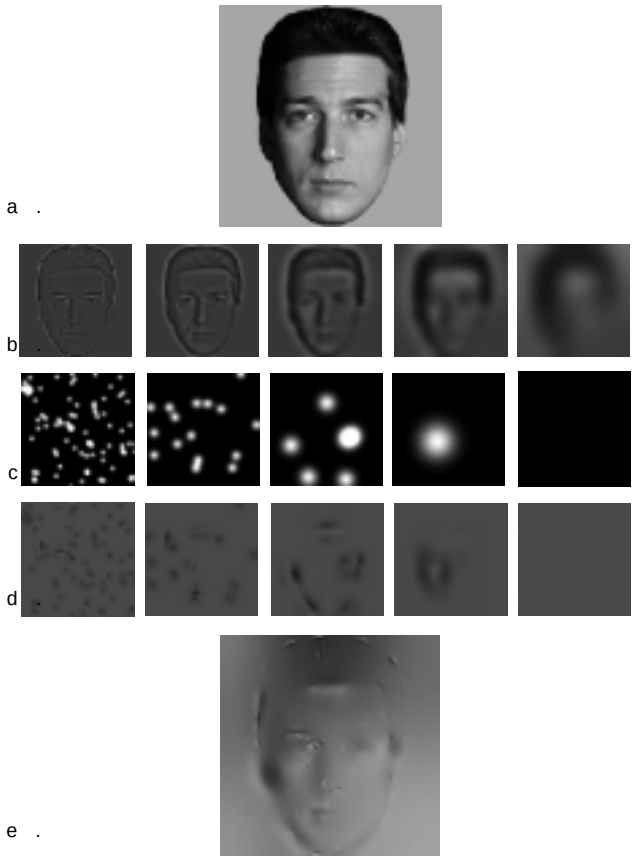

Figure 1 illustrates the application of Bubbles to the 3D space composed of a 2D face in Experiment 2. Pictures in (b) represent five different scales of (a); (c) illustrate the bubbles applied to each scale; (d) are the revealed information of (b) by the bubbles of (c). Note that on this trial there is no revealed information at the fifth scale. By integrating the pictures in (d) we obtain (e), a stimulus subjects actually saw.

Procedure

Prior to experimentation, all participants learned to criterion (perfect identification of all faces twice in a row) the gender, expression and the name attached to each face from printed pictures with corresponding name at the bottom. Each participant was then randomly assigned to one of the three different categorization tasks. In IDENTITY, participants had to determine the identity of each face stimulus. In the GENDER task, participants were instructed to decide whether the stimulus was male or female. In EXNEX, participants had to judge whether the face was expressive or not. Thus, each group performed different categorizations on the same stimulus set.

In a trial, one sparse face computed as just described appeared on the screen. To respond, participants pressed labelled computer-keyboard keys. No feedback was provided. The experiment comprised two sessions of 500 trials (25 presentations of the 20 faces), but we only used the data of the last 500 trials, when subjects were really familiar with the faces and experimental procedure. A chinrest was used to maintain subjects at a constant viewing distance (of 100 cm). Stimuli subtended 5.72 x 5.72 deg of visual angle on the screen.

Results

On average, a total of 33, 20 and 15 bubbles were needed for subjects to reach the 75% performance criterion in the identity, gender and expressive or not task, respectively. Remember that these bubbles resided at different scales of the same stimulus, and were randomly distributed within each scale. Thus, *Bubbles* performs a random search of the input space that is exhaustive after many trials.

Following Gosselin and Schyns' (2000) methodology, we used subjects responses to determine which stimulus information was, and was not diagnostic. The correct categorization of one sparse stimulus indicates that the information revealed in the bubbles was sufficient for its categorization. When this happened, we added the mask of bubbles to a CorrectPlane, for each scale—henceforth, CorrectPlane(scale), for scale = 1 to 5. We also added these masks to a TotalPlane(scale), for each scale. Across trials, TotalPlane(scale) represents the addition of all masks leading to a correct categorization *and* a miscategorization.

From CorrectPlane(scale) and TotalPlane(scale), we can compute for each subject the diagnositicity of each region of the input space with ProportionPlane(scale) = CorrectPlane(scale)/TotalPlane(scale). For each scale, the ProportionPlane(scale) is the ratio of the number of times a specific region of the input space has led to a successful categorization over the number of times this region has been presented. Across subjects, the averaged ProportionPlane(scale) weighs the importance of the regions of each scale for the categorization task at hand (Gosselin & Schyns, 2000). If all regions had equal diagnosticity, ProportionPlane(scale) would be uniformly grey. That is, the probability that any randomly chosen bubble of information led to a correct categorization of the input would be equal to the performance criterion—here, .75. By the same reasoning, whiter regions are significantly above the performance criterion, and therefore more diagnostic of these tasks.

To compute the significance of diagnostic regions, a confidence interval is built around the mean of the ProportionPlane(scale), for each proportion ($p < .01$). To depict the complex interaction between categorization tasks, spatial scales and use of information, we can visualize the *effective stimulus* of each task (see Figure 2). The effective stimulus is a concrete image of the information the visual system uses in each task. It is obtained by multiplying the face information in Figure 2 with the diagnostic masks.

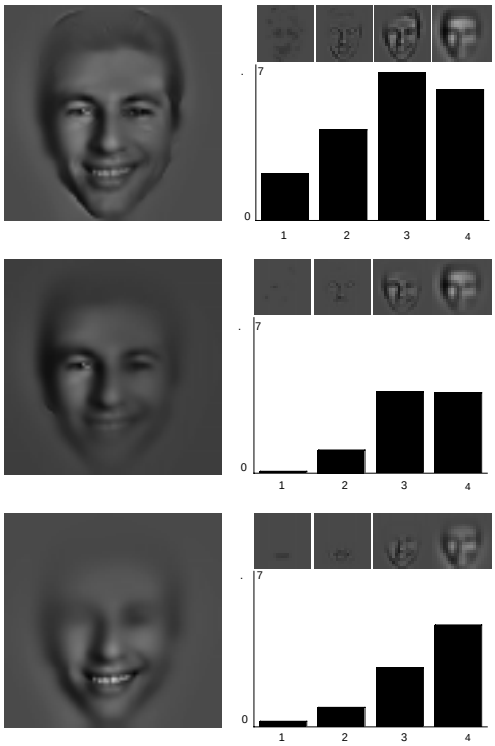

Figure 2. (a) The larger face depicts the effective face stimulus for the identity task. The smaller pictures illustrate the diagnostic information used to resolve the identity task at each independent scale from fine to coarse, respectively. The coarsest scale is not depicted as it contains no meaningful information. The bar chart provides a quantitative illustration of the proportion of the face area used to resolve the task at each scale. Figures (b) and (c) follow the same format as figure (a) illustrating the potent face for the gender task and expressive or not task respectively, the diagnostic information for each task at each scale and a quantitative account of the use of information is illustrated in the bar charts.

Discussion

Use of scale information between categorization tasks. Figure 2 presents a comparison of the relative use of scale information across tasks. From top to bottom, the large face pictures depict the information used in identity, gender and expressive or not. The figure reveals that the use of diagnostic information differs across categorization tasks, and scales. For example, whereas the mouth is well-defined at all scales in the identity and expressive tasks it is neglected at the finest scales in the gender task. In a related vein, the eyes are both represented at all scales in identity, but only one of them is well represented in gender, and both are neglected in expressive. The chin is well defined in identity, but not in expressive and gender. Compared to the mouth and the eyes, the nose is less well defined in all tasks.

To quantify the use of spatial scales across tasks, we computed the diagnostic areas revealed at each scale over the total area covered by the face in the image plane. The histograms in Figure 2 plot the use of diagnostic information across spatial scales--1 means finest, and 4 coarsest scale. The small face pictures corresponding to each scale illustrate what this face information is. The pictures reveal that the use of fine scale information (labelled 1 in the histograms, and depicted in the leftmost small picture) is most differentiated across the three tasks. In identity, it depicts the eyes, the mouth and the chin, whereas in gender it is only used for the left side eye, and the mouth in expressive. In contrast to the finest scale, the coarsest scale (i.e., the fourth scale) is much less differentiated, revealing only a holistic representation of the face features. This forms a skeleton that is progressively distinguished and fleshed out with increasing spatial resolution (see the progression of face information from coarse to fine in the small pictures of Figure 2, from right to left.) The asymmetry in extracting diagnostic information to resolve the gender task is consistent with studies showing that there is a right-hemisphere bias (the left-side of the image) in processing various facial attributes, including gender (Burt & Perrett, 1997).

Turning to the relative use of scales within each task, there is a clear advantage for the third scale in identity, corresponding to face information comprised between 11.25 and 22.5 cycles per face. This is consistent with the face recognition literature where the best scale for face recognition is between 8 and 32 cycles per face, depending on authors (see Morrison & Schyns, in press, for a review). Note, however, that our analysis is more refined because not only can we specify what the best scale is, but also where this information is located in the image plane. In contrast, the best scale for expressive or not (here, the discrimination between neutral and happy) is information comprised between 5.62 and 11.25 cycles per face (the fourth scale). This is in line with Jenkins et al. (1997) and Bayer, Scwartz & Pelli, (1998) who also found that the detection of the happy expression was most resilient to changes in viewing distances (i.e., with information corresponding to coarser scales). For gender, scales 3 and 4 were most used, and across task, there appears to be a bias for face information comprised between 5.62 and 22.5 cycles per face (the coarser scales) when information was available from the entire scale spectrum. At this stage, it is worth pointing out that the self-calibration property of Gosselin and Schyns' (2000) technique ensures that if subjects required only information from the finest scale to resolve the tasks, they would not reach the performance criterion of 75% and the average number of bubbles would increase at each scale, until they displayed enough information at the finest scale to reach criterion. In other words, the reported biases for the coarser scales do not arise from the technique, which is unbiased, but from the biases of observers who use information in categorization tasks.

Ideal Observers. In *Bubbles*, the observer determines the informative subset of a randomly, and sparsely sampled search space. To highlight this unique property, we here contrast human and ideal observers (Tjan, Braje, Legge & Kersten, 1987). The ideal observer will provide a benchmark of the information available in the stimulus set to resolve each task. We have biased the ideal to capture all the regions of the image that have highest local variance between the considered categories (identity, male vs. female, and neutral vs. expressive). This ideal considers the stimuli as images (not as faces composed of eyes, a nose and a mouth, as humans do). The ideal might not necessarily be sensitive to the regions that humans find most useful (the diagnostic regions), but to the information that is mostly available in the data set for the task at hand. We constructed a different ideal observer for the tasks of identity, gender, and expressive or not and submitted them to *Bubbles*, using the same parameters as those of our experiment with humans. Here, however, the number of bubbles remained constant (equal to the average required in each task), and we added to the face

stimuli a varying percentage of white noise to maintain categorization performance at 75% correct. In a Winner-Take-All algorithm, the ideal matched the information revealed in the bubbles with the same bubbles applied to the 32 memorized face pictures. The identity, gender or expressive or not categorization response of the ideal was the best matched picture. We then computed the ProportionPlane(scale) and DiagnosticPlane(scale), as explained earlier, to derive the effective face of each categorization task (see Figure 3). A comparison between the human and the ideal effective faces reveal only a partial correlation of use of information. This indicates that the highest variations of information in the image were not necessarily used by humans, who instead focused on the diagnostic face information. It further stresses that *Bubbles* is a human, partially efficient, not a formal, optimally efficient, feature extraction algorithm (Gosselin & Schyns, 2000).

Figure 3. The effective face stimulus of the Ideal Observer for each categorization task, identity, gender and expressive or not, respectively.

Deriving a two-dimensional map of attention. So far, we have examined the use of information across the different spatial scales of a face. We can now derive a precise measure of the diagnosticity of each image locations for the different face categorizations. Remember that the DiagnosticPlane(scale) represent a with value of 1 the presence of diagnostic information at all image locations. To measure the gradient of probability of finding diagnostic information at any image location, we simply multiply the normalized probability of using a scale with the DiagnosticPlane of this scale, and add together all the DiagnosticPlane(scale). When diagnostic information was present (vs. absent) at all scales for this image location, it has a probability of 1 (vs. 0). Figure 4 renders with a grey scale the gradient of probability (white = 1, black = 0) of finding diagnostic information at any location of the image in identity, gender, and expressive or not. If the attention is alloctated (or eye movements are guided) to the most relevant image locations in a task, the maps of Figure 4 have a predictive value. For example, Figure 2 reveals that the regions of the eyes and the mouth are diagnostic across the entire scale spectrum, and so these locations have highest probability in Figure 4. From the seminal work of Yarbus (1965), studies in eye movements have consistently demonstrated that the eyes and the mouth were mostly scanned in face identification tasks.

Figure 4. The 2D attentional maps for each categorization task, identity, gender and expressive or not, respectively.

Concluding Remarks

Our goal was to address the problem of recognition without directly asking questions about internal representations. Our analysis established how three face categorization tasks selectively used information from a three-dimensional input space (the two-dimensional image plane x spatial scales). From this selective use, we derived a gradient of probability of locating diagnostic information in the image plane. A rational categorizer should selectively allocate its attention to the regions of the image that maximize this probability thus minimizing the uncertainty of locating diagnostic information, see Figure 4.

Abstract

This study, performed on children aged 5, 8, and 10, and on adults, deals with conceptual knowledge organization using a word association task. Participants were presented with concept nouns at superordinate, basic, and subordinate level. Their productions were coded according to 4 kinds of relations: taxonomic, thematic, attributive, and evaluative relations. The following results were found at all the considered ages: a. not only lower but also superordinate level concepts elicit attributive relations; b. the production of thematic relations outnumbers that of taxonomic relations thus showing that there is no thematic to taxonomic shift. These results suggest a revision of the criteria on which cognitive economy rests in knowledge organization that will probably lead to a more complex view of the cognitive economy principle.

Introduction

Many models of conceptual organization, from the classical theory and its revised version, the binary theory, to the prototype and some connectionist models, but not the exemplar models, rest on the assumption that the cognitive economy principle underlies both the storing and the retrieval of conceptual information. Accordingly, concepts are defined by the properties and the attributes that establish their identity as well as by their relationships. It is the hierarchical organization of taxonomic relations binding them together that allows people to infer the shared properties and attributes which make the conceptual network coherent.

In this perspective, cognitive development is a progression towards the attainment of this taxonomically and hierarchically organized knowledge structure. During development children undergo a thematic - to - taxonomic shift that is responsible for their mastering their dealings with the environment. This is possible thanks to a well structured knowledge organization that rests on the hierarchical array of taxonomic relations. Thus, cognitive development involves the transition from a contextual or thematic knowledge, based on the acquisition of recurrent properties of objects and events directly experienced, to a more abstract knowledge based on the taxonomic relations responsible for the way objects and events are grouped into categories (Lucariello & Nelson, 1985; Lucariello, Kyratzis & Nelson, 1992).

It is reasonable to argue, however, that also information that is not necessarily inferred from the hierarchical levels of concept plays a relevant role in conceptual organization. It has been claimed that conceptual knowledge is situated and contextually set up (Tschacher & Scheier, 1999). In everyday life, at different times, people perceive different objects in the same spatial context. On the other hand, the same object can be perceived in different spatial contexts (Barsalou, 1993, 1999; Barsalou & Hale, 1993; Barsalou & Prinz, 1997).

In cognitive development these arguments lead to the questioning of the traditional cognitive economy principle based on the hierarchical organization of conceptual knowledge. Some authors have pointed out that the kind of task given to children biases their preference for thematic or taxonomic relations (Waxman & Kosowsky, 1990; Waxman & Namy, 1997) and that thematic relations still play a role in both older children's and adults' conceptual organization (Markman, 1989; Sell, 1992). Therefore there should be no reason to suppose that children undergo a thematic - to - taxonomic shift, i.e. that, with age, the taxonomic organization of conceptual knowledge replaces thematic knowledge (Osborne & Calhoun, 1998).

Moreover, other approaches assume that even abstract information is grounded in perception and action (Barsalou, 1999; Glenberg, 1997; Mandler, 1992; 1997; Smith, 1995; Smith & Heise, 1992). However, these views based on the role of perception and action in shaping conceptual knowledge deal with difficulty with superordinate level concepts, i.e. concepts, as 'animal', that do not refer to a particular, concrete referent.

This study is aimed at shedding some light on two points: a. does thematic knowledge concur with the taxonomic organization of concepts in shaping knowledge in children as well in adults, instead of

loosing its relevance? b. Can superordinate level concepts, not referring to concrete objects, convey perceptual information?

In order to answer these questions, the following hypotheses can be advanced:

1. Hierarchical Levels: if perceptual and action views of categorization hold, superordinate level concepts, not referring to concrete objects, should convey not only abstract but also perceptually and action grounded information. As their activation should involve the activation of their exemplars, they are also expected to elicit attributive relations (Callanan, Repp, McCarthy, & Latzke, 1994; Markman, 1985). Moreover, the relations elicited by basic and subordinate level concepts should be more similar to each other than those elicited by superordinate level concepts as both of them refer to concrete objects. Therefore their activation should elicit mainly attributive and thematic relations.

2. Conceptual Relations: assuming the perceptual and action views of categorization, the perceptually and contextually grounded thematic and attributive relations should characterize not only children's but also adults' conceptual organization. Therefore no thematic - to - taxonomic shift should occur.

These hypotheses were tested on children aged 5, 8, 10 in experiment 1, and on adults in experiment 2. Participants were given a word association task to be performed on concepts at different hierarchical levels, i.e. superordinate (e.g. animal), basic (e.g. dog), and subordinate (e.g. hunting dog) level. The conceptual relations produced by participants were classified as taxonomic, thematic, attributive, and evaluative (Chaffin, 1992; 1997).

Experiment 1

Method

Participants One-hundred and twenty middle class children, 40 aged 5, 40 aged 8 and 40 aged 10, living in Bologna and the surrounding area took part in the study.

Materials To maintain children's attention, only 9 concept-nouns were selected, 3 superordinate (e.g. furniture), 3 basic (e.g. chair), and 3 subordinate level concepts (e.g. high chair). The basic level was defined by the common shape criterion according to which basic level concepts whose members share a common shape are the most inclusive ones (Lassaline, Wisniewski, & Medin, 1992). The superordinate and the subordinate levels were defined respectively as more general and inclusive and more specific than the basic level. All the selected concepts were countable nouns.

Procedure The children were interviewed, one at a time, in their kindergarten or school. They were presented with a booklet. On each page there was a circle and at its center there was a concept-noun. They were asked to say and then to write on the circle from a minimum of 5 to a maximum of 10 associations to each concept-noun. The circle was supposed to prevent children from producing chain-like associations. The free association task, already used with success also with very young children (Nelson, 1986; Sell, 1992), was introduced to the children as if it were a game. At the end of the task, to better assess the intended meaning of the produced associations, the experimenter asked the children why they had said or written what they had said or written for each produced association and tape-recorded their answers.

Coding The data were transcribed and coded by two independent judges (2% cases of disagreement solved after brief discussion), according to 4 different kinds of relations (A) Taxonomic Relations: including superordinate, subordinate, and co-ordinate relations: e.g. bird-animal', bird-parrot', 'sparrow-parrot'. The production of taxonomic relations does not imply that children master class inclusion (Greene, 1994); (B) Thematic Relations: including spatial (physician-hospital), temporal (bird-spring), action (agent, object, and action) (bird-flies), function (chair-to sit on), and event relation when the child reported a whole story; (C) Attributive Relations: including partonomic (chair-leg), property (chair-brown), and matter relation (chair-wood); (D) Evaluative Relations: including meta-linguistic evaluations (oculist-I don't like him/her) as well as stereotyped associations (bird-airplane).

The relations that could not be included in the previous categories, 2% of the relations produced, were not analyzed.

Data analysis and results

To test the hypothesis 1, the percentage of the 4 kinds of the produced relations was computed for each age level and for each hierarchical level (see Table 1, 2, and 3). Three Correspondence Analyses were performed in order to verify whether, at each age level, the distribution of the frequencies of the 4 groups of relations varied across the hierarchical levels. In this analysis, based on the chi square test, the frequencies of the produced relations, from which a broad data matrix is derived, allow the identification of the weight of the different coded dimensions and their graphical representation. On the graph, the geometrical proximity of the points shows the degree of their association and the similarity of their distribution (Hair, Anderson, Tatham & Black, 1992; Greenacre & Blasius, 1994).

The analysis on the relations produced by 5 year olds shows that on the first dimension (explaining 85% of the total variance) superordinate level concepts, characterized by taxonomic relations, differ from subordinate relations characterized by thematic relations. On the second dimension (explaining 15% of the variance), attributive relations, that characterize basic level concepts, differ from evaluative relations.

Table 1: Five year olds. Percentage of the 4 kinds of relation at each hierarchical level.

Relation	Sup	Bas	Sub
Taxonomic	33	20	11
Thematic	48	61	69
Attributive	10	15	12
Evaluative	9	4	9

The analysis on the relations produced by 8 year olds shows that on the first dimension, which explains 97% of the total variance, superordinate level concepts, characterized by taxonomic relations, differ from both basic and subordinate level concepts characterized by thematic relations.

Table 2: Eight year olds. Percentage of the 4 kinds of relation at each hierarchical level.

Relation	Sup	Bas	Sub
Taxonomic	33	13	11
Thematic	34	53	49
Attributive	29	32	36
Evaluative	4	3	4

The analysis on the relations produced by 10 year olds shows that on the first dimension, which explains almost all the variance (99%), superordinate level concepts, characterized by taxonomic relations, differ from subordinate level concepts characterized by thematic relations.

Table 3: Ten year olds. Percentage of the 4 kinds of relation at each hierarchical level.

Relation	Sup	Bas	Sub
Taxonomic	30	15	12
Thematic	26	42	46
Attributive	32	32	32
Evaluative	12	11	9

As the percentages and the correspondence analyses suggest, at all the ages considered, the main difference between superordinate and lower level concepts does not depend on the production of attributive and evaluative relations, but on the production of taxonomic and thematic relations. Superordinate level concepts elicit more taxonomic and less thematic relations than the lower level concepts. However, it is worth noting that superordinate level concepts elicit as many attributive relations as the other hierarchical levels. This could mean that perceptual information that is involved in attributive relations is conveyed not only by lower but also by superordinate level concepts. This result brings new evidence to the perceptual and action views of conceptual knowledge organization. Superordinate level concepts elicit mainly taxonomic relations at the subordinate level, i. e. instantiations (Heit & Barsalou, 1996), (98%, 99%, and 97% in 5, 8, and 10 year olds respectively), thus showing their 'plural force' (Markman, 1985; 1989; Murphy & Wisniewski, 1989). The same is found also in basic level concepts (88%, 72%, and 76% respectively), though the percentage of instantiations decreases consistently. Subordinate level concepts, instead, elicit mostly items at the superordinate level (55%, 53%, and 52% respectively).

To test hypothesis 2 a Correspondence Analysis was performed on the 4 kinds of relation crossed with the age levels. The first dimension, explaining 76% of the variance, shows the difference between 5 year olds, who produce mostly thematic relations, and 10 year olds who produce mostly attributive relations. The far less relevant second dimension, explaining 24% of the variance, shows the difference between 8 and 10 year olds as these last produce evaluative relations (see Figure 1).

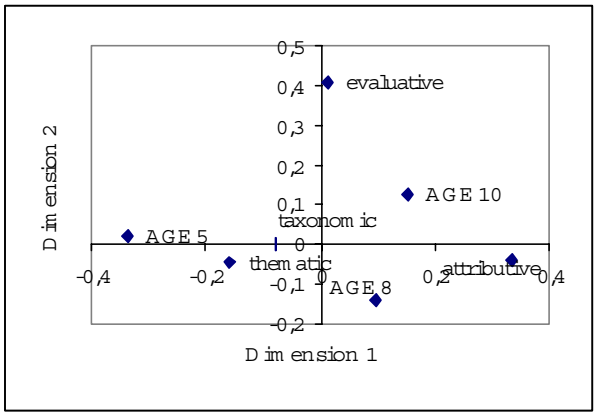

Figure 1: Correspondence Analysis on the 4 kinds of relation at each age level. Dimension 1 = 76% - Dimension 2 = 24%.

Even though the production of thematic relations decreases with age, at all the age levels the production of thematic relations outnumbers that of the other relations, while that of taxonomic relations does not consistently change (see Table 4). Thus, there seems to be no evidence of a thematic - to - taxonomic shift.

Furthermore, the production of perceptually grounded relations, i.e. attributive relations, increases consistently from 5 to 8 years.

Table 4: Percentage of the 4 kinds of relation produced at each age level.

Relation	Age 5	Age 8	Age 10
Taxonomic	23	20	19
Thematic	57	45	38
Attributive	12	32	32
Evaluative	8	4	10

This last result can be interpreted in the light of the growing analytical attitude children develop with schooling. The production of evaluative relations drops in 8 year olds and then increases again in 10 year olds.

Experiment 2

Experiment 2 was a replica of Experiment 1 but with adult participants and hence with slight variations. The aim was to test whether the trends found in Experiment 1 in 10 year old children are maintained in adults.

Method

Participants Two hundred students of the University of Bologna volunteered for their participation.

Materials Twenty-seven concepts were selected; each presented at the 3 hierarchical levels.

Procedure The procedure was the same as in Experiment 1 with minor adaptations for the adult participants. The task was not presented as a game and participants were allowed to write associations of associations. When presented with 'flower', for example, they could think of 'geranium' and had to write this word linked to 'flower'. If 'geranium' made them think of 'vase', they had to write 'vase' linked to 'geranium'. Thus, it was possible to distinguish between direct and indirect associations elicited by the given concept nouns. Participants could produce as many associations as they wanted in a maximum time of 5 minutes for each concept. Only direct associations were analyzed in this research

Coding The coding procedure and codes were the same as those used in Experiment 1. The two judges solved 8% cases of disagreement after brief discussion.

Data analysis and results

In order to test hypothesis 1, the percentages of the 4 kinds of the produced relations were computed for each hierarchical level of the concept-nouns (see Table 5). A Correspondence Analysis was performed on the frequencies of the relations produced crossed with the hierarchical levels of the concept-nouns. On the first dimension, explaining almost all the variance (98%), superordinate level concepts, that elicit taxonomic relations, differ from subordinate level concepts that elicit thematic relations.

Table 5: Adults. Percentage of the 4 kinds of relation at each hierarchical level.

Relation	Sup	Bas	Sub
Taxonomic	30	19	15
Thematic	29	37	42
Attributive	21	21	23
Evaluative	20	22	21

Both percentages and Correspondence Analysis replicate the same pattern of results as that found in children. Superordinate level concepts elicit more taxonomic relations and less thematic relations than lower level concepts. Again, attributive relations are elicited in the same proportion by superordinate level concepts as by lower level concepts.

Comparison between Experiment 1 and 2

In order to test hypothesis 2, the relations produced by children at the different age levels and by adults were compared.

As Figure 2 shows, the production of thematic relations gradually decreases between 5 and 10 years, and then it increases again. It is also worth noting that thematic relations are the most frequently produced by both children and adults. The production of taxonomic relations, instead, is more stable across the age levels than that of thematic relation. A greater variability is found in the production of attributive relations.

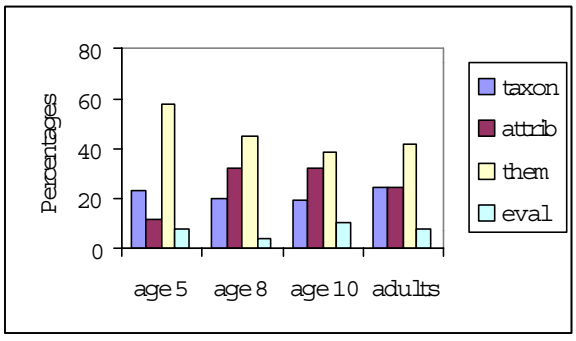

Figure 2: Percentage of the 4 kinds of relations at each age level.

A Correspondence Analysis was performed crossing the 4 groups of relations produced with the 4

different age levels (children aged 5, 8, and 10, and adults). The first dimension (explaining 67% of the total variance) shows the difference between 5 year olds, who produce thematic relations, and 10 year olds who produce attributive relations. On the second dimension (explaining 24% of the variance) both 5 and 8 year olds who produce attributive and thematic relations, differ from 10 year olds who produce taxonomic relations (see Figure 3). In this analysis adult's productions have no weight; this means that the pattern of relations they produce does not differ from that produced by children.

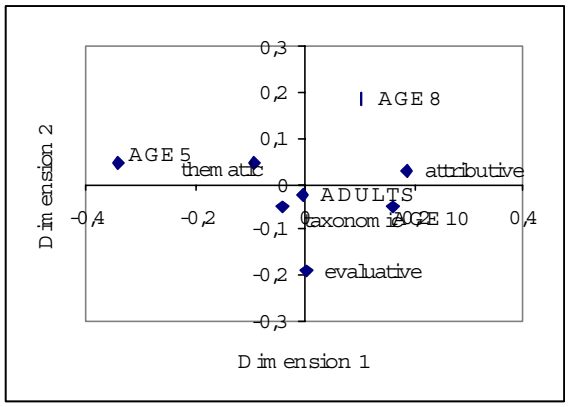

Figure 3: Correspondence Analysis on the 4 kinds of relations at each age level. Dimension 1 = 67% ; Dimension 2 = 24%

General Discussion

The results verify the two hypotheses set forth at the beginning and support perceptual and action-based views of conceptual organization. They show that:

1. At each considered age, superordinate, basic and subordinate level concepts convey attributive, i. e. perceptually grounded, information. Such finding is consistent with the view advanced by Smith & Heise (1992) and Jones & Smith (1998) that perceptual properties are relevant in distinguishing between different kinds of superordinate level concepts. For example, both textural information and the difference between biological and non-biological movement help to distinguish between very general superordinate concepts such as artifacts and natural kind concepts.

The fact that superordinate level concepts convey more taxonomic and less thematic and contextual information than lower level concepts can be a consequence of the instantiation principle (Heit & Barsalou, 1996). The activation of superordinate level concepts elicit information about their exemplars thanks to their eliciting both attributive relations and instantiations of the subordinate kind. This result is consistent with the widely acknowledged result that superordinate level concepts activate their exemplars (Callanan & al., 1994; Markman, 1985; 1989; Murphy & Wisniewski, 1989).

2. Contextual and thematic information plays a relevant part in organizing knowledge not only in children but also in adults. There is no evidence of a shift from taxonomic - to - thematic knowledge organization at least using a production task, as is the case in this study. In fact, the production of taxonomic relations does not change across the age levels. At all the ages considered, concepts convey more thematic than taxonomic information while the weight of attributive information becomes more relevant with age in shaping conceptual knowledge. This finding is supported also by recent evidence on the lack of a consistent preference for either thematic or taxonomic relations by pre-school children (Osborne & Calhoun, 1998; Waxman & Namy, 1997) and on conceptual flexibility and variability (Smith & Samuelson, 1997).

This research shows that the cognitive economy principle, resting on a hierarchical organization of taxonomic relations, is not able to handle the way conceptual knowledge is really organized (for a similar conclusion see Sloman, 1998). The cognitive economy principle has to be revised so that it can handle all the nuances knowledge inherits from our complex dealings with the environment. This does not mean that abstraction has no part in knowledge organization, it only means that even abstract knowledge originates from direct experience.

Abstract

How are we able to think about things we've never seen or touched? We demonstrate that abstract knowledge is built analogically from more experience-based knowledge. People's understanding of the abstract domain of time, for example, is so intimately dependent on the more experience-based domain of space, that when people make a an air journey or bet on a racehorse, they also unwittingly (and dramatically) change their thinking about time. Further, it appears that abstract thinking is built on representations of more experience-based domains that are functionally separable from those involved directly in sensorimotor experience itself.

How are we able to think about things we've never seen or touched? Whether we are theorizing about invisible forces, studying the behaviors of atoms, or trying to characterize the nature of private mental experience, much scientific progress depends on generating new ways of describing and conceptualizing phenomena which are not perceivable through the senses. We face the same problems in everyday life with abstract notions like time, justice, and love. How do we come to represent and reason about abstract domains despite the dearth of sensory information available about them?

One suggestion is that abstract domains are understood through analogical extensions from richer, more experience-based domains (Boroditsky, 2000; Gentner et al., in press; Gibbs, 1994; Holyoak & Thagard, 1995; Lakoff & Johnson, 1980, 1999). This experience-based structuring view can be formulated in several strengths. A very strong "embodied" formulation might be that knowledge of abstract domains is tied directly to the body such that abstract notions are understood directly through image schemas and motor schemas (Lakoff & Johnson, 1999). A milder view might be that abstract knowledge is based on representations of more experience-based domains that are functionally separable from those directly involved in sensorimotor experience.

The studies reported in this paper show that people's understanding of the abstract domain of time is substrated by their knowledge and experiences in the more concrete domain of space[1]. In fact, people's representations of time are so intimately dependent on space that when people engage in particular types of spatial thinking (e.g., embarking on a train journey, or urging on a horse in a race), they unwittingly also change how they think about time. Further (and contrary to the very strong embodied view), it appears that abstract thinking is built on *representations* of more experience-based domains, and not necessarily on the physical experience itself.

Suppose you are told that next Wednesday's meeting has been moved forward two days. What day is the meeting now that it has been rescheduled? The answer to this question depends on how you choose to think about time. If you think of yourself as moving forward through time (the ego-moving perspective), then moving a meeting "forward" is moving it further in your direction of motion—that is, from Wednesday to Friday. If, on the other hand, you think of time as coming toward you (the time-moving perspective), then moving a meeting "forward" is moving it closer to you—that is, from Wednesday to Monday (Boroditsky, 2000; McGlone & Harding, 1998; McTaggart, 1908). In a neutral context, people are equally likely to think of themselves as moving through time as they are to think of time as coming toward them, and so are equally

[1] This paper only examines one aspect of how people think about time. The domain of time comprises an incredibly complex, heterogeneous and sophisticated set of representations, and much more investigation will be necessary to properly characterize the domain as a whole.

likely to say that the meeting has been moved to Friday (the ego-moving answer) as to Monday (the time-moving answer) (Boroditsky, 2000; McGlone & Harding, 1998).

But where do these representations of time come from? Is thinking about moving through time based on our more concrete experiences of moving through space? If so – if representations of time are indeed tied to representations of space – then getting people to think about space in a particular way should also influence how they think about time.

Study 1

To investigate the relationship between spatial thinking and people's thinking about time, we asked 239 Stanford undergraduates to fill out a one-page questionnaire that contained a spatial prime followed by the ambiguous "Next Wednesday's meeting..." question described above. The spatial primes (shown in Figure 1) were designed to get people to think about themselves moving through space on an office-chair (see Figure 1a), or of making an office-chair come toward them through space (see Figure 1b). In both cases, participants were asked to imagine how they would "manuever the chair to the X," and to "draw an arrow indicating the path of motion." The left-right orientation of the diagrams was counterbalanced across subjects. Immediately after subjects completed the spatial prime, they were asked the ambiguous "Next Wednesday's meeting has been moved forward two days" question described above. We were interested in whether subjects would think differently about time right after imagining themselves as moving through space, or imagining things coming toward them.

Figure 1a: Spatial prime used in Study 1. Participants were given the following instructions "Imagine you are the person in the picture. Notice there is a chair on wheels, and a track. You are sitting in the chair. While sitting in the chair, imagine how you would manuever the chair to the **X**. Draw an arrow indicating the path of motion."

Figure 1b: Spatial prime used in Study 1. Participants were given the following instructions "Imagine you are the person in the picture. Notice there is a chair on wheels, and a track. You are holding a rope attached to the chair. With the rope, imagine how you would manuever the chair to the **X**. Draw an arrow indicating the path of motion."

As predicted, people used primed spatial information to think about time. Subjects primed to think of objects coming toward them through space, were much more likely to think of time as coming toward them (67% said Wednesday's meeting had moved to Monday), than they were to think of themselves as moving through time (only 33% said the meeting has moved to Friday). Subjects primed to think of themselves as moving through space showed the opposite pattern (only 43% said Monday, and 57% said Friday), chi-square=13.3, $p<.001$. It appears that people's thinking about time is indeed tied to their spatial thinking. This raises a further question: do people unwittingly change their thinking about time during everyday spatial experiences and activities (not just when processing specially designed spatial primes in a laboratory setting)?

Study 2: The Lunch-line

To investigate the relationship between spatial experience and people's thinking about time, we asked 70 people waiting in a lunch-line the ambiguous question about Wednesday's meeting described above. The lunch-line was for a café in the basement of Stanford's Psychology department. The line is usually about 50 meters long, but moves quickly with a waiting time of about 10 minutes. After participants answered our ambiguous question, we asked them how long they felt they had waited in line, and also recorded which quartile of the line they were in when interviewed. This second index served as an objective measure of how much forward motion in line people had experienced (with people furthest along in line having experienced the most motion). We were interested in whether the spatial experience of moving forward in a line would make people more likely to also think of themselves as moving forward in time (as opposed to thinking of time as coming toward them).

As predicted, the further along in line people were (the more forward spatial motion they had experienced), the more likely they were to also think of themselves as moving through time (to say the meeting had been moved to Friday), $r=.33$, $p<.005$ (see Figure 2). People's estimates of their waiting time were also predictive of their answers to the question about next Wednesday's meeting ($r=.26$, $p<.05$). Interestingly,

people's estimates of their waiting time were less predictive of their answer to the "Next Wednesday's meeting…" question than was their spatial position in line. When the effect of spatial position was controlled for, people's estimates of their waiting time were no longer predictive of their answers to the ambiguous question about time, r=.05, p=.67. It appears that spatial position in line (and hence the amount of forward spatial motion that a person had just experienced) was the best predictor of their thinking about time.

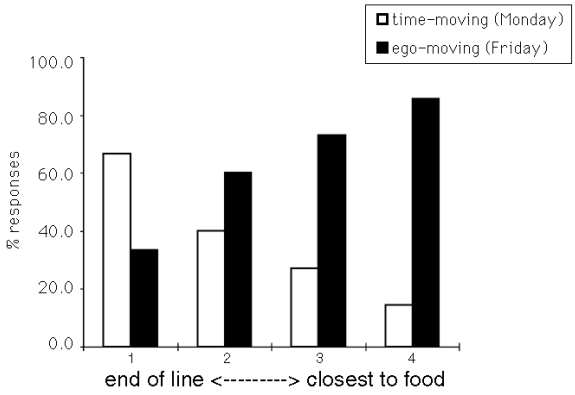

Figure 2: Responses of 70 people waiting in a lunch-line. Responses are plotted by position in line (from the end quartile of the line to the quartile closest to the food). The further along in line people were (and hence the more forward spatial motion they had experienced), the more likely they were to take the ego-moving perspective on time (say that next Wednesday's meeting has been "moved forward" to Friday).

In the next study we were interested in whether spatial motion per se was necessary, or whether simply thinking about or anticipating a journey would be enough to influence how people think about time.

Study 3: The Airport

To investigate the relationship between spatial experience and people's thinking about time, we asked 333 visitors to San Francisco International Airport the ambiguous question about Wednesday's meeting described above. After the participants answered, we asked them whether they were waiting for someone to arrive, waiting to depart, or had just flown in. We were interested in two things: (1) whether a lengthy experience of moving through space would make people more likely to take the ego-moving perspective on time (think of themselves as moving through time as opposed to thinking of time as coming toward them), and (2) whether the actual experience of motion was necessary to change one's thinking about time, or if just thinking about motion was enough.

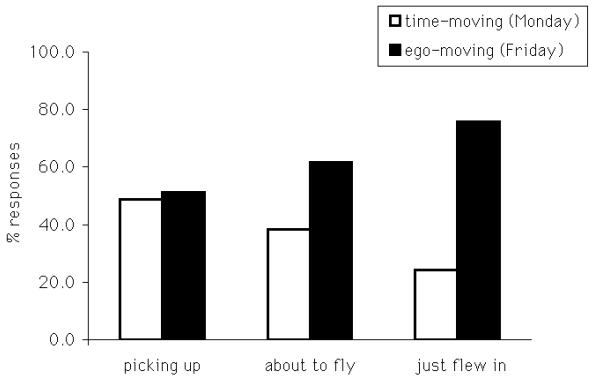

Figure 3: Responses of 333 people queried at the airport. People who had just flown in were most likely to produce an ego-moving response (say that next Wednesday's meeting has been "moved forward" to Friday).

As shown in Figure 3, people who had just flown in were much more likely to take the ego-moving perspective (think of themselves as moving through time and answer Friday) (76%) than people who were just waiting for someone to arrive (51%), χ^2=14.3, p<.01. Further, even people who hadn't yet flown, but were only waiting to depart were already more likely to think of themselves as moving through time (62%), χ^2=4.3, p<.05 (when compared to people waiting for someone to arrive). This set of findings suggests that (1) people's ideas about time are indeed intimately related to their representations of space, and (2) just thinking about spatial motion is sufficient to change one's thinking about time. But this also raises an interesting question: why were people who had just flown in more likely to take an ego-moving perspective than people who were only about to depart? Was it because they had spent more time actually moving through space, or was it just because they had had more time to think about it?

Study 4: The Train

To investigate this further, we posed the ambiguous question about Wednesday's meeting to 219 patrons of CalTrain (a train-line connecting San Francisco and San Jose). Of these, 101 were people waiting for the train, and 118 were passengers actually on the train. All of them were seated at the time that they were approached by the experimenter. After participants answered our question, we asked them about how long they had been waiting for (or been on) the train, and how much further they had to go. Participants indicated their

waiting/travel times using a multiple-choice questionnaire.

First, we found that both people waiting for the train and people actually riding on the train were more likely to take the ego-moving perspective (63%) than the time-moving perspective (37%), χ^2=13.9, p<.01. Interestingly, the data from people waiting for the train didn't look any different from those of people actually on the train (61% and 64% ego-moving response respectively), suggesting that it is not the experience of spatial motion per se, but rather thinking about spatial motion that underlies our representation of time.

We then examined people's responses based on how long they had been waiting for the train (see Figure 4). The longer people sat around thinking about their journey, the more likely they were to take the ego-moving perspective for time. People who had waited less than a minute were equally likely to think of themselves as moving through time as they were to think of time as coming toward them. People who had had five minutes of anticipating their journey, were much more likely to take the ego-moving perspective on time (68%), χ^2=4.5, p<.05 (when compared to people waiting less than a minute).

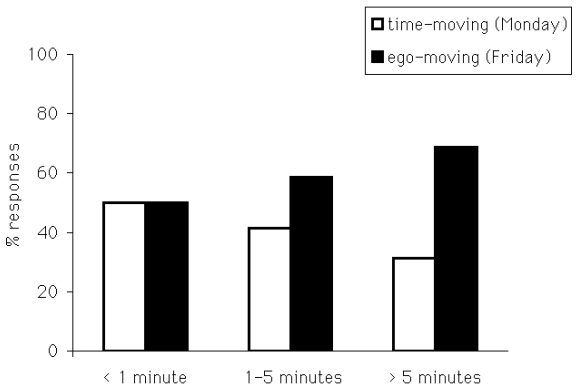

Figure 4: Responses of 101 people waiting for the train plotted by time spent waiting. The more time people had to anticipate their journey, the more likely they became to adopt the ego-moving perspective on time (say that next Wednesday's meeting has been "moved forward" to Friday).

Finally, we analyzed the responses of people on the train based on whether they had answered our ambiguous time question at the beginning, middle, or at end of their journey. We conjectured that people should be most involved in thinking about their journey when they had just boarded the train, or when they were getting close to their destination. In the middle of their journey, people tend to relax, read, talk loudly on cell-phones, and otherwise mentally disengage from being on the train.

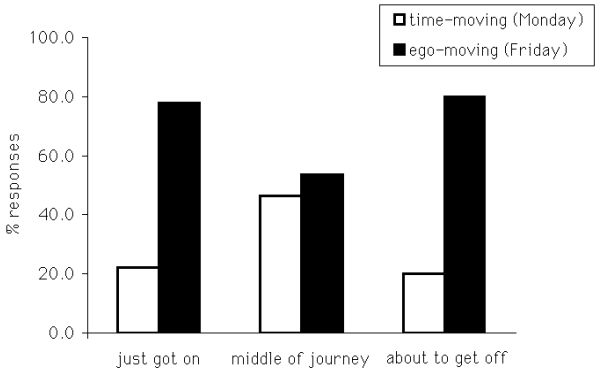

Figure 5: Responses of 118 passengers on the train plotted by point in journey. People became much more likely to adopt the ego-moving perspective for time (say that next Wednesday's meeting has been "moved forward" to Friday) when they were most engaged in thinking about their spatial journey (at the beginnings and ends of the trip). In the middle of their journey, people were about equally likely to adopt the ego-moving perspective (say the meeting has been "moved forward" to Friday) as the time-moving perspective (say the meeting has been "moved forward" to Monday).

Amazingly, people's biases for thinking about time mimicked this pattern of engaging and disengaging from spatial thinking perfectly (see Figure 5). Within five minutes of getting on the train, people were very likely to take the ego-moving perspective on time (78%), χ^2=6.38, p<.02 (when compared to people in the middle of their journey). People were also very likely to take the ego-moving perspective when they were within ten minutes of arriving at their destination (80%), χ^2=5.63, p<.02 (when compared to people in the middle of their journey). Passengers in the middle of their journey, however, showed no ego-moving bias. They were just as likely to think of themselves as moving through time (54%), as they were to think of time as coming toward them (46%). Once again it appears that people's thinking about time is substrated by thinking about spatial motion and not necessarily by the experience of motion itself. Although all three groups of passengers were having the same physical experience (all were simply sitting on the train), the two groups that were most likely to be involved in thinking about their journey showed the most change in their thinking about time.

Study 5: The Race-Track

So far, we have only looked at people who themselves were moving or planning to move. Could thinking

about spatial motion have a similar effect even when people are not planning any of their own motion? To investigate this question, we asked the "Next Wednesday's meeting…" question of 53 visitors to the Bay Meadows racetrack. We predicted that the more involved people were in the forward motion of the racehorses, the more likely they would also be to take the ego-moving perspective on time (and say that the meeting has been moved to Friday). After asking people the question about next Wednesday's meeting, we also asked them how many races they had watched that day and how many races they had bet on. Both indices turned out to be good predictors of people's answers to the "Next Wednesday's meeting…" question. As shown in Figure 6, people who hadn't bet on any races were as likely to think of themselves as moving through time (50% said Friday), as they were to think of time as coming toward them (50% said Monday). In contrast, people who had bet on 3 races or more were three times more likely to think of themselves as moving through time (76% said Friday) than they were to think of time as coming toward them (24% said Monday), %), χ^2=12.39, p<.01 (when compared to people who hadn't bet on any races). It appears that simply thinking about forward motion (willing a horse towards a finish line, as opposed to actually planning to go somewhere yourself) is enough to change people's thinking about time.

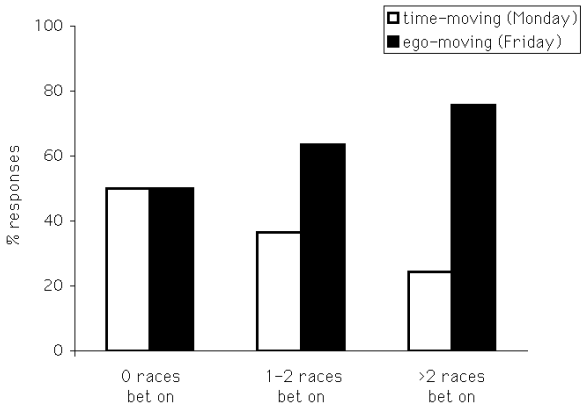

Figure 6: Responses of 53 visitors to the racetrack plotted by number of races bet on. People who had bet on more races (and so were more involved in the forward motions of the racehorses) also became much more likely to adopt the ego-moving perspective for time (say that next Wednesday's meeting has been "moved forward" to Friday).

Study 6: The Office-Chair Rodeo

Thus far we have shown that people's thinking about spatial motion is a good predictor of their thinking about time and that actual spatial motion is not necessary. A further question is whether actual motion is *sufficient* to influence people's thinking about time even in the absence of involved spatial thinking.

To try to address this question, we designed a real-motion version of Study 1 (see Figure 1). We set up a 25 ft track outside of the Stanford University Bookstore and invited students to participate in an "office-chair rodeo." Half of the participants were asked to ride an office chair from one end of the track to the other (the ego-moving prime), and half were asked to rope the chair in from the opposite end of the track (the time-moving prime) (see Figure 1 for a diagram). The track was marked out in the asphalt using colored masking tape, with one end of the track marked in red, and one in yellow. Seventy-eight Stanford undergraduates participated in the study in exchange for lollipops. The verbal instructions were the same in both conditions. Participants riding the chair sat in an office-chair at one end of the track and were asked to "maneuver the chair to the red/yellow line" (whichever was at the opposite end of the track). Participants roping the chair were given a rope that was connected to the office-chair at the opposite end of the track and were likewise instructed to "maneuver the chair to the red/yellow line" (whichever was where the participant was standing).

Immediately after the participant completed the motion task (either riding or roping the chair), they were asked the question about next Wednesday's meeting. Interestingly, performing these spatial motion tasks had no effect on subjects' thinking about time. People riding the chair (actually moving through space), were as likely to think of themselves as moving through time (55% said the meeting would be on Friday), as were people roping the chair (actually making and object move toward them) (58% said the meeting would be on Friday). It appears that just moving through space, is not sufficient to influence people's thinking about time. This finding is especially striking when compared to the findings of Study 1 where just thinking about spatial motion (in the absence of any actual motion) was enough to influence people's thinking about time (see also Boroditsky, 2000).

Discussion

Taken together these studies demonstrate the intimate relationship between abstract thinking and more experience-based forms of knowledge. People's thinking about time is closely linked to their spatial thinking.

When people engage in particular types of spatial thinking (e.g., thinking about their journey on a train, or urging on a horse in a race), they also unwittingly and dramatically change how they think about time. Further, and contrary to the very strong embodied view, it appears that this kind of abstract thinking is built on representations of more experience-based domains that are functionally separable from those directly involved in sensorimotor experience itself.

A further question is how do these relationships between abstract and concrete domains come about in the first place? Surely, some relationships come from correspondences that can be observed in experience. For example, progression in space and time are often correlated -- movements that are longer spatially are also likely to take a longer amount of time. These simple correspondences in experience can then be amplified and built on by language. People often use metaphors from more experienced-based domains to talk about more abstract domains, and often these metaphors go beyond what can be observed in experience. This means that some abstract knowledge might be constructed and shaped by language. In fact, this turns out to be the case. For example, English and Mandarin speakers use different spatial metaphors to talk about time, and this difference in language leads to important differences in the way the two groups think about time (Boroditsky, in press). It follows that to properly characterize abstract thought, it will be important to look not only at what comes from innate wiring and physical experience, but also at the ways in which languages and cultures have allowed us to go beyond these to make us smart and sophisticated as are.

Abstract

We investigate deverbal noun and verb morphology in Modern Standard Arabic (MSA), using two masked priming experiments in which the morphological, orthographic and semantic relationship between prime and targets are varied in four SOA conditions (32 ms, 48 ms, 64 ms, and 80 ms). Results show that early in the visual processing of MSA deverbal nouns and verbs, the role played by morphological structure (word patterns and roots), is significantly different from that played by orthographic and semantic factors. Additionally, while word pattern effects are transient and overlap with root morpheme effects only in the early stages of processing, effects of the root are reliably present throughout the recognition process.

Introduction

Unlike Indo-European languages where morphemic units are linearly strung one after the other to create new forms, Semitic languages like Modern Standard Arabic (MSA), or Hebrew draw on a non-linear word building principle whereby at least two abstract morphemes are interlaced one within the other (Holes, 1995, Versteegh, 1997). Reflecting this, surface word forms in such languages are traditionally analyzed into word patterns and roots. Word patterns are CV structures, primarily specifying vowels, that provide phonological structure and convey syntactic meaning, while roots consist solely of consonants and convey the broad semantic properties of the surface form (Wright, 1995). For example, the word [katama] "conceal" comprises the word pattern {fa ala}[1] with the syntactic meaning "perfective, active", and the root {ktm} meaning "concealing". Both of these units recur many times in the language in combination with other units. The word pattern {fa ala} is met in other forms like [sakaba] "pour", [daxala] "enter", [faqada] "miss". Likewise, the root {ktm} appears in such forms as [kattama] "cause to hide", [kaatama] "withhold", and [takattama] "keep mum".

Previous research on the use of word patterns and roots during the processing of Hebrew and MSA has yielded interesting, and largely consistent evidence that these units are actively used during processing (Frost, Forster & Deutsch, et al., 1997, Deutsch, Frost & Forster, 1998, Boudelaa & Marslen-Wilson, 2000). For instance, significant word pattern priming effects were found in Hebrew and MSA, although limited to verb morphology in Hebrew, but applying across syntactic class categories in MSA (Deutsch, et al., 1998, Boudelaa & Marslen-Wilson, 2000). Additionally, reliable root priming was also found in Hebrew and MSA nouns and verbs regardless of semantic transparency (Frost et al., 1997, Boudelaa & Marslen-Wilson, 2000). This research into Semitic morphology has provided some of the most compelling evidence in favour of the view that the role played by morphological structure in lexical processing and representation is distinct from form and meaning effects. Furthermore, the effects of word patterns and roots clearly show that bound and indeed disrupted morphemic units do influence processing.

Here we focus on MSA deverbal nouns and verbs and try to go beyond the research reported so far to examine how the prior presentation of a prime word affects lexical decision to a target as a function of (a) the relationship underlying prime and target, and (b) prime display duration. As regards (a), we vary morphological, orthographic and semantic relationships between primes and targets such that the respective contributions of each of these properties can be examined. With respect to (b), we use four display durations (or SOA's), of 32, 48, 64, and 80 ms, to assess the effects of priming across these dimensions of similarity. In an earlier masked priming investigation of Arabic morphology, we found reliable word pattern and root priming effects at an SOA of 48 ms. Since both morphemic units seem to be involved in the processing

[1] This is the conventional notation used to describe word patterns, where the letters "f, , l" are place holders indicating where the first, second and third root letters go when this unit is combined with a word pattern, and the vowels ("a, a" here) indicate which vowels are inserted into the surface CV template.

at such an SOA, we decided to include a shorter SOA of 32 ms, to determine whether word patterns and roots have different processing onsets. We also included the two longer SOA's (64 and 80 ms) to monitor for the life span of the priming likely to be generated by these units. It should be stressed that at SOA's of 32 ms and 48 ms, participants are not aware of the presence of a prime at all, while at 64 and 80 ms, the presence of a prime may be detectable, though never reliably enough to be reported. This means that masked priming performance is relatively insensitive to episodic and strategic confounds. Furthermore, previous research using this paradigm has shown it to be well suited to the study of morphological and orthographic effects at short SOA's (Frost et al., 1997, Forster & Azuma, 2000), and to the investigation of semantic effects at longer SOA's (Perea et al., 1995, Sereno, 1991). Accordingly, apart from minimizing strategic behavior, our choice of a small range of incremental steps in prime durations should allow us to track the dynamics of processing events as they unfold over time, and in a more fine-grained manner than earlier studies using this technique (Rastle et al., 2000, Feldman, 2000). Our hypothesis is that if morphological structure in MSA is playing a role that is genuinely distinct from that played by orthography and semantics, then this should be reflected in the differential priming effects observed in the morphological, orthographic and semantic conditions across the four SOA's. More specifically, word pattern and root effects should be able to emerge earlier than semantic effects, and should be stronger than orthography-driven effects. Additionally, since root morphemes convey semantic meaning, their effects are predicted to be more long-lived than those of the word patterns, which convey syntactic and phonological information. These predictions are tested in Experiment 1 and 2 using deverbal nouns and verbs respectively.

Experiment 1

While sharing the same stock of root morphemes with verbs, deverbal nouns draw on a specific set of word patterns which distinguishes them not only from verbs but also from the closed class of primitive nouns (Bohas and Guillaume, 1984). The purpose of this experiment is to investigate the time course of word pattern and root effects as opposed to semantic and form effects during the processing of deverbal nouns. To do this we used masked priming with four prime-display durations to assess priming between pairs of deverbal nouns which share either a word pattern, a root, or a non-structural orthographic or semantic relationship.

Method

Participants

A group of 138 volunteers aged 16 to 20 took part in the experiment. They were pupils at the high school of Tataouine in South Tunisia, and used MSA on regular basis.

Material

The prime and target pairs used fell into one of 6 conditions each of which comprised 24 pairs. In Condition 1, which we will refer to as [+WP], the prime and target share a word pattern (e.g., حارس-خالد [xaalid]-[aaris] "eternal"-guardian"). To control for the vocalic and consonantal overlap underlying the prime and target pairs in condition 1, Condition 2, [+Orth1] is an orthographic control condition matching the form overlap (primarily in shared vowels) of the word pattern pairs (e.g., سحابة-طلاق [sa aaba]-[t alaaq] "cloud"-"divorce"). In Condition 3, labeled [+R +S], the prime and target pairs share a root morpheme and a transparent semantic relationship (e.g., رئيس-رئاسة [ri aasa]-[ra iis] "presidency"-"president"). This is in contrast to Condition 4, labeled [+R –S], where the prime and target share a root but their semantic relationship is opaque (e.g., شرطة-شرط [art]-[urt a] "condition"-"police"). Con-dition 5, labeled [+Orth 2], is the orthographic control for the two conditions sharing a root (e.g., ثواب-ثابت [aabit]-[awaab] "firm"-"award"). The difference from [+Orth1] is that whereas the orthographic overlap in the latter relates to the shared vowels between prime and target, here overlap is specified solely in terms of shared consonants. Since vowels are not normally written in MSA (unless long), the form overlap in the [+Orth1] pairs is orthographically implicit, but fully explicit in the [+Orth2] pairs. Condition 6, [-R +S], consists of semantically but not morphologically related pairs (e.g., حرب-قتال [qitaal]-[arb] "fight"-"war"). Each of the related prime words was matched to an unrelated control prime. A similar number of pseudo-word-word pairs was constructed in such a way as to echo the form overlap between the word-word pairs.

Design and Procedure

Two versions were constructed such that all the targets appeared only once in each version, half

preceded by a related prime and half by an unrelated prime. Each trial consisted of three visual events. The first was a forward pattern mask, in the form of a sequence of 28 vertical lines in a 30-point traditional Arabic font size. The second event was a prime word written without diacritics in the same font but at 24 points. Four SOA's corresponding to a prime display duration of 32, 48, 64 and 80 ms were used. The third event was a target word or non-word written without diacritics in a 34 point font size. The larger font size of the target was used because MSA does not have the lower-case upper-case distinction. The stimulus words and non-words were written in the usual unvowelled script. Thirty two participants were assigned to the first SOA, forty to the second, thirty six to the third, and thirty to the fourth SOA. Participants were asked to make lexical decision about the target by pressing a "YES" or a "NO" key.

Results and discussion

Figure 1 plots the amount of priming (target RT when preceded by an unrelated prime minus target RT when preceded by a related prime) across condition and SOA.

Targets preceded by a prime with which they have a common word pattern were significantly facilitated only at SOA's 48 and 64 ms. The orthographic control for the word-pattern pairs [+Orth1] showed signs of priming at SOA 32, but no effects at any later SOA's, indicating that the word-pattern effects at SOA 48 and 64 are unlikely to be form-based. Word pattern priming in MSA deverbal nouns contrasts with the lack of word pattern priming in Hebrew nouns (Frost et al., 1997). This difference may be traced back to the differences underlying the word pairs making up the [+WP] condition in the present study and the Hebrew word pairs used in the same condition by Frost at al., (1997). In this study, as in our original study where we first report word pattern priming in Arabic nominal forms, we made a distinction between the syntactic meaning of the word pattern and its phonological structure (Boudelaa & Marslen-Wilson, 2000). Two surface forms may have a word pattern with the same surface phonological structure but with quite different syntactic meanings. For example, the pair قرود-نزول [quruud]-[nuzuul] ("monkeys"-"going down"), share the phonological structure of the word pattern, which is CVCVVC in both, but diverge with respect to its syntactic meaning. The word pattern has a "plural" meaning in [quruud], but a "singular deverbal noun" meaning in [nuzuul]. When we compared priming between deverbal nouns sharing both the syntactic meaning and the phonological structure of the word pattern with priming between nouns sharing only the phonological structure of the word pattern, it was only the former type of word pairs that yielded significant priming. The word pattern priming in the present experiment replicates our initial finding of reliable facilitation between deverbal nouns sharing the phonological as well as the syntactic meaning of the word pattern.

Turning to the two root conditions, [+R+S] and [+R-S], there was robust priming, at a constant level, across all four SOA's. In the [+Orth2] condition, where the prime and target shared a form overlap that mimicked the consonantal overlap in the root pairs, a facilitatory effect emerges at SOA 80 ms.

Similarly, significant facilitation emerges only at SOA 80 ms in the [-R+S] condition, where there is only a semantic relationship between prime and target. It is interesting to note that while the effects of morphology (here word pattern and root effects) are clearly distinct from orthographic and semantic effects at SOA's 32, 48 and 64 ms, the distinction between morphology-based and form-based and meaning-based effects dissipates at SOA 80. As can be seen in Figure 1 above, at SOA 80 the facilitation observed in the [+R +S] and the [+R-S] conditions is no longer different from that found in the [+Orth2] or the [-R+S] conditions.

A further point relates to the differences in priming between the two orthographic conditions. In [+Orth1], where the form overlap between prime and target is vowel-based, facilitation occurs only at the shortest SOA. In [+Orth2] where form overlap is consonantal in nature, significant priming takes place only at the longest SOA. These differential effects can be

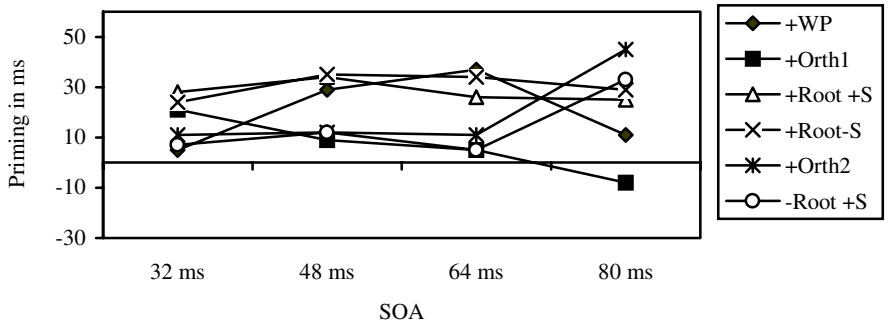

Figure (1): Priming in deverbal nouns as a function of relatedness and SOA

understood in the light of the different functional factors underlying word pattern and root priming – especially, as here, in the written modality, where consonantal information dominates the overt orthographic content of prime and target. The fact that root priming has a more precocious time course than word pattern priming suggests that the language processor monitors for the root consonants in order to access the meaning of the form at hand. Hence word pairs having a non-structural consonantal overlap may act as competitors early on in processing. Conversely, the slightly later onset of word pattern priming suggests that this unit comes into play once a root unit has been converged on. Since a root unit should be successfully extracted very quickly if meaning is to be accessed at all, word pairs sharing vocalic overlap need not compete with each other at the early stages of processing, hence the priming observed in the [+Orth1] condition.

In sum, the results of this experiment suggest that morphological effects take precedence over form driven and meaning driven effects. More importantly perhaps, from the perspective of Semitic morphology, both word pattern and root morphemes are actively used very early in processing. However, the effects of word patterns are rather transient yielding facilitation only over two SOA's, while the effects of the root are more durable (Deutsch et al., 2000). Arguably the qualitative difference underlying the effects of word patterns and roots reflects the difference between the information conveyed by these two units. Word patterns convey information that is syntactic and phonological in nature (Holes, 1995), whereas roots convey semantic information. The more consistent effects of roots by contrast to word patterns suggest that the information conveyed by the root is critically used throughout processing while that conveyed by the word pattern is only transiently salient.

Experiment 2

As we noted earlier, a primary division in Arabic morphology is between the sets of deverbal nouns and the verbs themselves. While roots are the same across deverbal nouns and verbs, word patterns are the unit that distinguishes these two syntactic categories. Accordingly, Experiment 2 was designed to ask three questions: First, will word patterns have similar transient priming effects in verbs as they do in nouns? Second, will root morphemes yield the same consistent priming effects in verbs? Third, are the effects of these two morphological units distinct from the effects produced by orthography and semantics?

Method

Participants

Another group of 108 participants from the same age group and linguistic background as those in Experiment 1 took part in this experiment.

Material and design

The design was analogous to that used in Experiment1. The material consisted of prime and target verb forms which made up 6 experimental conditions with 24 pairs each. In Condition 1, [+WP], the prime and target share a word pattern (e.g., أبلغ-أحرز [a raza]-[abla a] "obtain"-"inform"). Condition 2, [+Orth 1], was an orthographic control for the form overlap in condition 1 (e.g., أنكر-لجنة [la natun]-[ankara] "committee"-"deny"). In condition 3, [+R +S], prime and target share a root morpheme and a transparent semantic relationship (e.g., أحرق-احترق [i taraqa]-[a raqa] "get burned"-"burn"), while in condition 4, [+R –S], they share a root but have an opaque semantic relationship (e.g., تقدم-تقادم [taqaadama]-[taqaddama] "get old"-"progress"). As in Experiment 1, Condition 5, [+Orth 2], is the orthographic control for conditions 3 and 4 (e.g., بلل-بلع [bala a]-[ballala] "swallow"-"soak"). Condition 6, [-R +S], tests for purely semantic effects (e.g., تأكد -أيقن [ayqana]-[ta akkada] "ascertain"-"make sure"). Each of the related primes, across the 6 conditions, was matched as closely as possible to a control prime that shared no relationship with the target. A similar number of pseudo-word-word pairs was constructed in such a way as to echo the form overlap between the word-word pairs.

Procedure

The procedure was the same as in Experiment 1.

Results and discussion

Figure 2 shows net priming effects for the six experimental conditions across the four SOA's.

The results are even more clear cut than for the deverbal nouns. The effects of word pattern morphemes is again strong but highly transient, yielding significant priming at SOA 48 only. Its matched orthographic

control, [+Orth1] condition shows a marginal 12 ms facilitation at SOA 32 ms but no effects thereafter, suggesting that word pattern effects are genuine morphological effects that are not amenable to a form-based account. As regards roots, significant priming effects are observed across all four SOA's in both the [+R+S] and the [+R-S] conditions. Orthographic and semantic effects, as illustrated by the [+Orth2] and the [-R+S] conditions, again emerge only at SOA 80. This confirms that root morpheme effects and form-driven and meaning-driven effects have different time courses, the latter two effects taking more time to build up.

These results suggest that in MSA, morphological processing has a different locus from form-based and meaning-based processing. Moreover, verb word patterns, like deverbal noun word patterns, play a highly significant, though transient role during processing. Roots, by contrast, give rise to an evenly distributed pattern of facilitation across SOA's. The different time courses of word pattern and root processing observed in this experiment and in the previous one, suggest that the language processor uses the information conveyed by these two units in different ways and at different points in the internal process of linguistically interpreting a written form.

Conclusion

We have reported two experiments aimed at assessing the time course of morphological, orthographic and semantic effects. In so far as Semitic languages are concerned, there are at least three ways in which morphological effects can be said to be clearly distinct from orthographic and semantic effects:
First, word pattern morphemes, which are non-semantic in nature, yield significant priming, while their matched orthographic controls either do not yield any priming at all, as in Experiment 2, or do so much less reliably, as in Experiment 1. Second, root morphemes play a role irrespective of semantic transparency, with surface forms giving rise to reliable and significant priming as long as they share a morphemic unit. Third, morphological effects occur prior to orthographic and semantic effects and have a longer time-course - at least as far as the root is concerned. In the context of Semitic morphology, this is the first demonstration that word pattern and root morphemes have overlapping but different processing time courses. This state of affairs is a direct consequence of the kind of information that word patterns and roots convey. The reliable and long-lived root priming effects reflect the fact that lexical interpretation and integration of Arabic surface forms relies primarily on this unit. The transient word pattern priming effects point to the fact that this unit is the focus of the lexical mapping process only in so far as a consonantal root unit can be successfully extracted. Evidence supporting this comes from the finding that no word pattern priming is found with pseudowords consisting of existing word patterns and a non-existing root, while root priming is found in pseudo words consisting of an illegal combination of an existing word pattern and an existing root (Frost et al., 1997). Functionally, the results point to the conclusion that morphemic units that are non-linear and abstract are able to govern lexical access and lexical representation.

Turning to the orthographic effects observed in this study, it seems that in MSA, and arguably in other Semitic languages as well, vowels and consonants have a different status. This is clear from the differential priming yielded by word patterns and consonants on the one hand, and by the different loci of orthographic priming in the [+Orth1] and [+Orth2] on the other. Remember that when
orthographic overlap is defined in terms of shared vowels across primes and targets as in the [+Orth1] condition, facilitation is early and transient. By contrast, when it is defined in terms of the consonants shared by prime and target as in the [+Orth2] condition, facilitation is late and robust. Taken together, these results suggest that proximity in the Arabic lexical space is sensitive to similarity in vowels and to similarity in consonants, and that early on in processing lexical competition is initiated on the basis of the consonantal component of the surface form but not its vocalic component.

It is worth noting that in English, where the vowel-consonant distinction is not morphemic, and under experimental conditions that are most similar to ours, that is at 32 ms SOA (Feldman, 2000) and at 43 ms (Rastle et al., 2000), no orthographic effects are obtained. Nonetheless, overall orthographic effects in English tend to be facilitatory early in processing and inhibitory later on. In other words, English orthographic priming is more in keeping with the priming profile we observe in our [+Orth1] condition, and the mirror image of what we observe in our [+Orth2] condition. The emergence of relatively late form effects as evidenced by the priming in [+Orth2] at SOA 80 can perhaps be accommodated within a model where knowledge about the semantic and formal attributes of the input, be they phonological or orthographic, are at the same level in the perceptual system and are computed in parallel, rather than having the form computed prior to accessing the lexicon (Gaskell & Marslen-Wilson, 1998).

From the perspective of a general theory of morphological processing and representation, the current results put new constraints on how to account for morphological effects. For example, while connectionist models, as they now stand, may be able to account for morphological priming in the absence of synchronic semantic links between prime and target (Plaut & Gonnerman, 2000), it is less clear how word patterns, which are non-semantic units in essence, would be predicted to generate priming within such a framework. Nevertheless, it remains important to persevere with models which offer explicit and quantitative predictions about behavior.

Acknowledgement

We thank Mike Ford for his assistance in the preparation of the two experiments and Abdallah Megbli, headmaster of the High School in Tataouine, Tunisia for his generous help in providing testing facilities and access to participants for testing. We also thank Matt Davies, for helpful comments on an earlier version of this work.

Abstract

Comparison asymmetries are most often explained in terms of underlying asymmetries in the perceived similarity of the comparison items, which in turn are seen as arising from the differential weighting of distinctive features of the target and base representations. In two experiments, we fail to confirm the predictions of the standard account. Rather, comparison asymmetries seem to follow from two general principles. First, certain items act as cognitive reference points that other, less prominent category members are located in terms of or assimilated to. And second, the target and base terms of a comparison play different semantic roles, with the target acting as the figure and the base acting as the ground.

Introduction

The notion that similarity is a symmetric relation is highly intuitive. After all, if one claims that limes are similar to lemons, this would seem to entail that lemons are also similar to limes. This notion is further supported by the observation that many comparisons can be stated either directionally, as in Limes are similar to lemons, or non-directionally and reciprocally, as in Lemons and limes are similar to each other. Nevertheless, comparisons often behave asymmetrically. For example, Tversky (1977) showed that people frequently prefer one direction of comparison (e.g., North Korea is similar to China) over the other (e.g., China is similar to North Korea). Such asymmetries are even more pronounced in metaphors and similes, for which only one direction of comparison may be meaningful. For example, whereas Time is like a river is an informative statement, A river is like time is nonsensical. The general observation is that, whenever two items differ in prominence due to such factors as familiarity, salience, or concreteness, the less prominent item is compared to the more prominent item.

What is the source of these comparison asymmetries? That is, given that two items are recognized as being similar, why should one direction of comparison be more natural and meaningful than the other? Clearly, the answer to this question is important to any psychologically plausible model of comparison. Indeed, the existence of comparison asymmetries has been used to argue for and against different theories of similarity (e.g., Tversky, 1977) and metaphor comprehension (e.g., Glucksberg & Keysar, 1990; Ortony, 1979). In this paper we evaluate two different accounts of the cognitive factors underlying comparison asymmetries.

The Standard Account

Comparison asymmetries are most commonly explained in terms of Tversky's (1977) contrast model of similarity which predicts that, under certain circumstances, the similarity of item a to item b will actually seem greater than that of item b to item a. According to the contrast model, the perceived similarity of item a to item b, $s(a,b)$, is given by

$$s(a,b) = qf(A \cap B) - af(A - B) - bf(B - A)$$

where A and B are the features of a and b, f is a measure of salience, and q, a, and b are weights assigned to the feature sets. The basic idea is that the similarity of two items increases as a function of their common features and decreases as a function of their distinctive features. Asymmetries in the similarity of two items are predicted in terms of the focusing hypothesis: Because the target (first term) of a directional comparison is the subject of the statement, it will receive more attention than the base (second term). This means that the distinctive features of the target are weighted more heavily than those of the base – that is, $a > b$. Thus, the similarity of a to b will seem greater than that of b to a whenever b possesses the larger or more salient set of distinctive features.

Consistent with the contrast model, asymmetric similarity ratings have been obtained in a wide range of stimulus domains, such that less prominent items are seen as being more similar to more prominent items (e.g., Bartlett & Dowling, 1988; Holyoak & Gordon, 1983; Ortony, Vondruska, Foss, & Jones, 1985; Tversky, 1977). But how does this explain the fact that people typically prefer one direction of comparison between two items over the other? The standard answer is that, when interpreting a similarity comparison, the hearer seeks to maximize the similarity of the items. In other words, people prefer North Korea is similar to

China over the reverse direction of comparison precisely because North Korea is judged as being more similar to China than the reverse – presumably reflecting differences in the featural complexity of the two items. In support of this position, both Tversky (1977) and Ortony et al. (1985) found that items in the preferred comparison order typically received higher similarity ratings than the same items in the non-preferred order.

To summarize, the standard account of comparison asymmetries makes two claims. First, comparison asymmetries reflect underlying asymmetries in the perceived similarity of the items. And second, these underlying asymmetries are due to attentional factors, such that the distinctive features of the target are weighted more heavily than the distinctive features or spatial density of the base.

Cognitive Reference Points

Although the contrast model has been widely adopted, there is an alternative explanation of comparison asymmetries – namely, that such asymmetries follow from principles of reference point reasoning (e.g., Gleitman, Gleitman, Miller, & Ostrin, 1997; Roese, Sherman, & Hur, 1998; Rosch, 1975; Shen, 1989). One of the central claims of this position is that certain highly prominent items act as cognitive reference points that other items are seen in relation to. Some well-known examples of cognitive reference points are prototypes and ideals, which may be used to understand less prominent category members (Rosch, 1975), and the self concept, which serves as a habitual landmark in social judgments (e.g., Holyoak & Gordon, 1983; Srull & Gaelick, 1983). The basic idea is that many domains of knowledge are at least partially structured in terms of a small number of reference items.

Of course, the claim that non-reference (or deviant) items are seen in relation to reference items raises the question of what is meant by "seen in relation to." One way in which this relationship may manifest itself is conceptual location: Cognitive reference points provide landmarks that can be used to better specify the location of deviant items in a semantic or perceptual space. By doing so, reference items lend stability to the representations of deviant items. For example, it may be easier to conceptualize and reason with non-standard quantities (e.g., a length of two feet and nine inches) in terms of certain standards of measurement (e.g., a length of one yard). The beneficial use of reference items as landmarks for locating deviant items has been demonstrated in several studies of magnitude comparisons, where pairs of deviant items were discriminated with greater speed and accuracy when they were in the vicinity of a cognitive reference point (e.g., Holyoak & Mah, 1982; Hutchinson & Lockhead, 1977; te Linde & Paivio, 1979).

In addition to conceptual location, there is a second and more complex way in which deviant items may be seen in relation to cognitive reference points – namely, conceptual assimilation. The idea here is that deviant items are more easily assimilated to reference items than the reverse (e.g., Bowdle & Gentner, 1997; Rosch, 1975; Shen, 1989). Such assimilation effects have been obtained in numerous studies. For example, people are more likely to project new properties from prototypical category members to less prominent members than vice versa (Rips, 1975), and are more willing to make inferences and predictions about others based on the self than vice versa (e.g., Kunda & Nisbett, 1988; McFarland & Miller, 1990). Whenever such assimilation occurs, the representation of the deviant item is changed to make it more concordant with that of the reference item.

The above discussion of the functions of cognitive reference points suggests that, even prior to being placed in a comparison, there is a directional or asymmetric relationship between two items whenever one makes a better cognitive reference point than the other. But how does this translate into preferred comparison orders? An answer commonly given by reference point models is that the target and base terms of a comparison play different semantic roles, which specify the placement of deviant and reference items in the comparison frame.

It has been claimed that items in the subject and complement positions of many sentence types are assigned the roles of figure and ground, respectively (Gleitman et al., 1997; Langacker, 1990; Talmy, 1978). The figure is characterized as a moving or conceptually movable object whose site or path is the issue of interest. In contrast, the ground is characterized as a stationary landmark with respect to which the figure's site or path is defined. Thus, whichever item makes a more natural cognitive reference point will be the preferred ground of the sentence. In directional comparisons, this predicts that deviant items should be placed in the target position and reference items in the base position.

Perhaps the most notable distinction between the standard account of comparison asymmetries and the reference point account is that the latter does not rely on the notion of underlying asymmetries in the perceived similarity of the comparison items. That is, one does not have to judge whether item a seems more similar to item b or item b seems more similar to item a in order to determine their preferred ordering. Rather, comparison asymmetries reflect the fact that deviant items are more concordant with the semantic constrains of the target position, and reference items with the semantic constraints of the base position. Simply put, using a cognitive reference point as the base of a directional comparison results in a more natural and informative statement.

Comparing the Positions

Both the standard account and the reference point account are able to explain many of the comparison

asymmetries that have been observed in the literature, albeit using different mechanisms. In the present study, we sought to address an important limitation of existing research in this area. Specifically, the available evidence almost exclusively involves asymmetries in similarity comparisons, for which the two accounts make essentially the same predictions concerning which direction of comparison should be preferred. If one turns to consider the relationship between similarity and difference comparisons, however, then the two accounts can be shown to make distinct predictions.

According to the standard account, people prefer the direction of a similarity comparison that maximizes the perceived similarity of the target to the base. By analogy, then, people should also prefer the direction of a difference comparison that maximizes the perceived difference of the target from the base. This suggests that comparison asymmetries should go in opposite directions for similarity and difference statements, as asymmetries in similarity and difference ratings tend to be inversely related (Tversky, 1977). For example, if North Korea seems more similar to China than the reverse, then China will seem more different from North Korea than the reverse. Therefore, people should not only prefer North Korea is similar to China over China is similar to North Korea, they should also prefer China is different from North Korea over North Korea is different from China. In both cases, the preferred direction of comparison maximizes the value of the dimension specified by the comparison predicate.

In contrast to the standard account, the reference point account states that people simply prefer the direction of comparison that uses the better cognitive reference point as the ground, because this ordering maximizes the informativity of the statement. Given that the position of figure and ground in a statement should not be affected by the particular comparison predicate, the preferred direction of comparison between two items should place reference items in the base position for both similarity and difference statements. Thus, if people prefer North Korea is similar to China over the reverse, then they should also prefer North Korea is different from China over the reverse.

In addition to making different predictions about the direction of comparison asymmetries for similarity and difference statements, the standard and reference point accounts also make different predictions about the relative magnitude of such asymmetries. According to Tversky (1977), difference comparisons will tend to place more weight on the distinctive feature sets than will similarity comparisons. Because the standard account derives asymmetries from distinctive features, this means that difference comparisons should be more asymmetric than similarity comparisons. In contrast, the reference point account suggests precisely the opposite – similarity comparisons should be more asymmetric than difference comparisons. Although the use of reference items to specify the location of deviant items is presumably equally important in similarity and difference statements, conceptual assimilation of deviant items to reference items should be more likely to occur in similarity statements. As noted by a number of theorists, informative similarity comparisons do not merely point out obvious commonalities; rather, they highlight nonobvious commonalities, and promote the creation of new ones through processes such as inference projection (e.g., Bowdle & Gentner, 1997; Medin et al., 1993). While less work has been done concerning the communicative functions of difference comparisons, it is reasonable to assume that difference comparisons are less likely to invite such modes of conceptual assimilation. This is because difference comparisons serve more to suggest differences between items than to suggest commonalities. Thus, although there should be a general preference for comparing deviant items to reference items, the utility of doing so should be greater for similarity statements than for difference statements.

Experiment 1

In Experiment 1, we tested the central predictions of the standard and reference point accounts concerning comparison asymmetries. Subjects were given directional similarity or difference comparisons, each of which contained a less prominent (deviant) item and a more prominent (reference) item. All comparisons were presented in both possible orders – with the reference item in the base position (e.g., A zebra is similar to/different from a horse) or in the target position (e.g., A horse is similar to/different from a zebra). For convenience, we will refer to statements with the first ordering of items as forward comparisons, and statements with the second ordering of items as reverse comparisons. For each comparison, subjects were asked to indicate the strength of their preference for one direction of comparison over the other. Again, the standard account predicts that comparison asymmetries should go in opposite directions for similarity and difference statements, and should be stronger for difference statements. In contrast, the reference point account predicts that comparison asymmetries should go in the same direction for similarity and difference statements, and should be stronger for similarity statements.

Method

Subjects. Forty Northwestern University undergraduates participated in partial fulfillment of a course requirement.

Materials and Design. Each subject received 32 directional comparisons between a less prominent (deviant) item and a more prominent (reference) item. (The relative prominence of each item was initially determined by the authors and then confirmed by two judges.) To ensure generality, the 32 comparisons involved eight categories of items: animals (e.g., zebra – horse), artifacts (e.g., motel – hotel), colors (e.g., tan – brown), countries (e.g., North Korea – China), emotions

(e.g., admiration – love), famous individuals (e.g., Saddam Hussein – Adolf Hitler), measurements (e.g., $105.00 – $100.00), and occupations (e.g., dentist – surgeon).

Half of the subjects received all 32 comparisons as similarity statements (e.g., A zebra is similar to a horse), and half as difference statements (e.g., A zebra is different from a horse). Subjects saw each statement in both forward and reverse directions, with the two directions separated by a six-point numerical scale. The order of presentation of the two directions (forward first versus reverse first) was counterbalanced within and between subjects.

Procedure. Each subject was given a booklet containing the 32 pairs of comparison statements in a random order. Subjects indicated which direction of comparison they felt was "stronger, more sensible, or more natural" for each pair by circling a number on the six-point scale. They were told that the more strongly they preferred the direction on the left, the closer their answer should be to 1, and the more strongly they preferred the direction on the right, the closer their answer should be to 6.

Results and Discussion

All directional preference ratings were transformed so that higher numbers indicated a preference for forward comparisons over reverse comparisons. For similarity statements, the directional preference ($M = 4.77$, $SD = 0.39$) was significantly above the scale midpoint (3.5) by both subjects and items, $t_s(19) = 14.66$, $p < .001$ and $t_i(31) = 19.44$, $p < .001$. For difference statements, the directional preference ($M = 4.03$, $SD = 0.57$) was also significantly above the scale midpoint, $t_s(19) = 4.14$, $p < .001$ and $t_i(31) = 6.41$, $p < .001$. Thus, subjects consistently preferred comparing deviant items to reference items in both similarity and difference statements. This is consistent with the reference point account of comparison asymmetries: People prefer the direction of comparison that places the better cognitive reference point in the base position, regardless of the particular comparison predicate used.

Turning to the relative magnitudes of the comparison asymmetries, the preference for the forward direction of comparison was higher for similarity statements than for difference statements, $t_s(38) = 4.83$, $p < .001$ and $t_i(31) = 10.31$, $p < .001$. Again, this is as predicted by the reference point account: Because similarity statements are likely to elicit a greater degree of conceptual assimilation than difference statements, reference point effects should be stronger in similarity statements.

Asymmetries in Similarity and Difference Ratings

Contrary to the claims of the standard account, the results of Experiment 1 suggest that comparison asymmetries are not due to underlying asymmetries in the perceived similarity or difference of the comparison items. If this were the case, then – assuming that hearers seek to maximize the value of the dimension specified by the comparison predicate – comparison asymmetries should have gone in opposite directions for similarity and difference statements. But how, then, does one explain the fact that comparison asymmetries are typically associated with asymmetries in similarity and difference ratings (e.g., Ortony et al., 1985; Tversky, 1977)? We suggest that such ratings asymmetries might also be due to reference point reasoning.

According to the reference point account, the target and base terms of a directional comparison play different semantic roles, with the target acting as the figure and the base acting as the ground. Thus, information flows directionally from the base to the target, as when the base is used to generate new inferences about the target. Assuming that deviant items are more easily assimilated to reference items than the reverse, this means that assigning the reference item to the base position (forward comparisons) should result in a greater degree of conceptual assimilation than assigning it to the target position (reverse comparisons). Therefore, forward comparisons should elicit higher similarity ratings – and lower difference ratings – than reverse comparisons.

This explanation of ratings asymmetries is radically different from that offered by Tversky's (1977) contrast model. In this model, the representations of the comparison items are assumed to remain static, and asymmetries are simply due to attentional factors. On the reference point view, however, the representations of deviant items may shift towards those of reference items, thereby making the items more similar. This view is, in fact, consistent with a fair amount of evidence. Indeed, asymmetries in conceptual assimilation are often associated with asymmetries in similarity ratings. For example, people not only make more inferences and predictions about others based on the self than vice versa (e.g., Kunda & Nisbett, 1988; McFarland & Miller, 1990), they also rate others as being more similar to the self than vice versa (e.g., Catrambone, Beike, & Niedenthal, 1996; Holyoak & Gordon, 1983; Srull & Gaelick, 1983). We propose that the latter effect may be largely due to the former – projecting novel information from the self to others will make others seem more similar to the self.

In sum, the reference point account can explain asymmetries in similarity and difference judgments, and in fact predicts the same directionalities as the standard account. As was the case for comparison asymmetries, however, these approaches make different predictions about the relative magnitude of asymmetries in similarity and difference ratings. According to the standard account, difference comparisons will tend to place more weight on the comparison items' distinctive feature sets than will similarity comparisons. Because the standard account derives asymmetries from precisely these stimulus properties, this predicts that directional difference ratings should be more asymmetric than directional similarity ratings. According to the reference point account, however, this pattern of results

should not hold. This is because conceptual assimilation is more likely to occur in similarity comparisons. Assuming that conceptual assimilation is in fact a primary source of ratings asymmetries, then, directional similarity ratings should be more asymmetric than directional difference ratings.

Experiment 2

In Experiment 2, subjects were given the same directional comparisons used in Experiment 1, and rated either the similarity or the difference of both the deviant item to the reference item (e.g., How similar is a zebra to a horse?) and the reference item to the deviant item (e.g., How similar is a horse to a zebra?). Again, the standard account predicts that difference judgments should be more asymmetric, whereas the reference point account predicts that similarity judgments should be more asymmetric. We also gave a second group of subjects nondirectional versions these comparison questions (e.g., How similar are a zebra and a horse? or How similar are a horse and a zebra?). That is, these subjects were asked to rate either the similarity of or the difference between the two items without any specification of which item was the target and which was the base.

The inclusion of the nondirectional ratings condition was inspired by Catrambone et al. (1996), who argued that if the more prominent of two comparison items serves as a cognitive reference point for understanding the other item, then it should act as the implicit base of a nondirectional comparison. That is, nondirectional comparisons should be mentally translated into forward comparisons, in which the deviant item is directionally compared to the reference item. Supporting this claim, Catrambone et al. found that nondirectional similarity comparisons were rated as expressing the same degree of similarity as forward similarity comparisons, and a higher degree of similarity than reverse similarity comparisons. In the present experiment, we sought to replicate this finding for similarity comparisons, and extend it to difference comparisons. If both nondirectional similarity and difference ratings are closer to forward than reverse ratings, then this would further support the claim that asymmetries are due to reference point reasoning.

Method

Subjects. Eighty Northwestern University undergraduates served as paid subjects.

Materials and Design. Half of the subjects were assigned to the directional ratings condition, and half to the nondirectional ratings condition. In the directional condition, subjects received all 32 directional comparisons used in Experiment 1. Half of the subjects in this condition were asked to rate the similarity of the comparison items, and half the difference between the comparison items. For each comparison, subjects gave ratings for both the forward direction and the reverse direction. The order of presentation of the two directions was counterbalanced within and between subjects.

In the nondirectional ratings condition, subjects received nondirectional versions of the 32 comparison statements. As in the directional condition, half of the subjects were asked to rate the similarity of the comparison items, and half the difference between the comparison items. Because nondirectional comparisons lack target and base terms, however, subjects gave only one rating per comparison in this condition. The order of presentation of the deviant and reference items in a comparison (e.g., How similar are a zebra and a horse? versus How similar are a horse and a zebra?) was counterbalanced within and between subjects.

Procedure. Each subject was given a booklet containing the 32 comparison statements in a random order. Subjects gave similarity or difference ratings by circling a number on a 20-point scale below each comparison. For similarity ratings, the low end of the scale was labeled "not at all similar" and the high end "very similar". For difference ratings, the low end was labeled "not at all different" and the high end "very different".

Results and Discussion

Focusing first on the directional ratings, subjects gave higher similarity ratings to forward comparisons ($M = 11.02$, $SD = 2.44$) than to reverse comparisons ($M = 9.84$, $SD = 2.69$), $t_s(19) = 3.93$, $p < .001$ and $t_i(31) = 6.57$, $p < .001$. Likewise, subjects gave higher difference ratings to reverse comparisons ($M = 13.12$, $SD = 2.26$) than to forward comparisons ($M = 12.44$, $SD = 2.35$), $t_s(19) = 3.29$, $p < .005$ and $t_i(31) = 3.42$, $p < .005$. These results are consistent with both the standard account and the reference point account. More critically, however, the directional similarity ratings were more asymmetric than the directional difference ratings: The absolute mean difference in ratings between the forward and reverse comparisons was nearly twice as large for similarity comparisons ($M = 1.18$, $SD = 1.34$) as it was for difference comparisons ($M = 0.68$, $SD = 0.92$). This is only consistent with the reference point account, according to which conceptual assimilation will result in asymmetric similarity and difference ratings but is more likely to occur in similarity comparisons. However, this difference in the magnitude of the ratings asymmetries was only marginally significant by items, $t_i(31) = 1.91$, $p < .10$, and not by subjects, $t_s(38) = 1.38$, $p < .20$.

Turning now to consider the entire pattern of ratings, the nondirectional similarity ratings ($M = 11.42$, $SD = 2.71$) did not differ from forward similarity ratings, but were significantly larger than reverse similarity ratings, $t_s(38) = 2.23$, $p < .05$ and $t_i(31) = 6.41$, $p < .001$. This replicates the findings of Catrambone et al. (1996). Likewise, the nondirectional difference ratings ($M = 12.10$, $SD = 3.12$) did not differ from forward difference ratings, but were significantly smaller than reverse difference ratings by items, $t_i(31) = 4.25$, $p < .001$, but

not by subjects, $t_s(38) = 1.58, p < .20$. Thus, subjects seemed to interpret nondirectional similarity and difference comparisons as forward comparisons, in which the reference item played the implicit role of ground. This result cannot be explained by Tversky's (1977) contrast model, and further illustrates the centrality of reference point reasoning in comparisons.

Conclusions

Our findings suggest that asymmetries in similarity and difference comparisons cannot be explained in terms of the differential weighting of static representations. Rather, they seem to follow from two general principles. First, certain items act as cognitive reference points that other items are understood in terms of via conceptual location or conceptual assimilation. And second, the target and base terms of a comparison play different semantic roles – the base, acts as the ground, is used to understand the target, which acts as the figure. Thus, comparison asymmetries reflect the fact that deviant items are more concordant with the linguistic constrains of the target position, and reference items with the linguistic constraints of the base position. Directional comparisons are maximally informative when a cognitive reference point is used as the base. Further, this direction of comparison is most likely to result in higher similarity ratings – and lower difference ratings – due to the increased potential for conceptual assimilation. In sum, the comparison process would appear to be far more dynamic than is commonly assumed, with reference-point reasoning playing a prominent role in both similarity and difference.

Deference in Categorisation: Evidence for Essentialism?

Nick Braisby (N.R.Braisby@open.ac.uk)
Department of Psychology, The Open University, Walton Hall,
Milton Keynes, MK7 6AA, UK

Abstract

Many studies appear to show that categorization conforms to psychological essentialism (e.g., Gelman & Wellman, 1991). However, key implications of essentialism have not been scrutinized. These are that people's categorizations should shift as their knowledge of micro-structural properties shift, and that people should defer in their categorizations to appropriate experts. Three studies are reported. The first shows that even gross changes in genetic structure do not radically shift categorizations of living kinds. The second and third reveal a pattern of conditional deference to experts, coupled with systematic deference to non-experts. It is argued that these results point towards only a partial role for essentialism in explaining categorization, and a continuing role for theories that emphasize the importance of appearance and/or functional properties.

Introduction

Theories of concepts have shifted markedly over the past twenty years (Medin, 1989). Early theories were characterised by the view that similarity determines category membership, and that similarity-based models can account for a range of empirical evidence concerning human categorisation (e.g., Rosch, 1975; Rosch & Mervis, 1975). However, Murphy & Medin (1985), building on the earlier critiques of philosophers such as Goodman (1972), argued that similarity was a notion of weak explanatory value. Instead, they proposed that lay or common-sense theories were responsible for determining category membership.

There have since been many demonstrations of the influence of common-sense theories on category learning (e.g., Murphy, 1993; Kaplan & Murphy, 2000; Spalding & Murphy, 1996) and on categorisation itself (e.g., Keil, 1986, 1989; Rips, 1989). Nonetheless difficulties with theory-based accounts of categorisation remain. Margolis & Laurence (1999) and Fodor (1998) both point to the difficulties for theory-based views in accounting for error and ignorance.

A variant of the theory-based approach has also been proposed – psychological essentialism (Medin, 1989; Medin & Ortony, 1989). According to this, people tend to believe that objects have essences that are grounded in micro-structural properties (e.g., genetic properties for categorising organisms), and it is this belief that guides their categorisation, even though the belief may turn out to be false. This psychological essentialism differs from metaphysical essentialism (cf. Kripke, 1980; Putnam, 1975), which is the stronger doctrine that members of natural categories do in fact possess essences that determine their category membership.

Much evidence has been cited in support of psychological essentialism. Aside from earlier demonstrations from Carey (1985), Keil (1986, 1989) and Rips (1989) that similarity does not always determine categorisation, other studies have suggested that even young children are disposed to categorise objects according to presumed essences (Gelman & Medin, 1993; Gelman, 2000). Gelman & Wellman (1991) showed that 4 and 5 year old children appear to believe that an apple seed will grow into an apple tree, regardless of the environment in which this happens. Apparently children believe something inside the seed, and not contingent features of the environment, is causally responsible for the properties it later acquires.

In spite of the support essentialism has received, there have been counter claims. Malt (1994) showed that categorisation of instances of water is not fully explained by the proportion of H_2O people believe the instances contain. She argued for the importance of function instead. Braisby, Franks & Hampton (1996) showed that categorisation is at odds with predictions suggested by Putnam and Kripke's articulation of essentialism. Instead they argued categorisation was perspectival or context-sensitive. Kalish (1995) showed fuzziness in category boundaries that he argued was incompatible with essentialism. Yet, in a rejoinder, Diesendruck & Gelman (1999) have argued that findings such as these are compatible with essentialism.

This paper aims to add empirical evidence concerning psychological essentialism by examining an important implication of the essentialist view that has remained largely unexplored. Putnam (1975) developed a corollary of his essentialist view that he labelled the Division of Linguistic Labour. While being developed around word meaning, these arguments have nonetheless been taken to apply to concepts (e.g., Fodor, 1998). So interpreted they have the following implications. If categorisation is determined by micro-structural properties such as genetic, chemical or biological properties, then scientists who are expert in the appropriate domain are likely to have more information than lay-people on which to base their categorisations. If lay people are essentialist, they

should rationally defer to people with more knowledge of the relevant properties. For instance, if a metallurgist pronounces a gold watch to be "not gold," other things being equal, essentialism requires our categorizations to change accordingly. Deference arises from this division of linguistic labour – scientists are deemed to labour to uncover essential properties, while lay-people 'piggy-back' on their expertise. Putnam suggests there is a social dimension to concepts and categorization, one in which categorization by non-experts is intimately tied to, and parasitic on, categorization by experts.

There have been a number of recent theoretical examinations of deference (e.g., Fodor, 1998; though see Segal, 2000, for a different position), and different accounts proposed. Yet there has been no empirical evidence cited in support of these accounts. Similarly, studies have examined expertise in relation to categorization (e.g., Medin, Lynch, Coley & Atran, 1997), but have not been designed to tap the claims of essentialism. This paper seeks to establish, first, whether deference occurs and, second, parameters which govern that deference and, in so doing, offer a further evaluation of psychological essentialism.

The studies all examine the way in which genetically modified organisms are categorised. This is for two reasons. First, many prior examinations of essentialism have employed counterfactual scenarios involving fantastical transformations and/or discoveries of an object's properties. These scenarios may be hard to understand and use unfamiliar transformations. Second, few studies have examined how categorization changes as a function of changes in the information people possess about properties thought to be essential, such as genetic properties. Focusing on genetic modification allows the use of transformations of which people are likely to be aware, and allows a careful examination of the dependence of categorisation on genetic properties. It also allows the identification of groups thought to be expert and inexpert.

The first study examines the extent to which putative modifications in the genetic structure of organisms lead to changes in the way those organisms are categorized. Studies 2 and 3 examine the extent to which lay-people defer in categorisation. Study 2 examines deference to expert groups, predicted by essentialism, and study 3 functions as a control, examining deference to non-expert groups that is not predicted by essentialism.

Study 1

This study considers the way in which the categorisation of natural (living) kinds depends upon knowledge of the kind's genetic properties.

Design

Participants were randomly assigned to one of three conditions that varied according to the extent and nature of the modification – a Purification/Genetic Modification condition; a Same Super-ordinate category genetic modification condition; and an Other Super-ordinate category genetic modification condition.

Method

Participants 68 undergraduate psychology students attending an Open University residential school volunteered to participate.

Materials Four natural (living) kinds were chosen: apple, potato, salmon, chicken. These were chosen also to be food-stuffs so that they, and the prospect of their genetic modification, would be relatively familiar to the participants. Within these constraints, the kinds were also chosen to be as typical as possible of their immediate super-ordinate categories (i.e., fruit, vegetable, fish, bird).

Procedure Participants were presented with 8 scenarios, involving 2 different kinds of transformation for each natural kind category. In the Purification/Genetic Modification condition, half the scenarios referred to purification, half to genetic modification. In the Same Super-ordinate condition, transformations involved either 50% or approx. 100% of genetic material being taken from a member of the same super-ordinate category (e.g., for salmon, genetic material would come from other fish). In the Other Super-ordinate condition, transformations involved either 50% or approx. 100% of genetic material being taken from a category outside the super-ordinate (e.g., for salmon, from animals that are not fish).

The scenarios adopted the following form where X refers to one of the four kinds and Y refers to the relevant super-ordinate: "You have just bought an X from a reputable retailer. However, on examining its packaging closely, you discover that the X has been (genetically modified/purified, so as to remove many of the impurities often found in X/genetically modified, with around half of its genetic material coming from other Y/genetically modified, with nearly all of its genetic material coming from other Y/ genetically modified, with around half of its genetic material coming from [animals/plants] that are not Y/genetically modified, with nearly all of its genetic material coming from [animals/plants] that are not Y). In all other respects though the object looks, feels, smells and tastes just like an X." On reading each scenario, participants were asked to answer six questions, including a categorization question (Is the object that you have bought an X?).

Since the opening sentence of the scenarios refers to the object as a member of the category in question, this

procedure may lead to an underestimate of the impact of the transformations. However, this potential bias is difficult to avoid since failing to refer to the object as a member of a category would pragmatically imply that the object was thought not to be a member of the category, thus generating a potential opposing bias.

Results

Responses to the categorization question were analysed by a series of log-linear analyses (analysis of the other questions will not be reported). Different analyses were conducted for the three main conditions. The over-all results are shown in table 1.

Table 1. Percentage of Yes responses by condition

Transformation	% Yes responses
Purification	98.0
Modification	96.0
50% same super-ordinate	57.0
100% same super-ordinate	44.0
50% other super-ordinate	52.5
100% other super-ordinate	47.5

Purification/Genetic Modification Surprisingly, there was no effect of type of modification (i.e., purification vs. genetic modification), with 96.7% of all responses being Yes (i.e., responses that the purified or genetically modified object is a member of the kind).

Same Super-ordinate and Other Super-ordinate These conditions were combined for analysis. Categorisation depended upon the extent of the modification (i.e., 50% vs. approx. 100% genetic material being modified): when 50% of genetic material was modified, 55.0% of responses were Yes, which fell to 41.7% when approx. 100% of the material was modified (partial chi-square(1) = 12.45, $p < 0.001$). There was a marginal effect of the type of genetic material introduced: when material came from the same super-ordinate, 50.5% of responses were Yes, which fell to 45.6% when material came from another super-ordinate (partial chi-square(1) = 3.50, $p = 0.06$).

Discussion of Study 1

These results support the view that changes in genetic structure introduce changes in the way people categorize living kinds. While this is consistent with essentialism, what is striking about these results is how little categorization changes in the face of gross changes in genetic structure. Living kinds that have simply been 'genetically modified' are regarded almost universally as remaining members of the kind. Even when nearly all of a salmon's genetic material is said to come from animals that are not fish, approximately half of all responses still treat the object as a salmon. Given that humans and chimpanzees share approximately 98% of their DNA, the resistance of categorization to the influence of genetic modification is remarkable.

One explanation that is compatible with essentialism is that people's knowledge of genetic properties is so poor that the scenarios used here merely render them uncertain in their categorization. They may be unsure, for instance, whether genetic properties are likely to be essential or not. Indeed, a pattern of around 50% Yes and 50% no responses is suggestive of uncertainty. Another explanation, however, is that people are not only weighing the genetic properties of the objects, but also their appearance and functional properties and that, in these scenarios, they outweigh the genetic influence. Contra essentialism, this suggests that categorization is determined in part by non-micro-structural properties.

The patterns of approx. 50% Yes responses also imply that these scenarios are ideal for investigating Putnam's division of linguistic labour, since uncertainty is likely to increase the influence of expert opinion. This is the focus for studies 2 and 3.

Study 2

This study considers the way in which people's categorizations depend on those of expert scientists.

Design

Participants were randomly assigned to one of three conditions, selected from Study 1: a Genetic Modification condition; a 50% Same Super-ordinate condition; and a 50% Other Super-ordinate condition.

Method

Participants 90 undergraduate psychology students attending an Open University residential school volunteered to participate.

Materials The same materials as in Study 1 were used.

Procedure A similar procedure to Study 1 was used. However, information concerning how an expert group categorized each object was incorporated immediately after the description of the modification. In the genetic modification condition, the scenario read as follows: "You have just bought an X from a reputable retailer. However, on examining its packaging closely, you discover that the X has been genetically modified. According to most biologists the object (is/is not) an X. In all other respects though the object looks, feels, smells and tastes just like an X." Each of the 4 natural kinds was presented twice, once with an affirmative and once with a negative expert categorization judgement, yielding 8 scenarios. Participants were asked the same questions as in Study 1.

Results

Log-linear analyses were conducted for the three main conditions. Over-all results are shown in figure 1.

Genetic Modification Categorization varied according to how the biologists had judged the same categorizations: 87.5% of responses were Yes when the biologists had said Yes; 75.6% of responses were No when the biologists said No (partial chi-square(1) = 131.66, $p < 0.001$). Participants deferred more when the biologists said Yes than when the biologists said No (partial chi-square(1) = 6.57, $p < 0.05$).

50% Same Super-ordinate This condition yielded similar findings: 85.8% of categorization responses were Yes when the biologists had said Yes and 76.7% of responses were No when the biologists said No (partial chi-square(1) = 125.93, $p < 0.001$). Participants again deferred more when the biologists said Yes (partial chi-square(1) = 3.86, $p < 0.05$).

50% Other Super-ordinate Similar findings emerged: 62.9% of responses were Yes when the biologists had said Yes and 72.7% of responses were No when the biologists said No (partial chi-square(1) = 32.94, $p < 0.001$). This time, however, participants deferred more when the biologists said No than when the biologists said Yes (partial chi-square(1) = 3.32, $p < 0.05$).

Further analysis showed the number of Yes responses differed across these two latter conditions (partial chi-square(1) = 6.85, $p < 0.01$). Also, the dependence of categorization on the Biologists' prior categorization differed across these two conditions (partial chi-square(1) = 7.58, $p < 0.01$). These results are discussed in conjunction with those of Study 3.

Study 3

This study considers the way in which people's categorizations depend on those of non-experts.

Design

Participants were assigned to conditions as in Study 2.

Method

Participants 62 psychology students attending an Open University residential school volunteered to participate.

Materials The same materials as in Study 1 were used.

Procedure A similar procedure to Study 2 except that information concerning an expert group's categorization was replaced by information about a non-expert group's categorization. The word "biologists" was replaced with the word "shoppers" to produce the scenarios. Again, each natural kind was presented twice, once with an affirmative and once with a negative non-expert judgement. Participants were asked the same questions as in Studies 1 and 2.

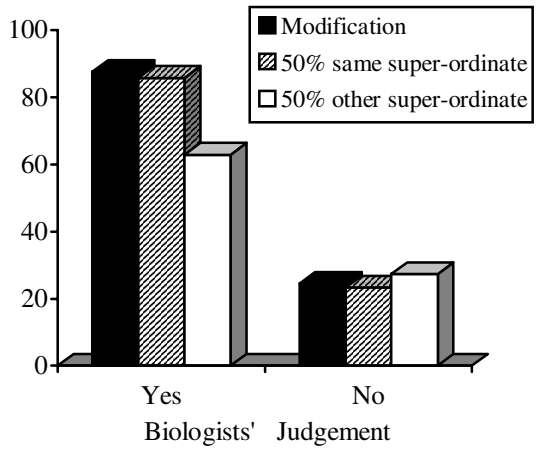

Figure 1. Percentage Yes responses by transformation type and the biologists' judgements

Results

Similar analyses to study 2 were conducted. Over-all results are shown in figure 2.

Genetic Modification Categorization varied according to how the shoppers had judged the same categorizations: 86.4.% of responses were Yes when the shoppers had said Yes; 36.4% of responses were No when the shoppers said No (partial chi-square(1) = 18.92, $p < 0.001$). Participants deferred more when the shoppers said Yes than when the shoppers said No (partial chi-square(1) = 53.24, $p < 0.001$).

50% Same Super-ordinate This condition yielded similar results: 71.3% of responses were Yes when the shoppers said Yes; 55.0% of responses were No when the shoppers said No (partial chi-square(1) = 19.02, $p < 0.001$). Deference was greater when the shoppers said Yes (partial chi-square(1) = 4.81, $p < 0.05$).

50% Other Super-ordinate Rather different results emerged: 44.3% of responses were Yes when the shoppers said Yes; 68.8% of responses were No when the shoppers said No (partial chi-square(1) = 4.16, $p < 0.05$). This deference was greater when the shoppers said No (partial chi-square(1) = 10.30, $p < 0.01$).

Further analysis showed that the number of Yes responses varied across these two latter conditions (partial chi-square(1) = 15.81, $p < 0.001$). Also, the dependence of categorization on the Shoppers' categorization varied marginally by these two conditions (partial chi-square(1) = 3.66, $p = 0.06$).

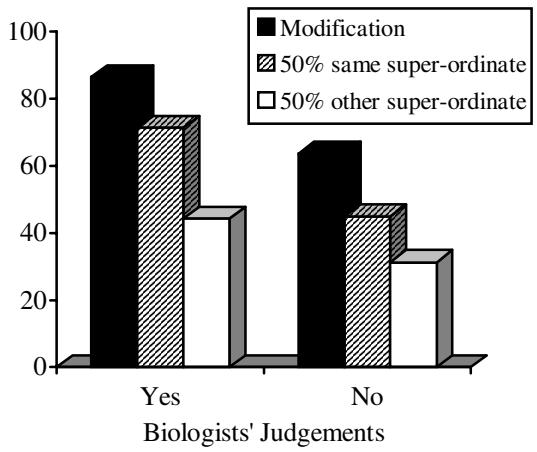

Figure 2. Percentage Yes responses by transformation type and by the shoppers' judgements

Discussion of Studies 2 and 3

Studies 2 and 3 show a complex pattern of responding. In study 2, most responses made by participants conform to those of the expert group (biologists). Superficially at least, this appears to show support for essentialism, and Putnam's division of linguistic labour. Nonetheless, study 2 also shows other influences on categorization, ones that are not so easily explained by an essentialist account. Firstly, there is a substantial minority of responses that are in opposition to those of the biologists. For the 50% Other Super-ordinate condition, there is greater opposition when the biologists' judge the organism to be a member of the kind. For the 50% Same Super-ordinate condition, there is greater opposition when the biologists' judge the organism not to be a member of the kind. While it would be difficult to argue these completely undermine the apparent support for essentialism that the majority of responses show, they do raise the question as to why participants are choosing to categorise in opposition to the experts, and so presumably in opposition to the micro-structural properties. They also raise the question as to how much deference essentialism predicts.

The findings of study 2 suggest that while people do defer to experts, they do so less when the experts' judgements are contrary to their own – the deference is conditional. The question then arises as to what is influencing people's categorization so strongly that they will disregard the opinions of experts to whom they will defer in other circumstances. One possibility is that these findings point towards a continuing role for appearance and functional properties in categorizing natural kinds.

Participants in all of the studies were given the opportunity to offer written comments, and some of these support the importance of appearance and functional properties. One participant wrote: "If biologists said it was a fruit, that's OK. If biologists said it was not a fruit, that's not OK." This comment bolsters the view that the pattern of deference that is revealed is conditional. Another participant wrote "The apple we eat is not defined by biologists but by how it looks and tastes to non-experts" thus revealing a strongly non-deferential position.

These suggestions from study 2 are supported by study 3. Since shoppers generally are not expert with regard to the genetic properties of organisms, there is no essentialist basis for people to defer to this group. Nonetheless, this study revealed deference, albeit to a much smaller degree than in study 2. It also revealed similar systematic variation in deference. For the 50% Same Super-ordinate condition, people showed greater conformity when the shoppers judged the organism to be a member of the kind. For the 50% Other Super-ordinate condition, there was greater conformity with the shoppers' judgement when the shoppers judged the organism not to be a member of the kind. Again, it may be that people are more willing to 'defer' when the shoppers' judgement conforms to their own.

General Discussion

Overall, it seems as if deference to expert groups occurs, and more so than to non-expert groups. However, the extent of the deference depends upon how the organism has been transformed, and on what categorization judgement the expert group gives. This then is a pattern of partial or conditional deference.

Deference to non-expert groups also occurs and this raises questions concerning the basis on which people may defer in categorization. If people defer to others, such as shoppers, who do not possess expertise with regard to the relevant micro-structural properties, then we may also question why people defer to experts. Could it be that people defer to experts not because of their presumed greater knowledge of micro-structural properties?

The systematic influences on deference, coupled with the striking resistance of categorization to gross changes in genetic properties, suggest that categorization is influenced both by micro-structural properties and by appearance and functional properties.

This may be explicable on a perspectival view of concepts, according to which concepts have multiple contents that shift systematically according to perspective and context (Braisby, 1998). On such a view, concepts might reflect essential, micro-structural properties from some perspectives, but appearance and/or functional properties from others. These findings would then reveal a conflict for people seeking to categorize natural kinds: between deferring to experts on the micro-structural properties on the one hand, while being influenced by appearance and functional properties on the other. If this is right, then the findings

reported here suggest that essentialism can provide only a partial explanation of concepts and categorization.

Nonetheless, these studies represent just the first step in a wider programme of much needed research, one that raises many difficult questions. These studies have used objects whose appearance and functional properties are stipulated to be fixed, and whose micro-structural properties are manipulated. What would happen under the reverse conditions? Essentialism would predict little impact of changes in appearance and function relative to micro-structural properties. How should deference be operationalised? It has been operationalised in these studies as a switch in categorization due to the categorizations of others. But are there other, better ways of operationalising it? Finally, how are we to make sense of the interplay between categorization and social influences? Finally, what is the relation between deference and conformity or compliance? These studies suggest a fruitful interaction between social psychological work on these issues and the cognitive psychology of categorization.

Abstract

The study of language, meaning and communication in the cognitive sciences has undergone a kind of conceptual inflation in the past twenty years or so. Not only has the very nature of human communication come to be seen as, in many respects, Gricean, but also linguistic meaning itself has come to be widely regarded in terms of the effect of language use on mental states. As a result, a more or less explicit assumption about the conceptual abilities of agents who have linguistic and communicative competence has been adopted in a variety of disciplines ranging from language acquisition to formal semantic theories: that these agents have the ability to represent and make inferences about the mental states of others. The purpose of this paper will be to offer considerations in support of the contrary, more minimalist view that neither meaning nor communication involve the representation of mental states essentially. Correspondingly, agents who are competent with regards language use and communication need not possess meta-cognitive abilities.

Introduction

The study of language, meaning and communication in the cognitive sciences has undergone a kind of conceptual inflation in the past twenty years or so. Not only has the very nature of human communication come to be seen as, in many respects, Gricean, but also linguistic meaning itself has come to be widely regarded in terms of the effect of language use on mental states. As a result, a more or less explicit assumption about the conceptual abilities of agents who have linguistic and communicative competence has been adopted in a variety of disciplines ranging from language acquisition to formal semantic theories: that these agents have the ability to represent and make inferences about the mental states of others. The purpose of this paper will be to offer considerations in support of the contrary, more minimalist view that neither meaning nor communication involve the representation of mental states essentially. Correspondingly, agents who are competent with regards language use and communication need not possess meta-cognitive abilities.

The Dilemma.

Different theories of language and communication presuppose different kinds of cognitive capacities - either explicitly or implicitly. Among the more prominent and most influential pragmatic theories - theories of speech acts, conversational implicature and the like - are theories which are broadly Gricean in their stance. Gricean theories can be defined as those theories which analyse utterances as acts by one agent which seek to alter the mental states or attitudes of other agents in part by getting the other agent to recognise their intention to so do. It follows that Gricean approaches to pragmatics presume that communicating agents posses the cognitive ability to represent the mental state or attitudes of other agents and/or to make inferences about these.

Of course, Grice's theory of conversation as presented in his "Logic and Conversation" (Grice 1975) contains a working-out schema for conversational implicature which is a piece of pure belief-desire psychology, with inferences being explicitly made about the attitudes of another agent. At a perhaps more fundamental level, influential theories of basic speech acts such as assertions adopt a more or less Gricean stance. Stalnaker's speaker presupposition framework, in particular, presumes that agents involved in conversation assume a common ground. A proposition is common ground, or presupposed by the speaker, if the speaker is disposed to act as if she believes it or assumes it is true and believes that her audience believes or assumes it is true. Assertions and suppositions are acts which seek "to change the presuppositions of the participants in the conversation by adding what is asserted to what is presupposed". (Stalnaker 1978:323). Thus, according to Stalnaker's model of assertion, in order to engage in conversation one must be able to represent speaker presupposition. And the structure of this presupposition "can be represented by a Kripke semantics in which the accessibility relation is serial, transitive and Euclidean, but not necessarily reflexive" (Stalnaker 1996:282). In other words, putting aside certain idiosyncrasies, speaker presupposition is structurally similar to other attitudes and therefore requires similar conceptual abilities to represent it. Other influential accounts of speech acts fundamentally incorporate some notion of common ground with basically the same structure - see Searle (1969), Lewis (1969), Schiffer (1972), and more recently Clark (1996). Sperber and Wilson's Relevance Theory (1986/95) also supposes that basic assertive

speech acts involve the recognition of complex intentions involving the intention to get the audience to believe what the speaker is saying.

These Gricean pragmatic theories have also inspired an approach to meaning which has been popular in the recent past. Consider again Stalnaker's proposal regarding assertions. They are seen as moves which are made on the common ground, a proposal to reduce the set of live possibilities consistent with what is presupposed in accordance with the content of what is said. In this framework, the meaning of the linguistic expressions used was thought about in traditional truth-conditional terms. Dynamic semantics (Kamp 1981, Heim 1982, Groenendijk & Stokhof 1990, 1991) takes the further step of supposing that the meaning of a sentence consists in its potential for transforming the input context set into the resultant output state. Thus meaning of sub-sentential elements lies in their contribution to the update potential of the sentences. So we could say that in dynamic approaches, the meaning of a predicate like "sleeps" no longer makes reference just to the property of sleeping or some such notion which would be central in stating the predicate's contribution to truth-conditions (say, a function from individuals to truth-values), but the predicate's meaning also involves an input state - something which has the same structure as Stalnaker's speaker presupposition. That is, it would be a function from individuals to a function from input states to output states. Thus dynamic semantics imputes to language users who can be said to know or grasp the meanings of basic expressions in their language, this sophisticated ability to represent mental states.

In summary, both at the level of semantic and pragmatic theory, it is a widely held assumption that agents who engage in basic communication are capable of thinking about or representing other agents as bearing propositional attitude-type relations to what is being communicated. However, it is also a widely held assumption in psychology that children under the age of four years do not posses this ability. This assumption is founded on a fairly impressive and largely conclusive body of experimental work over the past decade or so, starting with Wimmer & Perner (1983). So there is a tension between what these influential semantic and pragmatic theories assume about language users in general and what experimental evidence suggests about a significant minority of them. In the balance of this paper, we will consider three options for relieving this tension. Option I: We could argue that young children do not ever properly engage in communication and (optionally), that young children do not really understand the meaning of the expressions they use. Option II: We could challenge the results concerning so-called theory of mind abilities in young children. Option III: We could say that the above assayed theories do not capture the essence of communication but, at best, only the norm among sophisticated language users who have theory of mind abilities.

Are young children competent communicators?

The viability of Option I depends on how easily one can overturn the prima facie intuition that young children, aged two to three years, are capable communicators in the following sense: in at least some cases, their use of language or their understanding of others' use of language is at a level of performance equivalent to that of an adult. That is, in at least some situations when a child utters a sentence, S, their intentions with regards the content of the utterance are clearly comprehensible and are the same as those a normal adult would be attributed with if it uttered S in the same circumstances. Similarly, in at least some cases where a child is faced with an utterance of S by another agent, their grasp of that action is the same as that of an adult faced with the same utterance.

Of course, we agree that children of this age are not nearly as good at communication as adults. They are much more prone than adults to misunderstanding, mis-communications, irrelevancies and so on. Also their linguistic proficiency is in many ways not the same as adults. In particular they have a much more limited vocabulary. But this is a matter of degree. They do have the basic wherewithal to engage in linguistic communication, in spite of the fact that their cognitive capacities limit the degree of success in this matter.

For us to take Option I seriously, we would need a lot more evidence that children are not competent when it comes to basic communication. Presently, it does not seem all that likely that this evidence would be forthcoming. Consider for instance personal pronouns ("she", "he", "it" etc). These are among the first words children learn (Bloom 2000). Moreover, their usage of these forms evinces a more or less adult competence in circumstances where there are no extra demands placed on the child which are beyond their conceptual abilities. This particular fact is significant, given that Gricean-Stalnakerian theories of pronoun usage by and large attach sophisticated presuppositions (involving the common ground) to pronouns.

In the absence of any strong arguments for this option, we will put it aside and move on to consider the other two.

Challenging the theory of mind orthodoxy.

Option II seems far more promising in the light of recent research into word learning. Here the suggestion is that children younger than four years old have a much more sophisticated appreciation of others' mental

states than the classic Sally-Anne experiments suggest. There are two important strands to this argument which we need to consider here. Both are raised in Bloom & German (2000).

The first line of attack would be to question the assumption that the Sally-Anne task probes the onset of full theory of mind abilities. Bloom & German argue that this kind of false belief task involves abilities other than theory of mind (ibid:B26). In particular, they claim, citing a variety of experimental evidence, that it is reasoning about false beliefs that causes difficulty for children who otherwise might reasonably be supposed to have theory of mind ability. That is, false-belief tasks are difficult for young children because of the difficulties generally attached to reasoning about falsehoods rather than because they lack theory of mind abilities.

Experiments which are designed to lighten subjects' processing load have been found to facilitate performance. For example, German & Leslie's (2000) modified false belief tasks lowered the passing age by a few months. These results could be seen as significant in the context of theories which suggest that theory of mind abilities are in some sense modular. In the tradition of modular approaches to the mind, one could argue that young children's theory of mind module is 'switched on' or 'matures' earlier than classical Sally-Anne tasks suggest, but that due to the processing load demanded by reasoning about false beliefs, children fail.

Bloom & German argue that results from other experiments provides support for this view. These experiments involve thinking about non-actual states of the world but do not involve folk-psychological reasoning as such. The 'false photograph task' has the same structure as the false belief task except that it does not involve thinking about mental states. That is, children are asked about the content of a photograph when it does not match the current state of the world. Three year old children who fail false-belief tasks also fail the false photograph task (Leslie 2000). Other related evidence mentioned by Bloom & German involves children's performance on tasks involving counterfactuals. Their conclusion is that it is not necessary that children fail false-beliefs tasks because they do not have a working theory of mind. Moreover they suggest that it is more the general difficulty of the task which bars success. Bloom and German go on to cite positive evidence for younger children's theory of mind ability. Before we consider this important evidence, let us consider this first line of attack: Children fail false belief tasks because certain elements of the task are beyond them. These elements arise in non-theory of mind tasks such as the false photograph task and tasks involving counterfactuals so it is not lack of theory of mind abilities which is responsible. If this line of argument seems appealing at first, a moment's thought should reveal that it has things the wrong way around.

The false belief task was originally designed on reflection about the nature of theory of mind. Having a theory of mind means (at least) having an ability to think about the actions of other agents as governed by causally active, but unobservable, mental states. This ability presupposes having an ability to represent an agent as having propositional attitudes. Even if another agent has a true belief, representing that fact requires conceptual abilities far different from representing the content of that belief. The conceptual abilities involve an appreciation of the different accessibility relations that need to be associated with different agents. That is to say, according to one popular metaphor, one needs to set up different belief boxes (and desire boxes etc) for different agents.

One could argue that certain cognitive and conceptual abilities required for the false photograph task, for tasks involving counterfactual states and others are the same as those required for theory of mind tasks. In particular, there is a strong case to be made for the claim that to perform these latter tasks, one needs to think with different frames, using different accessibility relations. What this means in cognitive terms is something of an open question. At a minimum, it means over-riding basic dispositions regarding the representation of two situations. Consider, for instance, the false photograph task (Zaitchik 1990). The subject sees a Polaroid photo being taken of a scene in which a cat is on the mat. As the photo is developing, the subject sees the experimenter change things in the scene so that the cat is no longer on the mat. The child is asked, "In the photograph, where is the cat sitting?". In order to successfully complete the task, the child has to represent the situation in the photo, s', as well as the current situation, s. Now, normally if the child represents s and s' then it can infer that there is a situation, s'', which contains both. It would also be disposed to reject (or suppress) representations of one of two incompatible situations. To perform the task, these basic dispositions have to be overridden. It does not seem plausible that such basic inferences or processes would be overridden except where there are two different frames under consideration. That is, why else would the cognitive system develop a mechanism whereby these fundamental dispositions are forestalled?

So, contrary to Bloom & German, we should conclude from these experiments that there is no evidence that three year-olds posses the kind of abilities which are pre-requisite for having theory of mind.

Bloom & German's second line of argument has more substance. It is based on a growing body of experimental work in word learning and other developmental research which is at least as impressive

as the false-belief literature. I will mention briefly some key results here before discussing the third alternative. In the light of that discussion, I will propose that what may seem to be evidence of genuine theory of mind ability could equally well be accounted for in terms of an independently motivated ability of children to keep track of an object of joint attention between themselves and other agents. This ability does not presuppose those required for theory of mind tasks.

The crucial data for precocious theory of mind abilities comes from investigations which seek to establish the role in word learning of the interactional dimension of communication (joint attention etc) and children's appreciation of other agents as intentional - what Tomasello calls 'social cognition'. The data reviewed in Tomasello (1995), Tomasello (2000), Bloom (2000) involves experiments where young children (2-3 years) display an appreciation of others' intentions and apparently of others' mental states (ignorance) when learning words. For instance, Tomasello and Barton (1994) discuss an experiment where an adult announces that it is going to find a toma (a novel word) standing over a number of opaque containers. From each, the adult produces novel objects and reacts in a disappointed fashion to all but one to which she responds in a manner appropriate to successful finding. Afterwards, the child subject is tested to see whether it has learned the word 'toma'. The results are that the subjects learn the word as applying to the 'found' object, suggesting that the children are sensitive to the adult's intentions in such situations.

More interestingly, in their communicative behaviour, children seem to show an appreciation of adults' ignorance in both word learning scenarios (Akhtar, Carpenter & Tomasello 1996) and other scenarios (O'Neill 1996). In the former case, a child learns a word when it is mentioned by a parent in a context where there is one novel item for the parent and three other items which the parent and child had just played with but which had remained unnamed. In matching the novel word to the novel item, the children seem to be displaying an appreciation of the mental states of the parent. Perhaps even more interestingly, Happe & Loth (in press) have results from a word learning task based on the structure of Sally-Anne which suggests that children who fail the false-belief task manage to learn a word under the same conditions. Ie. Sally and child subject play with novel toy. Sally puts toy in container A and goes away. Anne comes with her own novel object. Anne makes the switch with her toy and Sally's. Sally returns and says, pointing to where she left her object, "Let's play with the modi". Children who fail basic false-belief tasks perform better at learning 'modi' as applying to not what is in the box but what Sally had put in there. What, then, can explain this apparent sensitivity on the part of children to the intentions and mental states of other agents, other than theory of mind? The answer to this question does not involve any kind of mysterious interim ability on the part of children. It can be found by thinking carefully through a developmental path commensurate with children's developing communicative and linguistic abilities.

Basic communication.

Although Sperber & Wilson are somewhat culpable in this conceptual inflation when it comes to communication, the essence of their theory is built around a much more parsimonious view: an act of communication is simply an act whereby one agent attempts to draw another agent's attention to something. They contend that agents to whom this kind of behaviour is directed decide on what their attention is being directed to by processing input stimuli for relevance - which is defined in terms of a kind of cognitive nutrition and processing effort. The food metaphor is apposite when we consider how a pre-linguistic child might come to respond to ostensive behaviour in this way and to eventually produce such behaviours itself.

The key to communicative development comes with conceptual development around 9-12 months. This development (surveyed in Tomasello 1995) involves the formation of concepts of actions. At this stage a child begins co-ordinating first person experience with memories of observed behaviour of others, with kinaesthetic memories etc. It is implicit in this abstraction over experience that there is an agent of the action (among other participants) and there are constituent acts in the action. Also, an action concept would be associated with episodic memory of prototypical situation types in which the action takes place. These in turn have constituent eventualities, including typical end states. Eating, for example, will be conceptualised as consisting of certain actions, and it will be associated with certain typical types of situation, including the end state associated with tasting and swallowing the food. Forming concepts of actions which are directed toward another agent presumably does not involve any extra conceptual abilities. Feeding, for a typical example, would be conceptualised in terms of constituent acts on the part of one agent directed towards another.

In general, recognising an action A as such does not presuppose any special abilities beyond this ability to break it down into constituent acts and to keep track of information about the typical eventualities involved. In particular, it does not involve theory of mind. Also, it does not presuppose that one witness the whole act, just some constituents of the action would normally suffice to trigger recognition. Hence a child can recognise a

failed attempt at A as such. This fact could be used to account for the data in Barton & Tomasello (1994).

Looking (or attending to) is an act which we can suppose that children with these basic abilities can conceptualise. It is an act directed toward a situation (in the sense of a chunk of the world as per Barwise and Perry 1983) which results (potentially) in certain cognitively nutritional effects. Contrary to Tomasello (1995) and others, joint attention need not involve mutual knowledge or any special social-cognitive skills. It is just a matter of following into the gaze of another (presumably in the hope of cognitive effects). Gaze monitoring is just a matter of monitoring the actions of another (again, possibly for reasons of self-interest). Showing and other ostensive acts, like feeding, are just actions on another. The third participant role in this kind of act is not filled by food but a situation. As mentioned above, as with gaze monitoring, children would naturally process such acts for relevance. So like feeding, it is a benevolent act. Why it is that children themselves come to show things to others is not clear - but nor is it clear why they offer food or engage in other reciprocating benevolent behaviours. That children do offer up things for attention would explain their inclination to indicate new things to their parents and other carers. It would provide for an alternative account of Akhtar, Carpenter & Tomasello's (1996) finding, if we assume the child can keep track of what objects the relevance of which it has and has not shared with significant others. We will see briefly that there is good independent evidence for this. In that case, when the adult returns in Akhtar et al's crucial condition, the child would be focussing on the newest toy since that is something yet to be shared. Thus the child will assume that the adult's (purposely vague) indicating will be directed toward the new toy since that will be its first accessible interpretation. (See Sperber 1994 for a discussion of different relevance-based interpretation strategies for individuals with different levels of theory of mind abilities).

With joint attention and with directing attention, there is not only a situational object but a larger situation involving the two agents. With Tomasello, we agree that language is acquired in the context of such interactions. Words and sentences are constituents of ostensive acts, being descriptive of the type of situation being indicated. Pronouns are learnt as acts of pointing at objects in the situation being indicated. There need be no Stalnakerian presupposition for the proper mastery of these forms (although sophisticated adults can optionally make such presuppositions - to the effect that the referent of a pronoun is in the object of joint attention). Thus children, like anyone else, can engage in communicative activities without concerning themselves with speaker presuppositions. Indeed, where young children need to take common ground into account to succeed, they tend to fail. For instance, Mitchell et al (1999) devised a Sally-Anne task with referring expressions (descriptions) and the results were predictably that three year-olds failed and four year-olds passed. So what is the difference between this and Happe and Loth's word learning case? Crucially, in the latter, it can be argued that the child can complete the task successfully simply by being able to track what the object of joint attention is between itself and a number of agents. In Mitchell et al's task, as with Sally-Anne, success depends on thinking about the mental state (common ground) of another agent. Notably, in Happe and Loth's study, they did a so-called 'true belief' version of the word learning task. On this task, children under four performed worse than in the corresponding true-belief Sally-Anne task but they performed with the same level of success as with the false-belief word-learning task. Happe and Loth have no explanation for this but there is an explanation given the focus of attention account: The 'true-belief' word-learning task involves exactly the same skills and demands as the 'false-belief' word-learning task. Sally puts object X in A and along comes Anne and introduces object Y. She replaces X with Y in A in Sally's presence. When Sally stands over A and says, "Let's play with the modi", there is understandable confusion since the child has presumably been tracking Anne's gaze on Y and not Sally's.

With other cases where children seem to be sensitive to what other agents do and do not know, proper attention to their abilities to track the objects of joint attention and their relevance guided abilities to lock onto what is being indicated would reveal that they are not so sophisticated after all.

Conclusion.

It seems fairly clear-cut what theory of mind is and what conceptual abilities it entails. The dominant tradition in pragmatics and the dynamic tradition in semantics presumes that language users have theory of mind or, at least, the conceptual abilities which underpin theory of mind. Young children do not possess these abilities and yet they seem to communicate perfectly adequately and they seem to have a firm grasp on the meaning of at least some basic expressions in their language. If we accept this, then we have to say that Gricean ideas about language use only apply to more sophisticated language users. A more minimal theory of basic communication has been offered here based around some ideas from situation theory and relevance theory. To be sure, according to the alternative suggested here, no communicative abilities can get off the ground without a child having certain affinities with other agents. In particular, the development of concepts of actions clearly entails co-ordinating first person and third person experience.

However, we have suggested here a way of thinking through social development which does not call for any mysterious interim psychological appreciation.

The Effects of Reducing Information on a Modified Prisoner's Dilemma Game

Abstract

Participants played a modified prisoner's dilemma game in which competition was created using a single player. The competition was between the player at the moment and the player in the future. The complexity of the game was increased across experiments. The transition from Experiment 1a to 1b saw the removal of information about future consequences and past behavior. Experiment 2 removed information about current outcomes. As the complexity of the game increased (both quantitatively and qualitatively) and therefore the external validity increased, the ability to "solve" the game decreased.

Introduction

Many choices we make are between things that make us feel good at the moment and things that are actually better for us in the long run. Choosing to consume alcohol at a party certainly feels better (at the moment) than not consuming alcohol, but in the long run (hangovers, loss of peer respect, etc.) we are certainly better to refrain from this consumption. When purchasing an automobile, assuming equal price, a sports car is definitely flashier than a mini-van, but the mini-van will probably last longer, be more practical, and cost less in insurance. Purchasing the sports car may make us feel better at the moment, but the total utility (over the life of the vehicles) would unquestionably be higher for the mini-van.

Impulsiveness is defined as the choice for the outcome that feels good at the moment (consuming alcohol; the sports car). Self-control is the choice for the outcome that is actually better in the long-run (refraining from alcohol consumption; the mini-van). Many factors affect our impulsiveness and ability to exhibit self-control. The experiments presented here address several of them.

A goal of this paper is to explore how people learn to choose between impulsivity and self-control. One can view this learning as an adjustment of strategy choices after feedback. Given the task studied in this paper, another relevant perspective views the learning as a growing understanding of cooperation in an iterated prisoners dilemma game.

In a traditional prisoner's dilemma game, two players each choose between two options (often called cooperate and defect) creating four possible outcomes (Rapoport & Chammah, 1965). These outcomes are associated with different rewards, labeled A, B, C and D, that must obey the following rules:

$$B > A > D > C$$
$$2A > B + C > 2D$$

Both players will receive outcome A (moderately good) if both choose to cooperate. Both players will receive outcome D (moderately bad) if both choose to defect. However, if Player 1 chooses to cooperate and Player 2 chooses to defect, then Player 1 will receive outcome C (the worst) while Player 2 will receive outcome B (the best). Defection tends to dominate in both one-shot and iterated playing of this game. However, if the players know each other, and, more importantly, trust each other, then cooperation can arise and persist. Rachlin, Brown and Baker (2001) have shown that Player 1 will cooperate only if he or she believes Player 2 will reciprocate that cooperation.

This result suggests that converting the two-player version of the game to a single-player version[1] would lead to high levels of cooperation. Nevertheless, previous work has shown that individual players chose to "cooperate" with themselves only 54% of the time (Brown & Rachlin, 1999). Why is this percentage so low? Consider the competition engendered by the single-player game: it is between the self at the moment and the self in the future, which is essentially a choice between impulsivity and self-control. The present experiments explore the processes by which individuals choose between these options in the single-player game.

Experiment 1a

The first experiment was designed to be a computer-based replication of previous work (see Brown & Rachlin, 1999 for full details) to obtain greater control

[1] A single-player prisoner's dilemma game, where that player makes two or more sequential choices, is identical to a two-player game in which the "other" player uses the tit-for-tat strategy perfectly (see Axelrod, 1987). In both instances, levels of uncertainty exist for the player at the moment of choice as to the future outcomes of the game. Whether that uncertainty arises from a lack of knowledge of another player's future actions or one's own future actions is inconsequential.

of delays and to obtain information on the amount of time participants took to make choices, that is, to increase internal validity.

Method

Participants

Fifty undergraduate students (23 males and 27 females) from the Carnegie Mellon University subject-pool participated in this experiment.

Apparatus and Procedure

All experimental stimuli were presented on an iMac computer with a 14 in. screen (13 in. viewable) using the cT programming language. Participants' choices were made using mouse clicks at the appropriate areas of the screen.

Participants were first asked a series of demographic questions including gender, age, SAT scores, etc. Following this, participants were shown an instruction screen that read as follows:

> You will be playing a game on the board shown on the left [See Figure 1] in which you will be using keys to open doors. These keys and doors will be Red and Green. Red keys open Red doors. Green keys open Green doors. At any given time you will possess a single key. This key can be used to open the appropriately colored door. Whenever you use a key to open a door, you will give up that key. Upon opening a door, you will receive the number of points contained in the box with the door, and a new key. Choices will be made by pressing buttons which will appear on the doors. While you are playing the computer will always show you the last choice you made and the number of points you have earned. You will be given a Red key to begin the game, but after that, the key you have will depend on your actions. Throughout the game, the board will look exactly as it does now. Your goal in playing this game is to earn as many points as you can.

A series of screens followed giving examples of the rules. Post-experimental questioning revealed that all participants understood the rules and procedures of the game upon reading the instructions.

Following the instructions, participants began the actual choice procedure. To avoid procedural errors during the choice procedure, only the currently valid choices (the top doors if the participant possessed a red key, the bottom two if green) were available for choice.

Participants were given a red key to begin the game and were allowed to choose between the top two doors (choose between 15 and 20 points). Regardless of the row in which the participants were currently choosing, choice for the greater points always led to the bottom of the board on the following trial and choice for the smaller points always led to the top of the board on the following trial. The "solution" to this game is such that choice for the smaller amount at the moment always led to more on future trials.

Participants made 100 choices on the screen shown in Figure 1. Participants were able to see the game board at all times, as well as the key they currently possessed, their previous choice, and the total points they had earned. An inter-trial interval (ITI) occurred between each choice (default value 3 s). During the ITI all text was removed from the screen as were the current key and previous choice information. During the ITI the key from the chosen square moved down to the current key position and the points from the chosen square were moved to the points bucket. Following the ITI of the 50th choice, a 4-min filler task (drawing) was employed. Following the filler task, participants made the final 50 choices.

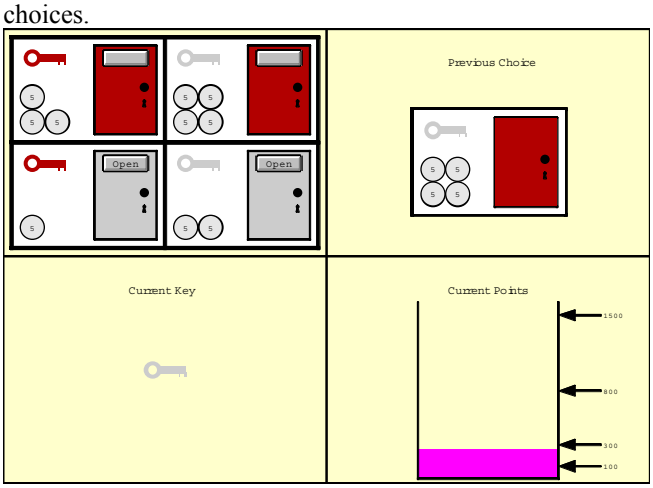

Figure 1: Screenshot of the game. Note: The top two doors are red; the bottom two doors are green; the left compartments contain red keys; the right compartments contain green keys.

Other non-prisoners' dilemma work suggests two features of the game that can impact participants' choices. These are reward amount and ITI. Within the limits of the equations presented earlier, these features can be manipulated. While the ratio of the rewards is the most important factor in choice, absolute levels of the rewards also has a considerable effect (Rachlin, Brown, & Cross, 2000). With regard to the ITI, previous work has shown that engendering commitment to a choice increases cooperation (Rachlin, 1991; Stuart, 1967). One way to accomplish this is by delaying the time until the choice takes place, in other words, increasing ITI.

Experiment 1a manipulated ITI as a between-groups factor to take the values of 3, 6, or 9 s. Additionally, within the 3 s level of ITI, the absolute level of reward was manipulated by a factor of five as a between-groups factor by writing either 5's in the circles of each choice box (as shown in Figure 1) or by writing 1's in the circles.

Results and Discussion

Performance on the iterated prisoner's dilemma game is a function of learning. As such, typical measures of

learning, including both latency and performance, were measured. Performance was measured with the percent of trials on which participants cooperated (chose the options that contained fewer points, top left or bottom left box). The first two results address whether cooperation was influenced by ITI or the absolute level of the reward.

An independent-measures ANOVA was performed across the three levels of ITI. Cooperation over all 100 trials did not significantly differ across ITI levels of 3 s (M = 86.4%, sd = .166), 6 s (M = 87.1%, sd = .170), and 9 s (M = 86.1%, sd = .162), $F(2, 47) = .01$, $p > .05$. The absolute level of reward variable was varied only within participants using an ITI of 3 s. An independent-measures t-test with these participants revealed that having 5's in the circles (M = 86.7%, sd = .157) did not engender significantly different cooperation than having 1's (M = 85.8%, sd = .191), $t(28) = .13$, $p > .05$. Because neither of the manipulated factors had a significant impact on cooperation further testing collapsed across these factors.

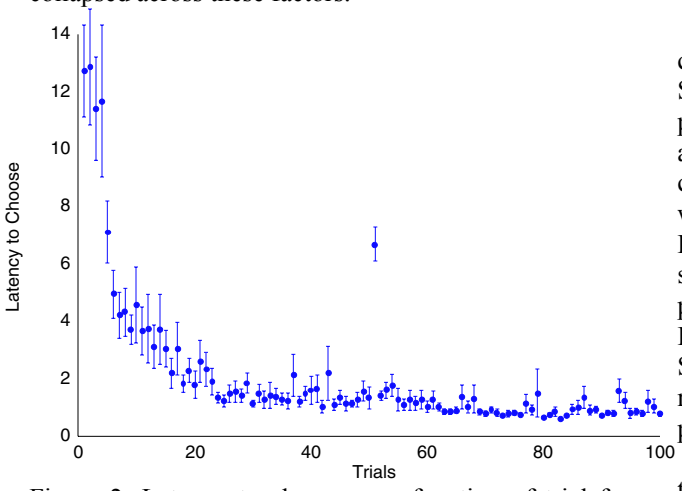

Figure 2: Latency to choose as a function of trial for Experiment 1a. Note: Bars represent ± 1 SE; the single extreme data point at trial 51 occurred immediately following the filler task.

The latencies to choose decreased in an inverse relationship with trials (see Figure 2). The best fitting curve for this data (r^2 = .823) was:

$$\text{Latency(Trials)} = 1.7026/\text{Trials}^{.6636}$$

Cooperation by the participants across the 100 trials of Experiment 1a increased logarithmically (see Figure 3). The best fitting curve for this data (r^2 = .634) was:

$$\text{Cooperation(Trials)} = 7.203*\ln(\text{Trials}) + 60.25$$

The previously mentioned manual experiment (Brown & Rachlin, 1999) was run for only 40 trials. An independent-measures t-test using only the first 40 trials of the present experiment showed that the participants in Experiment 1a (n = 50; M = 81.6%, sd = .170) cooperated significantly more than the participants in the previous experiment (n = 20; M = 53.75%, sd = .097), $t(59) = 8.61$, $p < .001$.

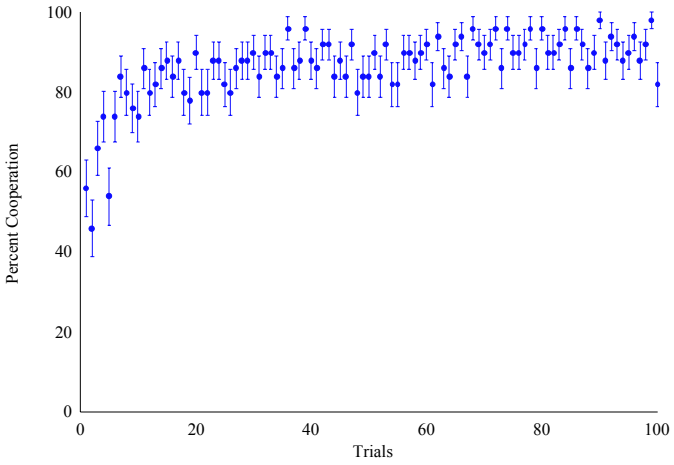

Figure 3: Percent cooperation as a function of trials during Experiment 1a. Note: Bars represent ± 1 SE.

Experiment 1a revealed a ceiling effect on cooperation that had not been seen in previous work. Several possible explanations for this effect exist. First, previous work had been performed using physical apparatus which may be viewed differently from a computer. Second, Experiment 1a was 100 trials long whereas previous work had continued for only 40 trials. However, the ceiling effect was already beginning to show by the 40th trial of Experiment 1a. Third, and perhaps most importantly, the participants in Experiment 1a were extremely analytical (average SAT-M score over 700). Post-experimental questioning revealed that participants treated the experiment as a problem to be solved mathematically.

Experiment 1b was created primarily to investigate the final concern. However, Experiment 1b was also created to increase the external validity of the game.

Experiment 1b

When making choices in life, one rarely knows for certain the consequences of those choices. In fact, it is only through prior experience that we have any idea of future consequences. This experience-based learning was missing from Experiment 1a and was created in Experiment 1b by removing the keys from the boxes.

Method

Participants

Thirty undergraduate students (19 males and 11 females) from the Carnegie Mellon University subject-pool participated in this experiment.

Apparatus and Procedure

Experiment 1b used exactly the same apparatus as Experiment 1a. The ITI in Experiment 1b was 3 s and the circles had 1's written in them. Experiment 1b differed from 1a in that some of the information which had previously been available to the participants was removed from the game. Namely, participants no longer had access to information about their actions on the previous trial and the locations of the keys in the game board (representing future consequences). Additionally, ten of the participants provided a verbal protocol while performing the experiment.

Results and Discussion

An independent-measures *t*-test on the overall percent cooperation showed that participants providing a verbal protocol (M = 83.2%, sd = .172) did not significantly differ from those not providing it (M = 79.9%, sd = .223), $t(28) = -0.41$, $p > .05$. Because of this, further analyses collapsed across this factor.

However, protocol data revealed that participants were still "solving" the game as a math problem. Participants were adding together the outcomes of different combinations of multiple trials, comparing these totals, then merely selecting the combination with the highest total. These participants were again highly analytical (SAT-M average over 700).

In much the same way as Experiment 1a, latency decreased across trials in an inverse relationship. The best fitting curve for this data (r^2 = .739) was:

$$\text{Latency(Trials)} = 8.77/\text{Trials}^{.5468}$$

The cooperation in Experiment 1b increased across trials logarithmically as Experiment 1a. The best fitting curve for this data (r^2 = .653) was:

$$\text{Cooperation(Trials)} = 15.18*\ln(\text{Trials}) + 25.75$$

A 2 X 10 (Experiment X Ten Trial Blocks) mixed-factorial ANOVA was performed. The overall cooperation in Experiment 1a (M = 86.5%, sd = .163) was not significantly different from Experiment 1b (M = 81%, sd = .205), $F(1, 78) = 1.73$, $p > .05$. The cooperation across the ten ten-trial blocks (M's = 59.9%, 81.3%, 82.4%, 86.4%, 85.9%, 82.9%, 89.4%, 92%, 92.0%, 92.1%; sd's = .263, .242, .240, .229, .240, .216, .204, .185, .174, .166) was significantly different, $F(9, 702) = 53.59$, $p < .001$. A trend-analysis revealed a significant linear component, $F(1, 79) = 76.64$, $p < .001$, suggesting that steady learning occurred across the experiments. Additionally, the interaction of Experiment and trial block was significant, $F(9, 702) = 7.66$, $p < .001$. Planned comparisons showed that the essential differences in Experiments 1a and 1b occurred during the first [$F(1, 78) = 15.86$, $p < .001$] and sixth [$F(1, 78) = 8.19$, $p < .01$] blocks of ten trials in which the participants' in Experiment 1b cooperated less.

Procedurally, Experiment 1a and 1b differed in a quantitative manner. The task was made slightly more difficult by removal of the keys (information about future consequences) and the previous trial reminder (information about past behavior). This quantitative change in task difficulty created only a slight difference in overall cooperation, with its effects felt mainly in the first and sixth block of trials (immediately following the filler task).

Throughout Experiments 1a and 1b, all participants (N = 80) "solved" the game in a sudden fashion using one of several strategies. The first strategy was total cooperation, which was achieved by selecting the top-left door continually. The second strategy, which yielded approximately 66% cooperation, involved choosing the top left door, then the top right door, then the bottom left door, then repeating the sequence. The third common strategy, which created approximately 50% cooperation, involved choosing the top right door, then the bottom left, over and over. Participants using the first strategy (n = 61) tended to do so during the early trials of the experiment (M = 12.3, sd = 15.1). Participants using the second strategy (n = 11) tended to begin it late (M = 40.1, sd = 24.7). Participants implementing the third strategy (n = 8) did so in between (M = 29, sd = 26.9). Once participants moved into one of these strategies, they stuck with them nearly exclusively. Strategy onset was defined using the following two rules. First, the behavior for at least 10 trials following the point of strategy onset must be consistent. Second, the participant must have followed this strategy throughout the game.

A one-way repeated measures ANOVA was performed on the latency to choose on the five trials surrounding the strategy onset (two trials prior to onset, actual onset, and two trials following onset). Eleven participants were removed from this analysis (all using the pure cooperation strategy) because their strategy onset occurred on the 1st or 2nd trial such that they provided no data for trials prior to onset (if included, the effect is more pronounced). These latencies as a function of position, which can be seen in Figure 4, were significantly different, $F(4, 272) = 3.58$, $p < .01$. A planned comparison revealed that the latency on the trial immediately following strategy onset (M = 8.45 s, sd = 15.9) was significantly longer than all other trials averaged together (M = 4.28 s, sd = 7.5), $F(1, 68) = 6.39$, $p < .05$.

Prior to the onset of a steady strategy, verbal protocol data revealed that participants' comments tended to focus on the outcome of the immediate trial. The trial on which strategy onset occurred was treated no differently from previous trials. However, on the trial following strategy onset, the participants would stop and reconsider the entire game, focusing on the game as a "whole", hence, the increased latency on the trial

immediately following strategy onset. The results are particularly striking given that earlier trials tend to have a longer latency (see Figure 2 and the downward slope among 4 of the 5 points in Figure 4). This aspect of the data would have the effect of negating the increased latency on the trial following strategy onset.

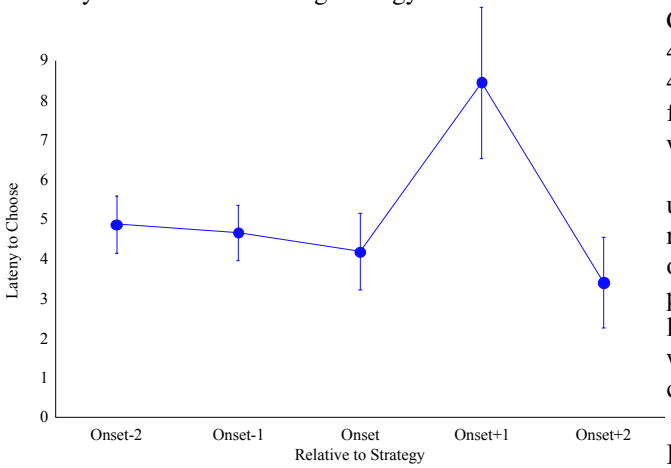

Figure 4: The latency to choose on the trials surrounding strategy onset in Experiment 1a and 1b. Note: Bars represent ± 1 SE.

Experiment 2

Due to the ceiling effects experienced in both Experiments 1a and 1b, participants' treatment of the game as a mathematical problem to be solved was addressed. Real-life choices rarely can be solved mathematically. It is often impossible to verbalize why option A was chosen over option B, it may simply "feel" better. This intuitive nature of decision-making was sought by creating two probability combinations such that reinforcement was unknown in advance rather than deterministic as it had been in Experiment 1.

Method

Participants

Forty undergraduate students (27 males and 13 females) from the Carnegie Mellon University subject-pool participated in this experiment.

Apparatus and Procedure

Experiment 2 used the same apparatus as Experiments 1a and 1b. The ITI was 3 s and the circles had 1's written in them. It will be remembered that in Experiment 1 (see Figure 1) the game board contained 3, 4, 2, and 1 circles in the different compartments. In Experiment 2 all compartments contained 5 circles. However, in Experiment 2, upon making a choice, the receiving of points was probabilistic. If a participant chose any given door, they may or may not receive the 5 points. The probabilities used were manipulated. Participants in Group 1 (n = 20) received the 5 points 60%, 80%, 40%, or 20% of the time (starting in the top left and going clockwise). This created expected values for these choices that were 3, 4, 2, and 1 (i.e. 5 points received 60% of the time has an expected value of 3), exactly as they were in Experiment 1. Participants in Group 2 (n = 20) received the 5 points 80%, 100%, 40%, and 20% of the time creating expected values of 4, 5, 2, and 1. Due to an apparent lack of asymptote following 100 trials, 12 of the participants in Group 2 were given 100 additional trials for a total of 200.

The previously listed probabilities were generated using a true probability mechanism, However, several rules were employed which ensured both that the obtained probabilities approximated the programmed probabilities at both the local and global level and that long strings of wins or losses (such that the string would be expected to occur less than 5% of the time by chance) were avoided.

Results and Discussion

A 2 X 10 (Group X Block of ten trials) mixed-factorial ANOVA was performed on the cooperation during the first 100 trials. Group 1 (M = 53.5%, sd = .143) did not cooperate significantly less overall than Group 2 (M = 58%, sd = .106), $F(1, 38) = 1.28$, $p > .05$. The cooperation across the ten ten-trial blocks did not significantly differ, $F(9, 342) = .36$, $p > .05$. The interaction of Group and block was not significant, $F(9, 342) = 1.2$, $p > .05$.

In a similar manner seen in the differences between Experiments 1a and 1b, the slight difference in results for Groups 1 and 2 seemed to reflect a quantitative change in task difficulty. Group 2's more divergent probabilities, and hence expected values, created more cooperation.

A single-sample t-test on the overall cooperation for Group 1 showed that it did not significantly differ from random responding (50%), $t(19) = 1.08$, $p > .05$. A second single-sample t-test on cooperation during the final ten-trials (when responding is most stable, M = 55.5%, sd = .233) revealed the same lack of difference, $t(19) = 1.06$, $p > .05$.

Perhaps the probabilities of reinforcement used with Group 1 were too subtle even though the expected values were identical to the points used in Experiment 1. Inspection of the data shows virtually no change in cooperation from the beginning to the end of the experiment. The effects of continuing the experiment beyond 100 trials remain to be seen.

A single-sample t-test on the cooperation for Group 2 during the first 100 trials (n = 20) showed that it was significantly higher than chance, $t(19) = 3.35$, $p < .01$. However, cooperation during the 10th block of ten trials

(M = 58.5%, sd = .223) was not significantly higher than expected by chance, $t(19) = 1.7$, $p > .05$.

A single sample t-test on cooperation over all 200 trials (M = 63.4%) for those that received them (n = 12) showed that it was significantly higher than chance, $t(11) = 3.33$, $p < .01$. Likewise, cooperation during the final ten-trial block (M = 73.3%, sd = .227) was significantly higher than chance, $t(11) = 3.56$, $p < .01$.

The cooperation of Group 2 continued a slow growth throughout the first 100 trials of the experiment. This growth also continued through the second 100 trials. One wonders where this group's cooperation would asymptote.

The latency data of Experiment 2 mirrored the inverse relationship seen in both Experiments 1a and 1b. Latency decreased across trials in an inverse relationship. The best fitting curve for this data, which created an r^2 of .896, was:

$$\text{Latency(Trials)} = 5.52 / \text{Trials}^{.4186}$$

An examination of the relationship of cooperation across trials for the participants in Group 1 showed that no function could account for more than 2% of the variance. The relationship between cooperation and trials was slightly better for Group 2. A logarithmic function captured the greatest amount of variance in this relationship creating an r^2 of .151:

$$\text{Cooperation(Trials)} = 5.11 * \ln(\text{Trials}) + 41.52$$

A similar analysis of strategy, as was done in Experiment 1, was attempted for Experiment 2. Even when using a lenient definition of strategy onset, only 16 of the 40 participants were classified as having employed a steady strategy. A one-way repeated measures ANOVA on the latency to choose on the trials surrounding strategy onset revealed no differences, $F(4, 60) = .89$, $p > .05$.

General Discussion

When the internal validity of the game was increased (prior experimentation to the present experiments), participants' ability to cooperate with themselves increased substantially (though population differences may have had a large impact on this change). As the complexity, external validity, and face validity of the game increased within these experiments (both quantitatively and qualitatively), participants' ability to cooperate with themselves decreased.

Participants' behavior in Experiments 1a and 1b was characterized by a sudden change: at one moment focusing on the current trial, at the next moment focusing on the whole game. This "insight learning" showed itself in the strategy results. There was some moment when each participant stopped responding semi-randomly and began responding according to a strategy. In Experiment 2 behavioral change occurred gradually, though slightly faster for Group 2. This "trial and error" learning was shown in two ways. First, by the absence of strategy results. Second, by the participants' use of a win-stay/lose-shift approach.

The procedural differences between Experiments 1a and 1b created a quantitative change in behavior, 1b was slightly more difficult than 1a. Participants in both experiments "solved" the problem in a moment of insight. The procedural differences between Group 1 and Group 2 in Experiment 2 created quantitative differences in behavior, with the more divergent expected values in Group 2 creating more cooperation. Both groups appeared to use a form of trial and error learning. However, the change from Experiment 1 to 2 was qualitative. Participants solved these experiments using completely different approaches.

The insight shown in Experiment 1 occurred only after the participants had started using a strategy. On the trial following strategy implementation, the participants stopped and viewed the entire experiment, adding together the points from various combinations of moves. Because no verbal protocols were used in Experiment 2, it is impossible to know for sure how these participants viewed the problem. Perhaps the participants viewed the game as they would a real life problem. Picking one option "feels" better than picking another. Perhaps a simpler explanation based on probability matching may be a better explanation.

Abstract

In an experiment eliciting noun-noun compounds, participants were more likely to produce plural nouns in the first position (e.g., *mice trap*) when presented with an irregular plural in the stimulus (e.g., *a trap for catching mice is a* _____) than when presented with stimuli containing regular plurals (e.g., *a trap for catching rats is a* _____). When they did produce a normatively correct singular (e.g., *mouse trap*) in response to a stimulus with an irregular plural, response time was longer than it was for producing a singular response to stimuli containing singulars or regular plurals. This finding suggests a priming-based processing problem in producing the singulars of irregular plurals in this paradigm. Such a problem is likely also to be present in young children, which would explain their production of forms like *mice trap* (Gordon, 1985; Pinker, 1994) without requiring recourse to the hypothesis that they have innate grammatical knowledge.

Introduction

It has been observed that irregular nouns and verbs often behave quite differently than their regular counterparts. A case in point is noun-noun compound formation in English. Pinker (e.g., 1994, pp. 146-147) and others have pointed out that in general, the first noun of a noun-noun compound must be singular, but that plurals of irregular nouns seem to be more acceptable in that position. For instance, one would not say **rats catcher* or **toys box*, even when talking about more than one rat or toy. However, *mice catcher* is far more acceptable. The typical explanation given is that this follows from the theory of Level Ordering of morphology (Kaisse & Shaw, 1985; Kiparsky, 1982, 1983).

In this theory, production of compounds (or at least, novel compounds) proceeds at several "levels." At Level 1, a base form (for almost all English nouns, the singular) or another memorized form (such as the irregular plural) is retrieved from the mental lexicon; at Level 2, compounds are formed; at Level 3, after compound formation, regular affixes such as the regular plural are added. If this production schema is taken to represent a sequence of real-time processes or a fixed mode operation of a mental grammar, the normative English pattern dispreferring **rats trap* is explained by saying that the regular plural *rats* is created too late (at Level 3) to be placed inside a compound (at Level 2). However, irregular plurals, being retrieved from memory at Level 1, are easily incorporated during compound formation. This theory, in its general form, successfully schematized a wide variety of data in English and other languages, although by now it has been shown to have serious limitations (Bauer, 1990; Fabb, 1988).

Gordon (1985) explored compound formation with children aged 3-5, and induced them to produce compounds containing plurals when presented with irregular nouns, but only singulars when primed with regular nouns. He took this result as support for the idea that level ordering in grammar must be innate, because, as he demonstrated, children are rarely exposed to irregular plurals inside compounds, so they cannot induce the rule permitting irregular plurals inside compounds from their input.

However, there is another way to formulate the English pattern: English compounds obey the (soft) constraint that the first element is singular, regardless of whether the semantics has stimulated the retrieval of a plural referent (e.g., *toys*, *cookies*). Thus, if a compound such as *cookie jar* is called for, the retrieved *cookies* must be made singular before proceeding. Young children have plenty of examples of this pattern in their early years (e.g., *toy box*, *raisin box*, *jelly bean jar*) and could well have adduced such a rule by age 3.

Using this second way of constructing compounds, we suggest a processing difficulty explanation for the experimentally observed behavior: It is harder to produce a singular when primed by an irregular plural (e.g., to produce *mouse* after just having heard or read *mice*) than it is to

produce a singular when primed by a regular plural (e.g., to produce *rat* just having heard or read *rats*), for reasons that will be discussed later. This difficulty should show up in two ways: first, the already observed predilection of both adults and children to produce the irregular plural noun in compounds more often than the regular plural (predicted by both explanations), and second, a longer time to produce such a compound when given an irregular plural as input (predicted by our explanation).

To examine these predictions, we constructed an experiment to elicit noun-noun compounds and obtain response times. The experiment was similar in some ways to that of Gordon (1985), but differed in several important features. As in Gordon's experiment, the compound was elicited by prompting with some form of the words that were intended to be used in the compound. The differences were as follows: First, adult speakers rather than children were used. Second, response times were recorded by a computer, and therefore the materials were also presented by the computer. Third, we included the set of regular and irregular nouns that Gordon used, but augmented it in three ways: (a) Both the singular and the plural forms of each noun were used as stimuli; (b) three additional sets of regular and irregular words were added to provide for more stimuli; and (c) in addition to semantically matched regular nouns, a set of regular nouns matched for form (length, frequency, and initial phoneme class) was included. Participants were trained on the individual words, then responded to fill-in-the-blank sentences as quickly as possible with compounds that included one of the target words as the first word and a container as the second word.

Method

Participants

16 University of Colorado psychology students participated in the experiment. All were native speakers of English. Participants were assigned to counterbalancing groups according to a fixed rotation on the basis of their time of arrival at the experiment.

Apparatus

Stimuli were presented on an Apple iMac computer using the PsyScope software (Cohen, MacWhinney, Flatt, & Provost, 1993) and a button box/voice key. Responses were recorded on a cassette tape recorder via a head-mounted microphone through a y-jack.

Procedure

There were two parts to the experiment, training and test. The entire experiment took approximately 35-45 minutes.

Training The training part of the experiment familiarized participants with the task and the set of words used in the experiment. During training, participants were shown words one at a time. Each word that was to be used in the test portion of the experiment was shown twice, in two different pseudorandom orders, for a total of 152 trials. Participants were instructed to name the word as quickly and clearly as possible.

For each trial, first a black dot was displayed. When participants were ready for the trial, they pressed the space bar, causing the dot to disappear and the word to be displayed. When the participant responded, the computer registered the response via the voice key; the time was recorded; the word was erased; a red asterisk was briefly displayed as feedback that recording had taken place; and then the black dot signaling the next trial was displayed. Response time was measured from the time the word was displayed to the time the response triggered the voice key. Self-pacing of trials gave participants control over the pacing of the experiment, and also allowed a participant to postpone a trial momentarily if he or she felt a need to cough or make other noise that could disrupt the voice key. The feedback asterisks also trained participants to speak loud enough to trigger the voice key.

Test The second part of the experiment was similar to the first, except that in addition to single-word trials, there were also complex trials involving reading a sentence of the form "a JAR containing COOKIES is a _____" and filling in the blank. This part began with examples to show the participants what the complex fill-in-the-blank stimulus sentences would be like, and instructing them to fill in the blank based on the sentence they saw. The first example showed the participant what a "typical" answer would be; the participant then practiced on seven more examples by answering what they thought the answer should be and then repeating what the computer printed in red as the "typical" answer. (The example sentences are described in the Materials section.)

In this part of the experiment, the self-pacing was done as in the training phase. There were 4 blocks in this part of the experiment. Each block had 60 complex trials mixed with 90 single-word trials; together with 10 practice trials (different from the 8 example trials) before the first block, there was a total of 610 trials in the second part of the experiment. The order of the four blocks was counterbalanced using a balanced Latin Square design, resulting in four different groups of participants.

Materials

Target Nouns There were three types of target nouns: irregular nouns, semantically matched regular nouns ("semantic match"), and form matched regular nouns ("form match"). Five of the irregular nouns and their semantic matches were taken from Gordon (1985). These lists were augmented with three more nouns for greater generalizability across items. To draw attention away from the irregular nouns and their semantic matches, a non-semantically related noun was matched with each irregular noun. This set of nouns was chosen such that each matched regular noun was similar in length and frequency to the irregular noun, and also started with a phoneme that had acoustic onset characteristics similar to the first phoneme of the irregular noun. In addition, six more nouns and their plurals (two irregular nouns and four regular nouns) were

Table 1: Target nouns by type.

	Regular noun	
Irregular noun	Semantic match	Form match
mouse*	rat*	nail
tooth*	bead*	tape
foot*	hand*	cent
goose*	duck*	bell
man*	baby*	letter
louse	fly	knight
child	doll	chain
ox	horse	ax

*From Gordon (1985)

used for filler trials. The complete set of target nouns (singular form) is presented in Table 1. Targets in the experiment included both singular and plural forms.

The three new irregular nouns were chosen to be imageable and concrete. Semantic match nouns were chosen with criteria similar to those of Gordon (1985). Form match nouns, in addition to fitting frequency and length constraints, also fit the acoustic onset match criterion. Frequency and word length were equated across irregular, semantic match, and form match lists.

Individual Stimuli Individual stimuli were either single-word or complex. Single-word stimuli consisted of a single word chosen from the target nouns, containers, fillers, and words from the practice trials of the second part of the experiment. Complex stimuli consisted of fill-in-the-blank sentences of the following format: "a CONTAINER filled with (a/an) TARGET NOUN is a/an _____". Table 2 lists the containers and the verb associated with each container; TARGET NOUN was replaced with the target noun for that trial. The goal was to elicit a noun-noun compound using some form of the target as the first noun and the container as the second noun. The container and target noun were in upper case and the rest of the sentence was in lower case.

Each of the 48 target nouns and 12 filler nouns was combined with each of the 4 containers for a total of 192 target and 48 filler complex stimuli. Each target and filler noun occurred once in each block; the containers were distributed over the 4 blocks using a modified balanced Latin Square pattern.

In addition, there were eight example stimuli (all complex) and 10 practice stimuli (six single-word and four complex) at the beginning of Part 2 of the experiment, which were included (a) to ensure that the participants were not merely reversing the words, and (b) to give participants experience with the second part of the experiment before beginning the experimental trials. The eight example trials alternated between using mass nouns as the target nouns (because mass nouns do not have a plural/singular distinction, and thus would not have a distinct plural form; i.e., *rice jar*, *dough pan, fish glass, soup pot*) and extremely common noun-noun collocations. These examples were intended to induce the participants to realize that changing the form of the target noun was allowable (i.e*., bird cage, tool chest, coin purse, egg carton*). In these example trials

Table 2: Containers and associated verbs.

CONTAINER	Verb (*replaces* "filled with"*)*
bowl	containing
box	for transporting
crate	for carrying
tub	holding

the plural form of the target noun was presented, but the expected or typical answer was the singular form. Common noun-noun compounds were also chosen for the four complex practice stimuli (i.e., *flower vase, pencil case, chicken coop, cookie jar*). As with the example stimuli, the plural form of the target noun was presented in the complex practice stimuli. The target nouns and containers from these complex examples were included as single-word trials in Part 1. The single-word trials in the practice stimulus set were taken from the eight example stimuli used at the beginning of the test part of the experiment.

Stimulus lists As noted earlier, in Part 1 all 48 experimental target words, 12 filler words, 4 container words, 4 compound practice containers, and 8 compound practice target words (both singular and plural forms) were presented twice, in two different pseudorandom orders. All participants saw the same order of stimuli.

In Part 2 (test), single-word trials and complex trials were intermixed. First, the complex trials for each block were pseudorandomly ordered. Within each subblock of 12 complex trials there were two words of each combined type (noun type x grammatical number). Preceding each complex trial was either 0 or 1 container single-word trial, and either 0 or 2 target word single-word trials. There were no more than 2 complex trials (i.e., with 0 intervening single-word trials) in a row.

Design

The dependent variables measured were the response time (RT) for each compound response in ms and the proportion of complex trials with a singular first noun response (out of all usable trials as defined in the section on scoring). Each measure was analyzed with a mixed 4 x 3 x 2 analysis of variance. The first factor (between-subjects) was counterbalancing group. The second factor (within-subjects) was the noun type (irregular, semantic-match regular, form-match regular) of the target noun. The third factor (within-subjects) was the grammatical number (singular, plural) of the target noun.

A number of participants gave no plural responses to one or both of semantic match plural and form match plural stimuli. To reduce the number of participants whose data therefore would have to be eliminated from the RT analyses, the third analysis was conducted over the combined results of the regular nouns. Collapsing these categories was further justified by post-hoc tests that determined that there was no significant difference between the results of the two sets of regular nouns. In this analysis, the dependent variable was RT, which was analyzed with a mixed 4 x 2 x 2 analysis of variance. The first factor (between-subjects) was counterbalancing group. The second factor (within-subjects)

was the noun type (irregular, regular) of the target noun. The third factor, although not properly an independent variable, was response type (singular, plural) and was also within subjects.

Scoring

Two independent scorers listened to each tape. Each trial, single-word or complex, was scored as singular, plural, or other. Problems that would affect the RT as recorded by the voice key, such as repeating a word more than once, coughs or other noises, giving the complex answers in the wrong order, and so forth, were noted. Discrepancies between the two scorers were resolved by a third listener. RTs for problem trials and trials with responses categorized as "other" were discarded, and those trials were not used in RT analyses. When a participant responded to a complex stimulus first with one complete answer and then with another, it was scored with the first response.

Results

All results are based only on complex trials that were not excluded due to problems, as discussed above.

Proportion of Trials with Singular First Noun Responses The first analysis examined how many responses used a singular first noun, no matter what the grammatical number of the stimulus. As expected, there was no effect of counterbalancing group, nor did this factor interact significantly with any other factor. Whereas approximately 93.8% of all semantic match trials and 94.6% of all form match trials were responded to with the singular form of that noun, only 64.1% of all trials with an irregular target noun were responded to with the singular form (thus, 35.9% were responded to with the plural form). This difference was significant, $F(2,24) = 75.31$, $MSE = .013$, $p < .001$. Of trials with a singular target noun, 99.1% of the responses were also singular, whereas only 69.2% of the trials with a plural target noun were responded to with the singular form. This difference was also significant, $F(1,12) = 46.94$, $MSE = .046$, $p < .001$.

What is interesting is the interaction between these two factors. As can be seen in Figure 1, when the trial contained an irregular plural target noun, the response was the singular form only 30.0% of the time. For all five of the other combinations, the singular form was used between 88.8% of the time (for the regular plural target nouns, including both semantic and form match) and 99.1% of the time (for the singular nouns of any type). This interaction was significant, $F(2,24) = 70.534$, $MSE = .012$, $p < .001$. This result confirms earlier findings, notably those of Gordon (1985), that irregular plurals are readily produced as the first noun of noun-noun compounds in response to this type of elicitation frame.

RTs to Singular First Noun Responses This analysis looks at the time to respond with singular *mouse box* when shown either "a BOX for transporting a MOUSE is a _____" or "a BOX for transporting MICE is a _____", compared to the time to respond when regular forms were

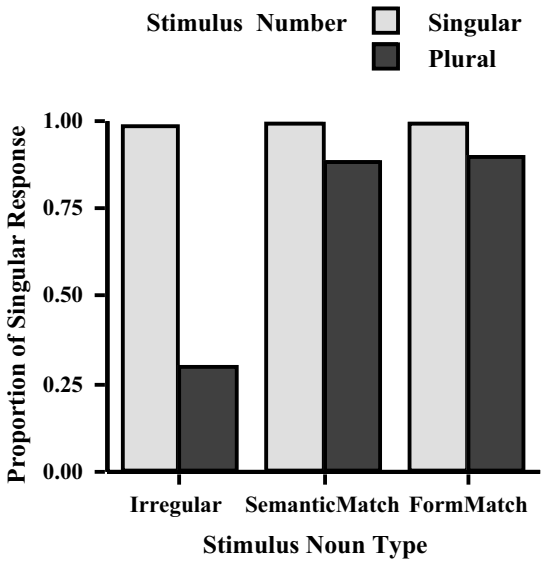

Figure 1: Proportion of singular response by noun type and grammatical number of the stimulus target word.

shown. This analysis includes only those trials in which the response was singular; thus fewer trials contributed to the irregular plural cell than to the other cells (as seen in Figure 1). Four participants responded with a plural 100% of the time when given an irregular plural stimulus. Thus, they had zero singular responses, and no mean RT could be computed for that cell. As a result, the data from those four participants were excluded from this analysis.

As expected, there was no effect of counterbalancing group, nor did this factor interact significantly with any other factor. RTs for the semantic match trials (796 ms) and the form match trials (799 ms) were significantly faster than for the irregular trials (894 ms), $F(2,16) = 6.18$, $MSE = 13179$, $p = .010$. RTs for singular-stimulus trials (787 ms) were significantly faster than for plural-stimulus trials (872 ms), $F(1,8) = 13.61$, $MSE = 10430$, $p = .006$. Most interestingly, the interaction between these factors, seen in Figure 2, was also significant, $F(2,16) = 6.90$, $MSE = 8075$, $p = .007$. As can be seen in the figure, it is the irregular plural stimuli that have the slowest RT; all other forms were responded to much more quickly.

An additional finding is that there was no significant difference between the semantic match and form match regular nouns, as can be seen in both Figure 1 and Figure 2, and confirmed by post-hoc tests. This result means the differences between regular and irregular nouns do not depend either on semantic or form similarity.

RTs to Trials with Plural Stimuli This analysis looks at the time to say *mouse box* or *mice box* when shown "a BOX for transporting MICE is a _____", compared to the time to say *rat box* or *rats box* when shown "a BOX for transporting RATS is a _____". In this analysis, both singular and plural responses were examined for all trials with a plural stimulus noun. As noted previously (and as can be inferred from Figure 1), the rate of plural response to

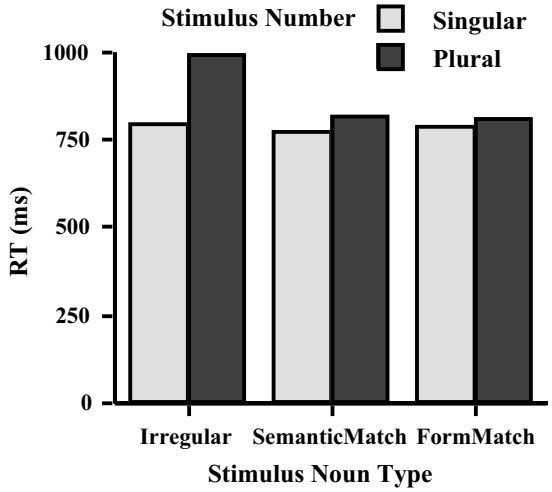

Figure 2: Response times in ms for singular responses.

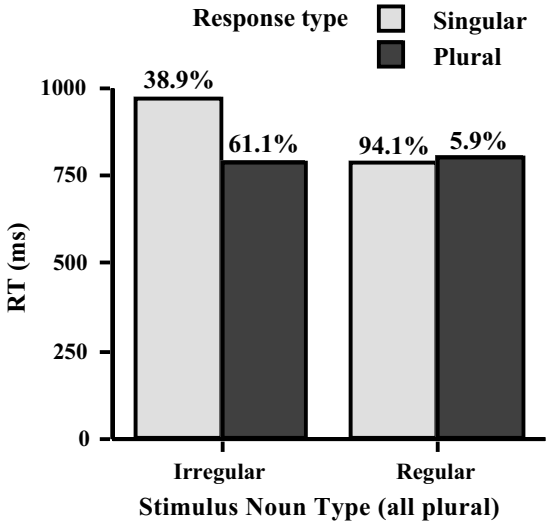

Figure 3: Response times in ms for both singular and plural responses to plural target noun stimuli. Numbers over the bars indicate the proportion of trials contributing to that cell.

regular plural stimuli was extremely low; so to increase the chance of a plural response, the two types of regular nouns were combined for this analysis. In addition to the four participants with no singular responses to irregular plural stimuli, one participant never responded to regular plural stimuli with a plural, and no mean RT could be computed for that cell. Thus, the data from these five participants were excluded from this analysis.

As expected, there was no effect of counterbalancing group, nor did this factor interact significantly with any other factor. In this analysis, neither the main effect of noun type nor the main effect of response type were significant. However, the interaction between these factors was significant, $F(1,7) = 6.36$, $MSE = 14120$, $p = .040$. As can be seen in Figure 3, there was no RT difference in producing a singular or a plural response to a regular plural stimulus or a plural response to an irregular plural stimulus. This can be thought of as the baseline time for responding. However, when participants were presented with an irregular plural stimulus to which the singular response was eventually made, the time was much longer.

Discussion

The proportion of singular response in this experiment showed a pattern similar to that found by Gordon (1985); that is, that when the participant is given an irregular plural noun in the stimulus, the response could be either singular or plural, but with all the other combinations of number and noun type, the response was almost invariably singular. Thus, this experiment, with added controls and stimuli, serves to verify that a typical college undergraduate population gives similar results to the children tested by Gordon. (Some of our participants, like some of Gordon's children, also provided self-corrections after their plural responses: "men bowl, oops, man bowl.")

What is new here are the response time findings. Specifically, when the response actually produced was singular, it took longer to produce when the stimulus was an irregular plural noun than when it was any other combination of number and noun type. Moreover, although it does not take longer to produce *rat* than *rats* when *rats* is seen, it DOES take longer to produce *mouse* than *mice* when *mice* is seen. We suggest that the times for the plural responses in Figure 3 show the times to inhibit the just-primed plural and produce the singular form instead. A model congruent with our findings would have the following properties: Given a form like *rats*, the plural affix *-s* is automatically segmented by the hearer/reader, allowing the regular singular *rat* to be strongly primed. On the other hand, given a form like *mice*, the singular is aroused only by re-accessing the lexicon where a *mouse-mice* link is stored, which presumably is a more time-consuming process.

To be more explicit, we think something like the following is going on. When the task is to respond to "a BOWL containing MICE is a _____", *mice* is strongly activated; *mouse* is likely activated as well but somewhat later and not as strongly, allowing both *mice bowl* and *mouse bowl* to be formed and compete with/inhibit each other. The constraint preferring singulars within compounds would also add inhibition to *mice bowl*, but because *mice bowl* starts out with higher activation, it wins more often. However, sometimes *mouse bowl* does win, when it and the constraint succeed in inhibiting *mice bowl*. In the regular case, when the task is to respond to "a BOWL containing RATS is a _____", *rats* is aroused, but *rat* is aroused as well. The constraint preferring singulars in compounds inhibits *rats bowl* even more strongly than it did *mice bowl*; that inhibition, along with the competition from *rat bowl*, serve to eliminate *rats bowl* in almost all cases, resulting in an output of *rat bowl* most of the time.

A number of theories of morphological structure, including Level Ordering, would be compatible with such a processing model. Our proposal does, however, postulate that speakers recognize and segment grammatical morphemes when the language structure supports it.

To be sure, our elicitation task, designed to parallel Gordon's (1985) task, and also to permit collecting reaction time data, is distinctly non-natural. The data we have collected do not speak directly to the problem of creating a real-time model of how plurals and compounds are created in natural speech. However, in the real world the situation is also not as neatly divided into regular and irregular nouns with different behavior. In the real world we find violations of the no-plurals-inside-compounds constraint (e.g., *civil rights legislation, fireworks display, parks commissioner*). Children also hear at least four nouns of English that have no singular form (e.g., *clothes*, *pants*, *scissors*, *glasses*). They hear these nouns both alone and in compounds (e.g., *clothes basket*, *pants leg*); such compounds are well-attested in input to children in CHILDES (MacWhinney, 2000). Eventually children will discover that these nouns are special in not having corresponding singulars, but initially the nouns may be apprehended as evidence that at least some plurals may be allowed within compounds.

The cornerstone of Gordon's (1985) and Pinker's (1994) argument for innateness of level ordering in grammar was that children who had no exposure to irregular plurals inside compounds nevertheless permitted them, as did adults. What we have shown is that adult production of plurals inside compounds in this type of elicitation task is probably a consequence of the difficulty in overcoming the strongly primed irregular plural form. Presumably children in Gordon's task faced the same problem. The fact that they behave like adults need not be due to their having an adult-like rule permitting irregular plurals in compounds, but rather to their having a similar human system for processing language stimuli.

To conclude, our finding points to a processing difficulty explanation for violations of the constraint against plurals within compounds in this elicitation situation: It is more difficult and time-consuming to produce the singular form of an irregular noun when primed with a stimulus of the plural form than it is to segment the regular plural marker, at least when it is an easily removable affix like the *–s* in English, and thereby retrieve the singular form. It is likely that the same explanation also works for the children examined by Gordon (1985). Given these results, we argue that Gordon's findings do not provide support for the notion of innate grammar.

Acknowledgements

We are grateful to Erica Wohldmann and James Kole for their assistance in scoring the tape recordings, to William Bright for editorial suggestions, to George Figgs for his CHILDES searches, and to Dan Jurafsky, Todd Haskell, and K. P. Mohanan for their comments and suggestions at various stages of this project. Simulating the Evolution of Modular Neural Systems

John A. Bullinaria (j.bullinaria@physics.org)
School of Computer Science, The University of Birmingham
Edgbaston, Birmingham, B15 2TT, UK

Abstract

The human brain is undoubtedly modular, and there are numerous reasons why it might have evolved to be that way. Rueckl, Cave & Kosslyn (1989) have shown how a clear advantage in having a modular architecture can exist in neural network models of a simplified version of the "what" and "where" vision tasks. In this paper I present a series of simulations of the evolution of such neural systems that show how the advantage *can* cause modularity to evolve. However, a careful analysis indicates that drawing reliable conclusions from such an approach is far from straightforward.

Introduction

Intuitively, given the obvious potential for disruptive interference, it seems quite reasonable that two independent tasks will be more efficiently carried out separately by two dedicated modules, rather than together by a homogeneous (fully distributed) system. Certainly there is considerable neuropsychological evidence that human brains do operate in such a modular manner (e.g. Shallice, 1988). In particular, the inference from double dissociation to modularity is one of the corner stones of cognitive neuropsychology, and over recent years double dissociation between many tasks have been established, with the implication of associated modularity.

Some early neural network models seemed to indicate that fully distributed systems could also result in double dissociation (e.g. Wood, 1978) and hence cast some doubt on the inference of modularity. Since then, the potential for double dissociation in connectionist systems with and without modularity has been well studied (e.g. Plaut, 1995; Bullinaria & Chater, 1995; Bullinaria, 1999), and the early connectionist double dissociations have been seen to be merely the result of small scale artefacts. Several later studies (e.g. Devlin, Gonnerman, Andersen & Seidenberg, 1998; Bullinaria, 1999) have shown how weak double dissociation can arise as a result of resource artifacts (e.g. Shallice, 1988, p232) in fully distributed systems, but it seems that strong double dissociation does require some form of modularity, though not necessarily in the strong (hard-wired, innate and informationally encapsulated) sense of Fodor (1983). Plaut (1995), for example, has shown that double dissociation can result from damage to different parts of a single neural network, and Shallice (1988, p249) lists a number of systems that could result in double dissociation without modularity in the conventional sense. In this paper, I am not so much interested in showing how double dissociation can arise in connectionist systems without modularity, but rather, how modularity can arise in connectionist systems and hence have the potential for exhibiting double dissociation.

Of particular interest to us here is the discovery that visual perception involves two distinct cortical pathways (Mishkin, Ungerleider & Macko, 1983) – one running ventrally for identifying objects ("what"), and another running dorsally for determining their spatial locations ("where"). Some time ago, Rueckl, Cave & Kosslyn (1989) considered the interesting question of why "what" and "where" should be processed by separate visual systems in this way. By performing explicit simulation and analysis of a series of simplified neural network models they were able to show that modular networks were able to generate more efficient internal representations than fully distributed networks, and that they learned more easily how to perform the two tasks. The implication is that any process of evolution by natural selection would result in a modular architecture and hence answer the question of why modularity has arisen.

Now, eleven years later, the power of modern computer technology has finally reached a level whereby the relevant explicit evolutionary simulations are now feasible. Already Di Ferdinando, Calabretta & Parisi (2001) have established that modularity *can* evolve. In this paper, I present the results of further simulations and conclude that, whilst modularity may arise, the situation is not quite as straight-forward as the original computational investigation of Rueckl et al. (1989) suggested.

Learning Multiple Tasks

Nowadays, the basic structure of simple feed-forward neural network models is well known. We typically use a three layer network of simplified neurons. The input layer activations represent the system's input (e.g. a simplified retinal image). These activations are passed via weighted connections to the hidden layer where each unit sums its inputs and passes the result through some form of squashing function (e.g. a sigmoid) to produce its own activation level. Finally, these activations are passed by a second layer of weighted connections to the output layer where they are again summed and squashed to produce the output activations (e.g. representations of "what" and "where"). The connection weights are typically learnt by some form of gradient descent training algorithm whereby the weights are iteratively adjusted so that the network produces increasingly accurate outputs for each input in a set of training data.

In this context, the question of modularity relates to the connectivity between the network's hidden and

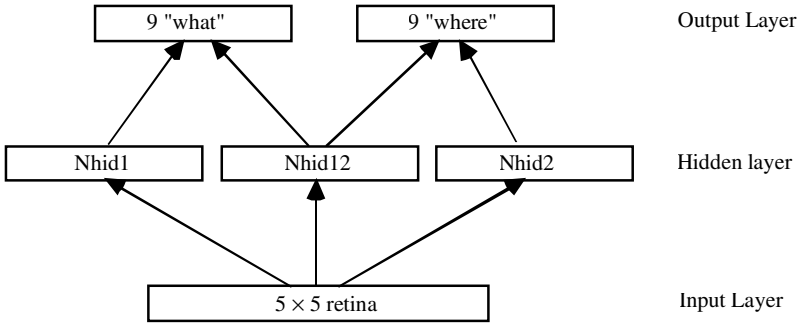

Figure 1: Architecture of the basic neural network model for the "what" and "where" tasks.

output layers. During training, a hidden unit that is being used to process information for two or more output units is likely to receive conflicting weight update contributions for the weights feeding into it, with a consequent degradation of performance relative to a network that has a separate set of hidden units for each output unit (Plaut & Hinton, 1987). However, such an extreme version of modularity with a set of hidden units (or module) for each output unit is likely to be rather inefficient in terms of computational resources, and an efficient learning algorithm should be able to deal appropriately with the conflicting weight update signals anyway. Nevertheless, splitting the hidden units up into disjoint sets corresponding to distinct output tasks, may be an efficient option. Indeed, it is hard to imagine how it could be optimal to expect a single set of hidden units to form more than one distinct internal representation.

It is well known that, when one trains a neural network using standard gradient descent type learning algorithms, the processing at the hidden layer tends to become fully distributed – in other words, there is no spontaneous emergence of modularity (e.g. Plaut, 1995; Bullinaria, 1997). However, the human brain is somewhat more sophisticated than a simple feed-forward network learning by gradient descent, and Jacobs, Jordan & Barto (1991) have shown explicitly how it is possible to set up gated mixtures of expert networks that can learn to process two tasks in a modular fashion. Such systems appear to have advantages in terms of learning speed, minimizing cross-talk (i.e. spatial interference), minimizing forgetting (i.e. temporal interference), and generalization. In a further computational study, Jacobs & Jordan (1992) have shown how a simple bias towards short range neural connectivity can also lead to the learning of modular architectures.

In this paper, I am more interested in the *evolution* of modularity than the *learning* of modularity. The old Nature-Nurture debate has come a long way in recent years (e.g. Elman et al., 1996), but it is still important to understand which characteristics are innate and which need to be learnt during ones lifetime. Moreover, as computer technology becomes more powerful, we are able to explore these issues by increasingly realistic simulations. Old ideas about the interaction of learning and evolution (e.g. Baldwin, 1896) can now be confirmed explicitly (e.g. Hinton & Nowlan, 1987). In suitably simplified systems, we have been able to observe the genetic assimilation of learnt characteristics without Lamarckian inheritance, see how appropriate innate values for network parameters and learning rates can evolve, understand how individual differences across evolved populations are constrained, and so on (e.g. Bullinaria, 2001). In the remainder of this paper I shall consider the evolution of modularity in neural network models of the "what" and "where" tasks previously studied by Rueckl et al. (1989). The lessons we learn here will be applicable to the learning and evolution of modularity more generally.

The "What" and "Where" Model

To avoid the need to repeat the extensive analyses of the learnt internal representations carried out by Rueckl et al. (1989), I shall study exactly the same simplified neural network model that they used, and explore whether the advantages of modularity they observed are sufficient to drive the evolution of modularity. I shall also follow Rueckl et al. (1989) and Jacobs et al. (1991) in emphasizing that the tasks we are simulating are vast over-simplifications of what real biological visual systems have to cope with. It makes sense to use them, however, despite their obvious unrealistic features, since they allow us to illustrate the relevant factors with simulations we can perform on current computational hardware in a reasonable amount of time.

The task consists of mapping a simplified retinal image (a 5 × 5 binary matrix) to a simplified representation of "what" (a 9 bit binary vector with one bit 'on') and a simplified representation of "where" (another 9 bit binary vector with one bit 'on'). I use the same 9 input patterns and 9 positions as in the previous studies, giving the same 81 retinal inputs for training on. Each of the 9 patterns consist of a different set of 5 cells 'on' within a 3 × 3 sub-retina array, and the 9 positions correspond to the possible centers of a 3 × 3 array within the full 5 × 5 array.

Figure 1 shows the basic network that was originally investigated by Rueckl et al. (1989). We have 25 input units, 18 output units and 81 training examples. The arrowed lines represent full connectivity, and *Nhid1*, *Nhid12*, *Nhid2* specify how many hidden units in each block. Rueckl et al. (1989) studied in detail the fully

distributed network (*Nhid1* = *Nhid2* = 0) and the purely modular network (*Nhid12* = 0). Our characterization will allow us to explore the full continuum between these extremes. If the maximum number of hidden units *Nhid* = *Nhid1* + *Nhid12* + *Nhid2* is fixed, then we need define only two innate architecture parameters *Con1* = *Nhid1* + *Nhid12* and *Con2* = *Nhid2* + *Nhid12* corresponding to the number of hidden units connecting to each output block.

Simulating Evolution

To simulate an evolutionary process for the models discussed above, we take a whole population of individual instantiations of each model and allow them to learn, procreate and die in a manner approximating these processes in real (living) systems. The genotype of each individual will depend on the genotypes of its two parents, and contain all the appropriate innate parameters. Then, throughout its life, the individual will learn from its environment how best to adjust its weights to perform most effectively. Each individual will eventually die, perhaps after producing a number of children.

In more realistic situations, the ability of an individual to survive or reproduce will rely on a number of factors which can depend in a complicated manner on that individual's performance over a range of related tasks (food gathering, fighting, running, and so on). For the purposes of our simplified model, however, we shall consider it to be a sufficiently good approximation to assume a simple relation between our single task fitness function and the survival or procreation fitness. Whilst any monotonic relation should result in similar evolutionary trends, we often find that, in simplified simulations, the details can have a big effect on what evolves and what gets lost in the noise.

I shall follow a more natural approach to procreation, mutation and survival than many evolutionary simulations have done in the past (e.g. in Belew & Mitchell, 1996). Rather than training each member of the whole population for a fixed time and then picking the fittest to breed and form the next generation, the populations will contain competing learning individuals of all ages, each with the potential for dying or procreation at each stage. During each simulated year, each individual will learn from their own experience with the environment (i.e. set of training/testing data) and have their fitness determined. A biased random subset of the least fit individuals, together with a flat random subset of the oldest individuals, will then die. These are replaced by children, each having one parent chosen randomly from the fittest members of the population, who randomly chooses a mate from the rest of the whole population. Each child inherits characteristics from both parents such that each innate free parameter is chosen at random somewhere between the values of its parents, with sufficient noise (or mutation) that there is a reasonable possibility of the parameter falling outside the range spanned by the parents. Ultimately, the simulations might benefit from more realistic encodings of the parameters, concepts such as recessive and dominant genes, learning and procreation costs, different inheritance and mutation details, different survival and procreation criteria, more restrictive mate selection regimes, protection for young offspring, different learning algorithms and fitness functions, and so on, but for the purposes of this paper, the simplified approach outlined above seems adequate. A similar regime has already been employed successfully elsewhere (Bullinaria, 2001) to study the Baldwin effect in the evolution of adaptable control systems.

The simulated genotypes naturally include all the innate parameters needed to specify the network details, namely the architecture, the learning algorithm, the learning rates, the initial connection weights, and so on. In real biological evolution, all these parameters will be free to evolve. In simulations that are designed to explore particular issues, it makes sense to fix some of these parameters to avoid the complication of un-foreseen interactions (and also to speed up the simulations). In my earlier study of genetic assimilation and the Baldwin effect (Bullinaria, 2001), for example, it made sense to keep the architecture fixed and to allow the initial innate connection weights and learning rates to evolve. Here it is more appropriate to have each individual start with random initial connection weights and allow the architecture to evolve. Then, since the optimal learning rates will vary with the architecture, we must allow these to evolve along with the architecture.

It is clearly important to fix the evolutionary parameters appropriately according to the details of the problem and the speed and coarseness of the simulations. For example, if all individuals learn the task perfectly by the end of their first year, and we only test their performance once per year, then the advantage of those that learn in two months over those that take ten is lost and our simulated evolution will not be very realistic. Since the networks were allowed to evolve their own learning rates, this had to be controlled by restricting the number of training data presentations per year to 10 for each individual. Choosing a fixed population size of 200 was a trade-off between maintaining genetic diversity and running the simulations reasonably quickly. The death rates were set in order to produce reasonable age distributions. This meant about 5 deaths per year due to competition, and another 5 individuals over the age of 30 dying each year due to old age. The mutation parameters were chosen to speed the evolution as much as possible by maintaining genetic diversity without introducing too much noise into the process. These parameter choices led to coarser simulations than one would like, but otherwise the simulations would still be running.

Experiment 1 – The Basic Model

I began by simulating the evolution of the system as stated above. For comparison purposes, this involved fixing the learning algorithm to be that used by Rueckl et al. (1989), namely online gradient descent with momentum on the Sum Squared Error cost function *E* (Hinton, 1989). As before, the target outputs were taken

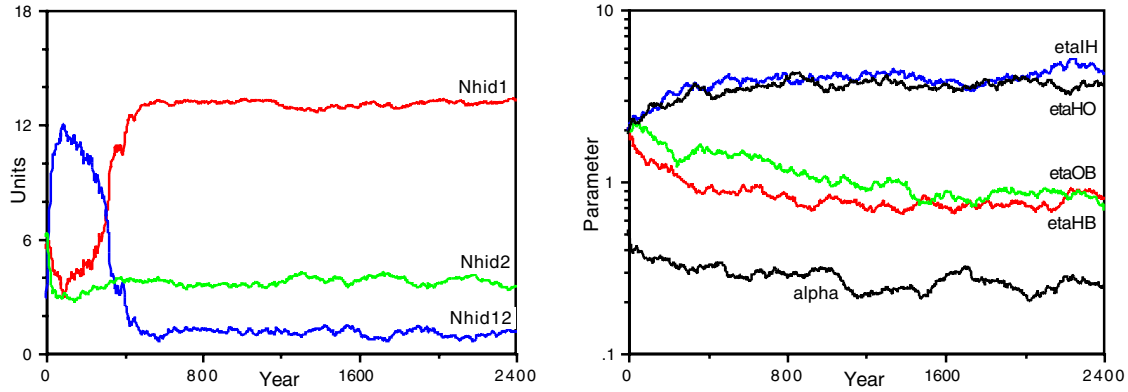

Figure 2: Evolution of the model in Figure 1 with Sum-Squared Error cost function and Log Cost fitness function.

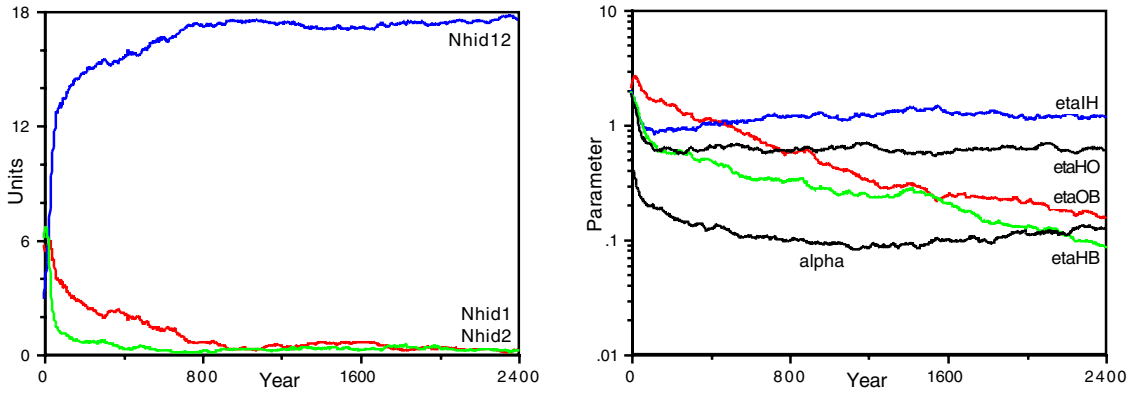

Figure 3: Evolution of the model in Figure 1 with Cross Entropy cost function and Log Error Count fitness.

to be 0.1 and 0.9, rather than 0 and 1, and appropriate outputs beyond these targets were deemed errorless. Experience indicates that the networks learn better if they have different learning rates for each of the different connection layers, and each of the different bias sets. So, to ensure that the architecture comparisons were fair in the sense that they were all learning at their full potential, each network had five learning parameters: the learning rate η_{IH} for the input to hidden layer, η_{HB} for the hidden layer biases, η_{HO} for the hidden to output layer, and η_{OB} for the output biases, and the momentum parameter α. These appear in the standard weight update equation

$$\Delta w_{ij}(n) = -\eta_L \frac{\partial E}{\partial w_{ij}} + \alpha \Delta w_{ij}(n-1).$$

Each genotype thus contained two parameters to control the network architecture, and five to control its learning rates. The Sum Squared Error cost distribution turns out to be rather skewed across the population, so the individual evolutionary fitnesses were defined to be –log(Cost).

I have found in my earlier studies (Bullinaria, 2001) that the evolution can depend on the initial conditions, i.e. on the distribution of the innate parameters across the initial population, and that the population settles into a near optimal state more quickly and reliably if it starts with a wide distribution of initial learning rates, rather than expecting the mutations to carry the system from a state in which there is little learning at all. Thus, in all the following experiments, the initial population learning rates were chosen randomly from the range [0.0. 2.0] and the momentum parameters randomly from the range [0.0, 1.0]. Following Rueckl et al. (1989), the initial weights were chosen randomly within the range [0.0,0.3].

Figure 2 shows how the innate parameters evolved when there were 18 hidden units in total (which is how many Rueckl et al., 1989, used). We see that the learning parameters soon settle down and, after a non-modular start, the population quickly evolves to take on a modular architecture with *Nhid12* near zero. This is exactly what we would expect from the Rueckl et al. (1989) study, right down the to optimal values for *Nhid1* and *Nhid2*.

Experiment 2 – Different Costs

The results of Experiment 1 make the evolution of modularity look almost inevitable. However, it would be misleading not to report on the countless simulations in which modularity did not evolve, and which could equally well correspond to human evolution, with the implication that modularity in the human brain must originate in some other manner. Figure 3 shows what can happen with one particularly reasonable alternative choice for the gradient descent cost function and

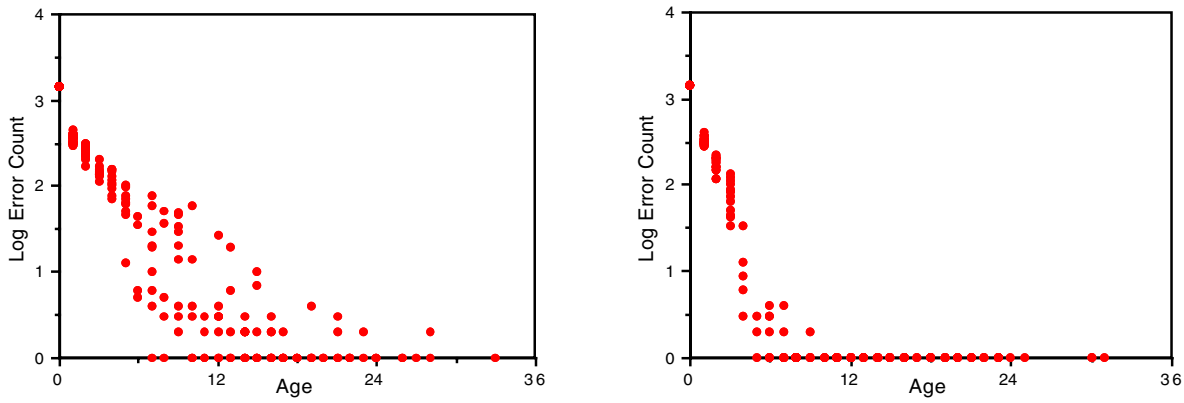

Figure 4: Comparison of evolved populations with Sum Squared Error (left) and Cross Entropy (right) cost functions.

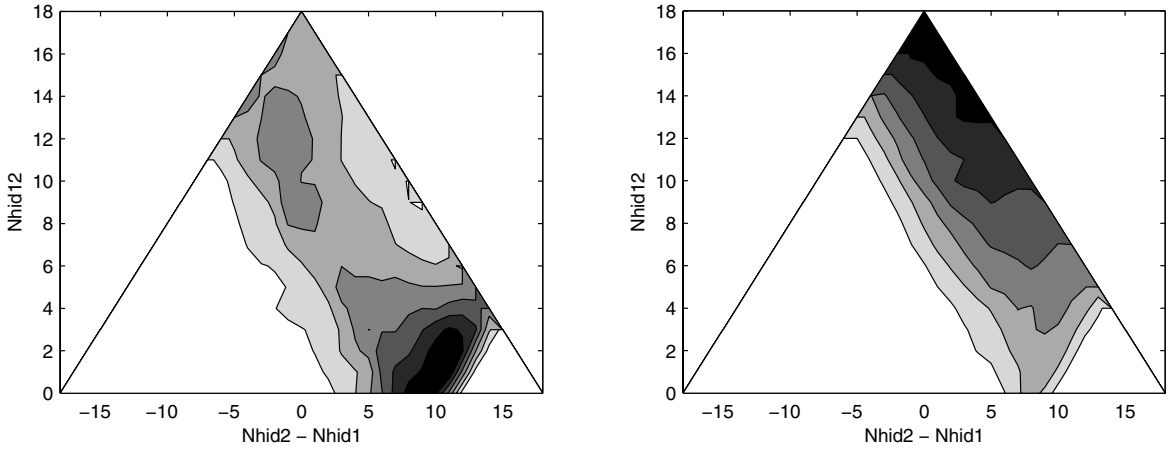

Figure 5: Mean learning times with Sum Squared Error (left) and Cross Entropy (right) cost functions.

evolutionary fitness function, namely the standard Cross-Entropy cost function (Hinton, 1989), and fitness defined by counting the total number of output units with errors above some small fixed value (0.2 say). This results in the evolution of a completely non-modular architecture. A systematic study reveals that changing the fitness between –Cost, –log(Cost), 1/Cost, –ErrorCount, and –log(1+ErrorCount) and has little effect on the results. However, the choice of cost function is crucial. Figure 4 compares the learning in the evolved populations for the Sum Squared Error and Cross Entropy cost functions with –log(1+ErrorCount) fitness. The non-modular Cross-Entropy population shows a clear superiority.

Although we should not rely on the mean learning rates to predict what will evolve (since the standard deviations, the worst and best cases, and so on, are also important), the plots in Figure 5 of the mean learning times as a function of the architecture do show quite clearly where the different optimal configurations (shown darkest) are situated.

Experiment 3 – Larger Networks

A final worry was that our simulations were suffering from small scale artefacts. Often when a network has barely enough hidden units to solve the task at hand, it behaves differently to when it has plenty of spare resources (e.g. Bullinaria & Chater, 1995; Bullinaria, 1997). Since 18 hidden units is near minimal for our task, all of the above simulations were repeated with 36 hidden units. This had little effect on the Cross Entropy simulations, but the results were rather variable with Sum Squared Error costs. Sometimes modularity evolved, sometimes it didn't, and often mixed populations arose. Apparently minor variations in the implementational details, or even just different random number seeds, could change the results completely.

Figure 6 shows the mean learning times here for comparison with those for the smaller networks in Figure 5. We see the Cross-Entropy plot has the same non-modular optimum as before, but the Sum-Squared Error case is now much noisier, with further, roughly equivalent, minima appearing in the non-modular regime. This is presumably why the evolutionary simulation results were so variable.

Conclusions

I have shown how it is possible to simulate the evolution of modularity in simple neural network models.

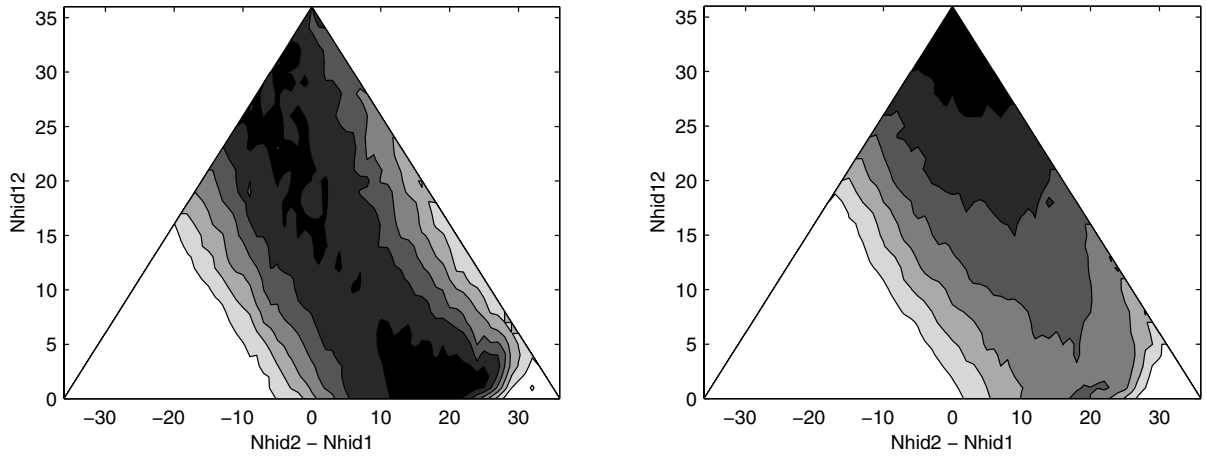

Figure 6: Large network learning times with Sum Squared Error (left) and Cross Entropy (right) cost functions.

However, drawing conclusions from them about the modularity in human brains is not so straightforward. If the results (i.e. modularity versus non-modularity) depend so crucially on such non-biologically plausible details as the learning algorithm, then it is clearly going to be rather difficult to extrapolate from them to biological systems. On one hand, we might expect that the human brain has evolved particularly efficient learning algorithms, in which case we could argue that the more efficient non-modular cross-entropy populations are the more realistic. On the other hand, real tasks are considerably harder than those used in our simulations, and so the modular populations might be deemed a more reliable representation of the actual relation between the human learning algorithm power and task complexity. The general simulation approach I have presented appears promising, but future simulations in this area will clearly have to be much more realistic if we are to draw reliable conclusions from them.

The Hot Hand in Basketball: Fallacy or Adaptive Thinking?

Bruce D. Burns (burnsbr@msu.edu)
Department of Psychology, Michigan State University
East Lansing, MI 48824-1117 USA

Abstract

In basketball, players believe that they should "feed the hot hand," by giving the ball to a player more often if that player has hit a number of shots in a row. However, Gilovich, Vallone & Tversky (1985) analyzed basketball players' successive shots and showed that they are independent events. Thus the hot hand seems to be a fallacy. Taking the correctness of their result as a starting point, I suggest that if one looks at the hot hand phenomena from Gigerenzer & Todd's (1999) adaptive thinking point of view, then the relevant question to ask is does belief in the hot hand lead to more scoring by a basketball team? By simulation I show that the answer to this question is yes, essentially because streaks are predictive of a player's shooting percentage. Thus belief in the hot hand may be an effective, fast and frugal heuristic for deciding how to allocate shots between member of a team.

The Hot Hand as Fallacy

Gilovich, Vallone and Tversky (1985) defined the "hot hand" in basketball as the belief that during a particular period a player's performance is significantly better than expected on the basis of a player's overall record. Gilovich et al. found that 91% of fans agreed that a player has "a better chance of making a shot after having just made his last two or three shots" and 68% said the same for free throws; 84% of fans believed that "it was important to pass the ball to someone who has just made several (two, three, or four) shots in a row." Numerical estimates reflected the same belief in streak shooting, and most players on a professional team endorsed the same beliefs. Thus belief in the hot hand appears to be widespread, and Gilovich et al. suggest that may it affect the selection of which player is given the chance to take the next shot in a game. This implication is captured by a phrase heard in basketball commentary: "feed the hot hand."

To test if the phenomena described by the hot hand actually exist, Gilovich et al. (1985) analyzed a professional basketball team's shooting over a season in order to see if streaks occur more often than expected by chance. They found that for each individual player, the proportion of shots hit was unrelated to how many previous shots in a row he had either hit or missed. Analysis also showed that the number of runs of hits or misses for each player was not significantly different from the expected number of runs calculated from a player's overall shooting percentage and assuming that all shots were independent of each other. The same independence was found for free-throws, as the probability of hitting a free-throw was the same after a hit as after a miss for a group of professional players. A controlled study of college players found the same independence between shots and found that observers could not predict which shots would be hit or missed. Thus the hot hand phenomenon appears to be a fallacy.

Why do fans and players believe in the hot hand if the empirical evidence shows that successive shots are independent? Gilovich et al. (1985) suggest that the persistence may be due to memory biases (streaks are more memorable) and misperception of chance, such as belief that small as well as large sequences are representative of their generating process (Tversky & Kahneman, 1974). Falk and Konold (1997) see the hot hand as a cognitive illusion that is another example of people's inability to perceive randomness. Again we see people inventing superfluous explanations because they perceive patterns in random phenomena.

Gilovich et al.'s (1985) result has been cited over 100 times in journals. Many of these citations are in the decision making literature, but it is also widely cited across a variety of fields. There are many citations in sports science (Vergin, 2000) and economics (Pressman, 1998), but it has also been cited in literature on law (Hanson & Kysar, 1999) and religion (Chaves & Montgomery, 1997).

There have been some challenges to Gilovich et al.'s (1985) conclusion that there are no more streaks than expected by chance in basketball, or at least to the finding's generalizability. Gilden and Wilson (1995) found some evidence of more streaks than expected in golf putting and darts, although they explain this as due to fluctuations in performance producing more streaks than expected rather than a real dependence between events. Miyoshi (2000) used simulations to suggest that Gilovich et al.'s analysis may not have been sensitive enough to detect the hot hand if hot-hand periods are relatively infrequent. However, in this paper I will assume Gilovich et al.'s (1985) conclusion that successive shots in basketball are independent events, in fact, my analysis will depend on it.

One reason for the wide interest in Gilovich et al.'s result may be the implications it appears to have for behavior. As Gilovich et al. (p. 313) state "...the belief in the 'hot hand' is not just erroneous, it could also be costly." This is because it may affect the way shots are allocated between members of a team. However, I will argue in this paper that this implication does not

necessarily follow from their analysis, rather belief in the hot hand may actually be adaptive.

The Hot Hand as Adaptive Thinking

Gigerenzer and Todd (1999) emphasize that humans and animals make decisions about their world with limited time, knowledge, and computational power. So they propose that much of human reasoning uses an adaptive tool-box containing fast and frugal heuristics that make inferences with limited time, knowledge and computation. Their viewpoint is based on a conception of bounded rationality. They contrast this with an assumption of unbounded rationality, which leads to a focus on the question: what is the normatively correct answer? Gigerenzer and Todd instead argue that one should ask: what is adaptive? That is, what behavior will meet the person's goals and uses a process that stays within the bounds of their resources?

From the point of view of basketball, whether successive shots are independent may not be the most relevant question to ask. What is adaptive for them is to maximize the number of points their team scores, so the question to be asked is does belief in the hot hand lead to more scoring than would disbelief in the hot hand?

The practical effect of belief in the hot hand is that it affects distribution of the ball. This is reflected in the statement that Gilovich et al. (1985) presented to fans and players, "it is important to pass the ball to someone who has just made several (two, or three, or four) shots in a row." Who should take the next shot is a question faced by the members of a team every time they have possession of the ball. In the absence of a time-out, it is a decision that each member of the team have to make by himself or herself in, at most, 30 seconds. Every player on a professional team is probably aware of the shooting percentage (i.e., what percentage of a players total number of shots a player hits) for each member of the team. However, knowing that one player has a 55% and another a 60% shooting percentage, does not tell one how often to give the ball to each player, given that one cannot simply give the ball to the player with the higher shooting percentage every time. Players are unlikely to be able to do a calculation to determine the optimal distribution, so fast and frugal heuristics for deciding who should take the next shot are likely to be exploited if they are effective in increasing scoring.

I propose that belief in the hot hand is such a heuristic. The basic argument is straight forward: if one accepts Gilovich et al.'s (1985) finding that successive shots are independent events, then the higher a player's shooting percentage is, the larger the number of runs of hits a player will have. Therefore, a bias to give the ball to players with the hot hand is equivalent to a bias to give the ball to players with higher shooting percentages. Giving the ball to the player with the hot hand requires no calculation, it requires only remembering the most recent shots, and it can be decided fast. Thus belief in the hot hand could be an example of adaptive thinking.

I will support this analysis with computer simulations testing whether a team that believes in the hot hand will outscore one that does not. However, I will first show empirically that players with higher shooting percentages experience more runs of hits.

Empirical Analysis

Gilovich et al. (1985, Table 1) presented the probabilities of players making a shot after runs of hits or misses of length one, two and three, as well as the frequencies of each run for players. The statistics came from analysis of the 48 home games of the Philadelphia 76ers during the 1980-81 season. In Table 1, I have re-analyzed this data to calculate for each player the proportions of his total number of shots (excluding a player's first shot in a game) which were parts of runs of hits or misses of length 1, 2, and 3.

Table 1: Proportions of players total shots that were parts of runs of 1, 2, or 3 hits, or 1, 2, or 3 misses. Correlations are between these proportions and the players' season long shooting percentage (all significant at $p < .01$)

Player	Shooting percentage	Total shots	3 misses	2 misses	1 miss	1 hit	2 hits	3 hits
Lionel Hollins	.46	371	.11	.25	.54	.46	.18	.07

Correlations with shooting percentage:			-.804	-.874	-.993	.993	.954	.899

If shots are independent events, then the higher a player's shooting percentage, the larger the number of runs of hits he should have and the fewer number of runs of misses he should have. Table 1 presents the correlations between a player's shooting percentage and the proportion of his shots that were parts of runs of each length. As can be seen, all runs of misses are highly negatively correlated with shooting percentage, and all runs of hits are highly positively correlated with shooting percentage (all $p < .01$). This supports Gilovich et al.'s (1985) argument that successive shots are independent events, and also the consequence of my argument that runs are predictive of a player's shooting percentage.

Design of the Computer Simulations

In creating the simulations I strove to make them as transparent as possible and to utilize as few free parameters as possible. The basic simulation of basketball shooting had two parameters for each player: an allocation and a shooting percentage. The *allocation* is the probability of a player being given the next shot, whereas the *shooting percentage* is how often the player hits a shot. The sum of allocation parameters for all players must be 1.0 and was used to represent some underlying bias to give the ball to a player. No assumption was made regarding the source of these biases, but it was fixed for the length of a simulation. Shooting percentage reflects a player's ability to hit shots, and was also fixed for the length of a simulation, as it was for Gilovich et al.'s (1985) analysis.

The program simulated basketball shooting, with one shot per trial. On each trial a player was randomly selected to be given the next shot, with each player having the probability of being given the shot indicated by their allocation. The player given the shot then randomly hits or misses the shot with a probability indicated by the player's shooting percentage.

To simplify the simulations, rather than represent all five members of a normal basketball team, only two will be included. This reduces the number of parameters and how many players are represented should not matter with regard to the conclusions I wish to draw from the simulations. To further reduce the number of free parameters the allocation and shooting percentages were only varied for one player, and the other player's parameters were simply one minus each of the first player's parameters. Thus a whole simulation was described by just two free parameters, allowing the entire parameter space to be explored.

To simulate belief in the hot hand, a simple rule was used that determine who should be given the next shot:

1) Give the next shot to a player which has the longest run of hits (in effect, the one who hits its most recent shot), then keep giving it to that player until a miss.

2) If both players have missed their last shot, then the allocations parameters were used to select a shooter randomly.

The hot-hand could be simulated in other ways, but this seems a simple, easily understandable version, and it is parameter-less. More complicated ways of calculating who has the hot-hand would involve arbitrary parameters but produce the same pattern of results.

To test the effect of belief in the hot-hand, two simulations were run with each combination of the two parameters. Simulations with a given combination of parameters were run in pairs. In one run, the hot hand rule was turned on, and in the other it was turned off so the player to take the shot was always determined randomly using the allocation parameter. All parameter combination for allocation values from 0.01 to 0.99 were run in increments of 0.01, and shooting percentage values from 0.50 to 0.99 in increments of 0.01 (0.00 to 0.49 would simply repeat the other combinations). Thus 4851 pairs of simulations were run.

Results of the Simulations

Each combination of parameters was run for 1,000,000 trials with the hot-hand rule, and 1,000,000 without it. Each simulation produced a score, which was how many of the trials were hits. To determine the effect of belief in the hot-hand, for each parameter pair the score for the simulation without the hot-hand rule was subtracted from the score from the simulation with the hot-hand. This difference was divided by the total number of trials to yield an advantage score (adv):

$$adv = \frac{\text{(score with hot hand) - (score without hot hand)}}{\text{total number of trials}}$$

Figure 1 presents a contour graph for the 4852 (49x99) pairs of simulations (the 0.50 shooting percent parameter is excluded because when there is no difference between players, there is nothing for the hot hand to exploit). This graph represents three dimensions of information: the allocation percentage, the shooting percentage, and the adv score in favor of the hot hand simulation for that combination of parameters. The numbered contours define boundaries in the distribution of adv scores found for parameter pairs. So, for example, for every combination of parameters above the line labeled "0.2" the hot hand simulation scores at least 0.2 points per trial of the simulation (on every trial the players score 0 or 1). The areas at the bottom of the graph labeled "0.0" indicate regions in which the hot hand lost in this set of simulations. (To creates these plots I used Sigma graph, which tried to "smooth" contours resulting in these odd shapes.)

Almost all the pairs of parameters yielded positive advantage scores. Not surprisingly, the greatest advantage occurs when shooting percentage is high and allocations are low, as in effect the hot hand rule increases the allocation for the player with the higher shooting percentage. As Figure 1 shows, only when the shooting percentage is low, which is when the two players differ little in shooting percentage, does the hot hand sometimes lose. Figure 1 also shows that there is no systematic relationship between allocation and shooting percentage which results in the hot hand doing worse. When the hot hand does worse is essentially random and only occurs when there is little difference between the players for the hot hand to exploit. The most negative advantage score obtained was -0.0018 points per trial.

Table 2 shows for how many of the simulations with each shooting percentage (99 as the allocation varies from .01 to .99) the hot hand wins. When shooting percentage is equal to .50 then it should be random which simulation wins because the hot hand cannot help the better shooter when the two players do not differ. As the shooting percentage increases, and thus the difference between players increases, loses by the hot hand simulation become rarer. There were no losses by the hot hand for shooting percentages in excess of .60. There was no systematic relationship between allocation parameters and loses by the hot hand, except for a few extra loses at allocations of 0.99.

Table 2: The number of allocation values (99) that the hot hand simulation wins or loses for each shooting percentage parameter less than .61.

Shooting percentage	Hot hand loses	Hot hand wins
.50	44	55
.51	48	51
.52	21	78
.53	10	89
.54	2	97
.55	2	97
.56	1	98
.57	2	97
.58	2	97
.59	1	98
.60	1	98

.

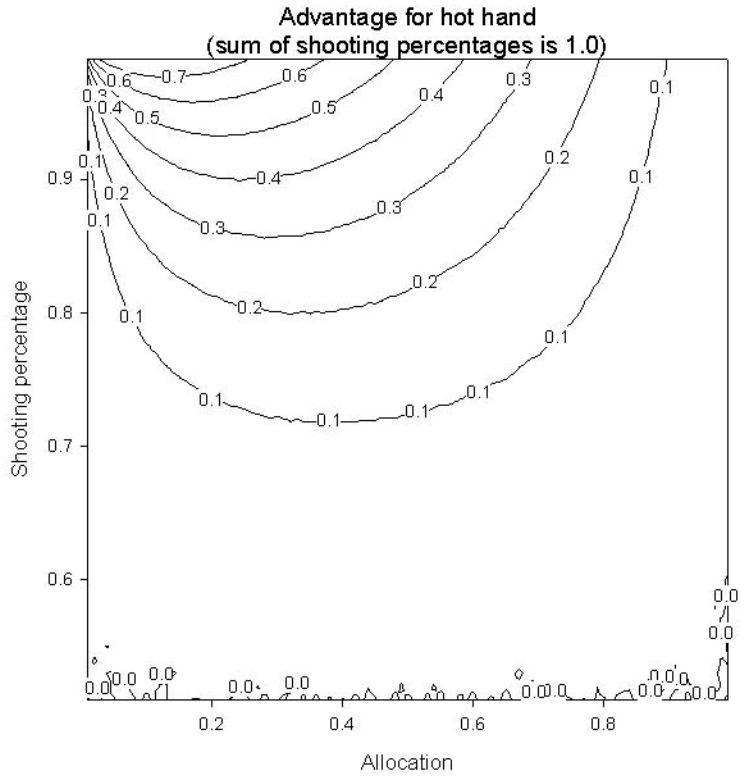

Figure 1: Contour graph showing how many points per trial the simulation using the hot hand rule came out ahead of the simulation not using the hot hand rule, for every pair of shooting percentage and allocation parameters. The lowest shooting percentage is 0.51 and highest is 0.99. The range for allocation parameters were 0.01 to 0.99.

One question that may be raised is whether the results are due to one player having a shooting percentage below 50% and the other above 50%. To check this, a set of simulations were run which were identical to the above set, but the sum of the two shooting percentages for the two players equaled 0.50. So the shooting percentage parameter was varied from 0.25 to 0.49. Very similar results were obtained with the hot hand only recording loses when the two shooting percentages were very close. Simulations of defenders acting on belief in the hot has also shown that it helps them.

Why the hot hand wins is quite clear. The hot hand rule has no effect on the percentage of shots hit by a player and does not introduce any dependencies between successive shots by the same player, instead it leads to the player with the higher shooting percentage being given more shots. In effect, the hot hand increases the allocation parameter for the player with the higher shooting percentage.

These simulations are of course not complete simulations of basketball games. Realistic simulations of ten players interacting on a basketball court are not possible, and thus this simulation cannot be compared directly to real data from basketball players. This however is not the point of the simulations, instead they are intended as an instantiation of the thought experiment conducted above, that belief in the hot hand should increase scoring by a team if successive shots are independent events. The belief increases the likelihood that the best scorers will take more shots, thus it is adaptive. The simulations are actually unnecessary if one already accepted the basic argument. However if one accepts this argument then it changes the interpretation of the data of Gilovich et al. (1985) and any other belief regarding streaks when the events making up the streaks are independent.

Fallacy and Adaptation

Is the hot hand a fallacy or adaptive thinking? In a sense it can viewed as both, it depends on what question one thinks is the most relevant one to ask.

The question that Gilovich et al. (1985) sought to answer was whether basketball players produce more streaks of hits or misses than expected by chance given their underlying shooting percentage. Their analysis showed that the answer to this question was "no", for an individual. The analysis presented here in no way challengers this result, in fact it is built into the simulations as an assumption. It may seem obvious that if a belief in the hot hand as defined for an individual is erroneous, then it must also be erroneous when applied to a team. Gilovich et al. (1985) make this quite understandable connection without comment, and thus make statements about the supposedly negative consequences for a team of passing the ball to the player with the hot hand.

The ease with which one can slip from referring to an individual's behavior to a team's behavior is reflected in the statements Gilovich et al. (1985) asked basketball fans and players to consider. Gilovich regard both of the following two statements as indicators of an erroneous belief in the hot hand:

1) "[a player] has a better chance of making a shot after having just made his last two or three shots than he does after having missed his last two or three shots"

2) "it is important to pass the ball to someone who has just made several (two, three, or four) shots in a row"

Statement 1 refers to an individual's streaks, and Gilovich et al. (1985) show empirically that it is incorrect. However, Statement 2 is about a team's decisions about how to allocate shots between players. Gilovich et al.'s data does not address this question, but the arguments and simulations presented here show that Statement 2 is correct. It is adaptive rather than an erroneous belief. From this conclusion, it is interesting to note that Statement 2 was the only statement given to the professional players by Gilovich et al. that was endorsed by every one of them.

The alternative question regarding the hot-hand is suggested by Gigerenzer and Todd's (1999) approach: is belief in the hot hand adaptive? Whether there actually are streaks in individual players' shooting is irrelevant from this point of view. The basketball players' primary goal when his or her team has possession of the ball is to maximize the number of points that the team scores (notwithstanding the behavior of some current NBA stars), as that is what determines the outcome of the game. If belief in the hot hand (as defined as giving the ball to the player experiencing a streak) tends to increase point scoring as compared to when the hot hand is disregarded, then the hot hand is adaptive thinking rather than a fallacy. "Feed the hot hand" can be seen as a fast and frugal heuristic for making a critical decision: who should get the next shot? Belief in the hot hand provides a quick and easily assessable answer to this question. (This is not to imply that the hot hand is the only way, or always the best way, to make this decision. Like any heuristic, it may fail.)

If there were fluctuations in a player's underlying shooting percentage, which could arise for various reasons, then the hot hand provides a further advantage over any calculations based on a shooting percentage or some other product of the history of a player. The hot hand is immediately sensitive to fluctuations because if a player's shooting percentage changes then his or her expected number of streaks will be affected immediately. The impact of fluctuations on a player's season long shooting percentage, or any other statistics,

will be delayed. Gilden and Wilson (1995) argue that such fluctuation could create streaks despite independence between successive events. Whether Gilovich et al.'s analysis was sensitive enough to detect such streaks is a question raised by the analysis of Miyoshi (2000) who points out that it would depend on the frequency and duration of such events. However, even if there are no fluctuation driven streaks in basketball, there may be in other multi-trial tasks, and thus belief in the hot-hand may be a general heuristic that people learn is effective in a variety of situations.

It could be argued that even if the belief in the hot hand is adaptive then it may originate and be sustained by a fallacy regarding the streaks of individuals. Thus basketball players may have just got lucky that their fallacy helps rather than hinders them. I have presented no evidence regarding the origin of the belief in the hot hand, and I doubt that players are consciously using the analysis I present here to support their belief in giving the ball to the player with the hot hand. However, it could be argued that what sustains belief in the hot hand is simply that players have learned that giving the ball to the player experiencing streaks has a positive outcome. The work on implicit learning shows that people may not necessarily know what they have learned. Nisbett and Wilson (1977) review evidence that people may make appropriate decisions without conscious awareness of the true reasons why they made that decision, and then they may make up plausible sounding reasons for their behavior. The erroneous beliefs fans and players make about the consequences of streaks by individual players may simply be an attempt to rationalize a behavior they have learned is adaptive. Thus belief in streaks for individuals may be a misanalysis of the reasons for an accurate perception of the hot hand as it applies to a team play, rather than a misperception of sequences which appears to be the basis of the gambler's fallacy. The connection between the gambler's fallacy and the hot hand, which may be related but describe the opposite behavior (i.e., go with the streak, verse go against the streak), may be a fruitful area for future research.

In summary, the final answer to the question posed by the title depends on which question one prefers to ask. Either, what is a normatively correct way of describing the performance of an individual basketball player, or what may lead to a higher score in a game? Even though the relevance of both questions can be seen, to an adaptive organism the later question should be more important on the basketball court.

Acknowledgments

Modelling Policies for Collaboration

Abstract

There are different ways in which learners can be organised when working together collaboratively. The issue discussed here is how to organise collaborative activities to help students *learn* how to collaborate — in particular, which *policy* is the best one to adopt for managing group communication to achieve this end. Here, different policies are considered which might apply during collaborative task performance. A computation model (Clarissa) is used to examine how these different policies perform in a collaborative task performance. The behaviour of the model is examined from the point of view that participants need to experience a range of dialogue roles which reflect the linguistic functions of utterances that are involved in collaboration. The results derived from the analysis of the behaviour of the computation model complements empirical work on small group behaviour.

Models of Collaboration

Collaboration may be mainly "in the eye of the beholder": in many educational settings the children collaborating are scarcely aware of any rules governing their work together. This leads to the notion that there are degrees of collaboration, that there may be a value for methods of assessing *how much* collaboration there is.

When the process of collaboration is examined, there is an issue about whether the current task is divided into parts tackled by different collaborators or whether collaboration entails synchronous effort with no division of the task. This task centred perspective may be appropriate when the focus is on task completion but other issues become important if the emphasis is on learning outcomes, or on the process of collaboration itself.

Whether collaboration is the means to the end of learning some domain material or whether collaboration is in some sense the end itself. In the former case, learning efficiency may be most important but in the latter case, efficiency is not the key issue — indeed, when learning to collaborate is the primary goal it may well be that inefficient domain learning is inevitable.

One view of collaboration is that part of the process of task performance requires that there is some agreement about the nature of the task — and this can be quite complex. For example, the view of Roschelle and Teasley that collaboration is "a coordinated, synchronous activity that is the result of a continued attempt to construct and maintain a shared conception of a problem" (Roschelle and Teasley, 1995). For Roschelle and Teasley, part of task performance involves synchronous effort with no division of that particular part of the task. This approach may serve to define when collaboration is taking place and when it is not — but it provides little help in determining, for example, the quality of the collaboration or how learners become more proficient at collaboration.

In contrast, here, learners are assumed to have some task to perform together, and that some way is required of estimating the quality of any perceived collaboration. The emphasis is therefore on the collaborative process as opposed to the collaborative state. The main issue that is examined is learning to collaborate so domain-based learning outcomes are of less interest.

The key notion is that good collaboration is characterised by an even distribution of dialogue roles. The justification is based on a model of distributed cognition in which cognitive processes communicate with each other (Minsky, 1987). The further assumption is that learning to collaborate is best for the group of learners when each learner exercises all the dialogue roles available, and all dialogue roles are exercised equally.

Defining dialogue features as dialogue roles, and analysing dialogue for these roles gives a broader framework in which to view collaboration. This is useful since Webb and Cohen (and others) come up with different necessary conditions for good collaboration (Webb, 1983; Cohen, 1994). For example, while Cohen suggests that the task may be responsible for determining what roles are possible in a situation, she also argues that roles (and dialogue features) are crucial in themselves.

Policies for Collaborative Activity

The aim is to examine which policy is likely to be "best" in terms of some measure. To achieve this, a number of likely candidates are described. The main hypothesis investigated is that "Normal" collaboration, unrestricted by any enforced distribution of dialogue roles[1], except that certain social norms operate, does not yield the optimum results for learning to collaborate (according to the measure we adopt below).

The basic policy that is closest to perhaps the most familiar form of collaboration is termed *Free*. For this

[1] i.e. linguistic functions of utterances used in collaboration

"normal" case, agents are permitted to drop roles whenever they wish. The primary restraint on their role usage is that two agents are not permitted to have the same role at the same time — roughly, normal social behaviour.

Other forms include *Multi*, *Swap* and *Polite*. Viewed as constraints on behaviour, some of these forms can be combined to yield, for example, *MultiSwap* and *MultiPolite*. The *Multi* policy allows agents to use the same role at the same time (to do so, the number of roles had to be slightly simplified). The resulting conversations will be "strange" in that the dialogue will seem to lose its coherence to some degree as questions are asked together, and agents may "reply" with other questions (Clarissa agents have a very good memory which is a key feature of this collaborative situation).

For the *Swap* policy, the opening of a new dialogue game is an indication of a new episode, and at this point, agents drop the roles they are playing (it does not follow that they would choose different ones for the next episode). This approach is derived from an observation by Soller who found that in the cases where people do choose different roles at the beginning of new episodes, collaborative activity is more beneficial (according to her measures) (Soller, 1997). The *Polite* policy arranges for agents to 'drop' their roles at the *end* of episodes. Rather than swapping roles at the beginning of a new episode, the participant who has lead an episode stands back for the next. In other words, if you have been taking the lead for a while, stop, and let somebody else take the floor.

MultiSwap, in an educational context, is equivalent to a situation in which collaborators can ask all the questions they have, and say everything they can about a problem. They pay careful attention to everything said by their partners. Questions, comments and suggestions must be noted down. An alternative approach is *MultiPolite* collaboration which differs from *MultiSwap* in the same way that *Polite* and *Swap* differ.

Clarissa's Architecture

The architecture is divided into two main subsystems: the cognitive and dialogue systems. The cognitive system is broken into separate units (cognitive processes), which then communicate with each other.

This architecture is rooted in notions of distributed cognition. Hutchins draws a parallel between the division of labour and the division of cognitive processes (Hutchins, 1995). Collaborative activity may not be obviously divided at the domain level, but individuals may each be exercising different cognitive processes. Clark and Chalmers advocate that cognition is not bounded by the skin, but encompasses a wider context (Clark and Chalmers, 1998). They develop active externalism, noting that internal cognitive processes are coupled in a two-way interaction with external entities. Bearing in mind that Vygotsky talks in terms of dialogue behaving as stimuli in the process(es) of solving a task, Clark and Chalmers go on to discuss the function of language as the means of coupling cognitive processes to the external environment. They conclude that the ability to communicate between internal and external processes, extended cognition "...is no simple add-on extra, but a core cognitive process". Here, this is taken as meaning that the mechanism by which processes are coupled (and communicated) internally are very similar to those which allow external coupling.

All communication that might normally be regarded as occurring within the cognitive system are made using the dialogue system (see below). The decision about which utterances are 'hearable', and which passed directly between cognitive processes within the agent are made within the dialogue system. Other than with respect to communication, individual cognitive processes may be implemented in any way. Clarissa itself uses a very simple forward chaining production rule system.

The dialogue system uses a 'dialogue game' mechanism to maintain the focus[2], and form a prediction about what might be said next. A dialogue game is defined to be a state machine which represents the entirety of possible dialogue utterances and the order in which they can occur. Parallel dialogue threads are used to let agents keep a number of topics active at the same time.

The dialogue role mechanism is used to control the communication between cognitive processes. A dialogue role can be seen as defining a (complex) zone within a dialogue game, a 'sub dialogue game'. Roles that one agent is playing cannot be used by another. Roles are swapped frequently, and the effect of this restriction is to model the way people normally respond to each other, one asking a question, the other replying and so on. To decide what is said next, both the role that individuals are playing, and the dialogue game is examined. Clarissa allows for a variety of dynamic mechanisms for distributing roles throughout the period of the ongoing dialogue.

The dialogue system must allow messages to be passed between the cognitive processes found in the cognitive system. To achieve this communication, a new abstraction is introduced, a *dialogue goal*. A dialogue goal is an expression of the communicative act (Maybury, 1993) that the cognitive system wishes to take place. The dialogue system can then choose how best to achieve this goal. The cognitive process initiates a dialogue goal whenever it wishes to pass a message to another process. These are 'thrown over the wall' to the dialogue system which requires that the goals the cognitive system generates are understandable by the dialogue system so there will be some dependency between these two systems. Goals so delivered, and acted upon by the dialogue system may eventually be completed. The desired result is that the relevant messages are delivered back to the cognitive system. To do so requires that there is some mechanism in the dialogue system for passing information back to the cognitive system.

Any number of Clarissa agents can collaborate, and they do so within a specific computational context. The task context used for this paper requires that the simulated novice physics students have to draw a diagram to

[2]Related to McCoy's approach (McCoy and Cheng, 1991)

represent how energy flows through a n electrical circuit with a charged battery connected to a bulb (with two wires), and makes a bulb shine. Space precludes a full discussion of the architectural issues — see (Burton, 1998; Burton et al., 2000) for more details.

Experimenting with Clarissa

The Clarissa system was set up to run two Clarissa agents collaborating on the standard test problem for a hundred runs for each of a number of policies (Clarissa agents act in a distributed network). The results were interpreted in terms of the distribution of roles throughout the task performance. This is in line with the underlying claim that exercising the range of available roles is advantageous, and that role usage is balanced between the participants.

Role usage is approximated by the number of utterances which are made by participants while an individual is 'playing' that role. Different policies are compared so that a provisional determination can be made about the ways in which collaboration can be organised to yield good collaboration. To analyse the various different collaborative environments samples of 100 pairs were used. Table 1 presents the important statistical measures.

There are two key ideas in the (non-standard) statistical analysis. Firstly, there is an analysis of the degree to which agents are split by the collaborative environment within a pair, so that one performs differently from the other. Secondly, it is also possible to discover something about how they perform differently by looking at the correlation between the agents. It might be hoped that agents in a pair perform equally. The above statistic (the significant split) will tell us whether it is likely that the differences between the participants in a pair can be accounted for simply by the variation in the population in general. Ideally, agents in a pair that uses a given role a lot shares this usage between the agents. In other words, if one agent uses a role a lot, the other should do likewise. For the purposes of this study, it is desirable to have a positive correlation between the two agents for all of the roles investigated. Negative correlations are likely to result in significantly split role usage. A negative correlation implies that the collaborative environment, of itself, is inducing the agents to divide the roles unevenly.

Any role usage which seems to be negatively correlated between two agents is of interest. Positive correlations are to be encouraged, as they imply that the agents are splitting the role between themselves sensibly. These statistics are used to determine how many of the roles are being played equally by participants in a pair, and how many are unevenly split, for a given collaborative environment. Additionally, the number of times agents receive interesting information from their partner is used[3]. In summary, the metric for good collaboration, according to the criteria that roles should be evenly distributed is that: Neither roles, nor the number of times agents receive interesting information from their partner, should be significantly split, or negatively correlated.

In Table 1 the results are interpreted in the case of the *Free* policy, 5 out of the 7 roles, and the number of "interesting" moves received by agents (6 out of 8 in other words) are significantly negatively correlated. this statistic indicates the degree to which the two agents in the pair share out the usage of a role.

In this case, as one agent used a role more, the other uses it correspondingly less, (and similarly the number of interesting events recoded by each agent follows a similar pattern). Correspondingly, all those roles which are significantly split, are also significantly negatively correlated (again, at the 1% level). Here the statistic is measuring the propensity of an agent to use a role more while their partner uses it less. Thus in the *Free* case, 6 out of 8 roles are negatively correlated, indicating that one agent tends to use the role more while the other uses it less.

The effects of this collaborative environment can be characterised in terms of the measure defined above as having 6 out of 8 roles significantly split and negatively correlated and a mean number of interesting events of 24.9 which is significantly split between agents in a pair, with the mean difference being 12.8.

The result of this experiment suggest that if all other factors are equal, students that collaborate together, with no control on their dialogue, are likely to benefit unequally from the experience. The first student who takes control of the conversation will remain in control, while the other participants adopt a more subservient role. This is undesirable from the perspective adopted here, but possibly common in small group work.

Examining the *Swap* policy, the reason role for the *Swap* policy is still significantly split to roughly the same degree as for the normal environment, but overall the picture is very different (Table 2). Now only 2 out of the 8 roles (and events) are significantly split while 5 are negatively correlated. The statistics suggest that it is no longer possible to be certain (at the 1% level) whether there is a significant split between agents in the pair. But in this case the mean of the difference between the agents is still relatively high (11.9) and fairly similar to the previous environment (12.8). The difference here is in the spread of the original population.

The correlation coefficient tells a similar story. It is worth noting at this point that in the case of the "interesting" events, 8 outliers have been removed from this data sample (by the procedure described above). If this had not been done, the resulting correlation would be about 0.614, significantly positive. However, in the overwhelming majority (92%) this would be misleading, as in their case the correlation is calculated as -0.462, significantly negatively correlated. The interest here is in the majority, so it is important to remove the outliers. The figure of -0.462 is still significant and leads us to believe that this sort of distribution would not have happened by chance, but it is clearly less so than the -0.99 seen in the previous example.

In common with the "interesting" case above, a number of the roles are split, but not significantly so (at the

[3] In this work, "interesting" information is information that leads to an agent's knowledge base changing.

1% level). They are on the borderline, and are rejected by our relatively stringent test. We expect that if roles are negatively correlated, they are also likely to be significantly split. In this case, while the correlation statistic yields a value which is significant at the 1% level, a number of the "split" statistics are not significant at this level. The implication is that the correlation between the two statistics is not as linear as might have been suspected. The fact that roles are significantly negatively correlated, but not significantly split means that both statistics need to be considered. The interpretation of such a scenario is that in this environment, the inclination of participants is that if one starts to use the role more, the other will use it less. However, this happens to a lesser degree than the overall distribution of the way in which participants use the roles anyway and (at this given level of significance) they do not divide the way in which they use the roles.

In conclusion, the *Swap* environment does indeed produce somewhat better collaboration according to our measure. This finding indicates that our first hypothesis is correct. Simple, unconstrained collaboration is not necessarily the most effective. But the *Swap* constraints still produce an environment in which a number of roles are split between participants, and many which are negatively correlated. In short, *Swap* is better, but not best! The mean of the number of interesting events found by the agents has also risen, and, as seen above, the degree to which the level of interest is split between partners in a group has fallen. However, the rise is less than our chosen statistical degree of significance, so the idea that this has happened by chance is not rejected.

Multi, the next policy to be examined, is based on allowing participants to put forward several ideas in parallel, not necessarily commenting on any of them. In practice, each participant may ask several questions, and their partners may not necessarily answer them directly (and likewise for other dialogue utterances).

It is important to remember at this stage that the Clarissa agents have infallible memories. If this form of collaboration were to be attempted between human participants, not only would the participants need to be trained in the dialogue structure (or forced to use it by an interface), but they would also require some assistance in terms of remembering what had been said.

In this case, neither the interesting events, nor the reason role, are significantly split (Table 3). However the interesting events show a strong negative correlation. Again, the pairwise difference being not significant in this case implies that while there is a tendency for one participant to receive more interesting events from their partner than vice versa, the degree to which this happens is less than the distribution of how interesting events are seen by participants anyway.

The only other role to be negatively correlated is also significantly split. That is the "interface" role. Effectively, this is the role used by participants wishing to use the mouse. In many respects we would guess that this would be the most difficult role to make sure was evenly divided between the participants.

The complete metric for the *Multi* policy is measured across 6 roles (including the "interesting" events). In this case, "check" has been amalgamated with "question" and "argue" with "response". These simplifications were made to keep the complexity of the dialogue game definition within a reasonable level (since all roles must be replicated for *Multi* and all replicated roles must be related to all others). The results are 1 out of 6 have significantly split role usage, and 2 have negative correlation. The mean of the interesting events is 26.6. Again, this mean is not significantly different from either of the means of the other two samples.

The collaborative environments which *Multi* represents seem to have allowed agents to distribute the roles more evenly, but at the cost of relying on agents having a perfect memory for what has been said by others, (so that they may return to these previous statements). The degree to which roles are more evenly distributed in this case could was not predicted. It seems that allowing agents to play the same role together allows them to avoid situations in which one agent simply takes control. This is a useful finding.

The model seems to be implying that it is not necessarily the case that the individuals should be encouraged to practise different collaborative skills than their partners (at any one time), but that it is both acceptable and possibly beneficial at least to allow them to practise sim-

Table 3: Results for the *Multi* policy (**Bold** entries statistically significant)

Split	2.59	0.39	**3.36**	1.07	0.80	1.10

ilar skills concurrently. A rise was noticed in the interest level shown in *Swap* collaboration above, which was not significant at the 1% level. The next step is to examine a policy which exploits this rise, in conjunction with the better role usage seen for the *Multi* policy.

Both the *Multi* and the *Swap* constraints can be combined, since they are addressing different aspects of the environment. The former is about the roles which can be used together at any one time, the latter is about the points at which agents are expected to swap roles. It is not so clear that by combining them the results are positive. Not only are the results positive, taking the best from both individual schemes, but that they are better than one would have imagined (Table 4). Neither of the two data sets show any degree of split or negative correlation, and this is common across all 6 data sets, including the "interface" role which in the "multi" environment was still split. In the case of the "reason" role there is a degree of positive correlation (which is significant at the 1% level, as it is greater than 0.254). This is highly desirable as it implies that one participants uses the role more, the other will follow suit.

Furthermore, the level of interest is higher than seen in the "multi" environment. This must be discounted as the difference is very small and statistically could easily have happened by chance. Indeed the probability of the rise in the degree of interest from the *Free* case (24.9) and this case (29.0) happening by chance is still about 27%, a very long way from the 1% cut off level.

Nonetheless, this mode of collaboration is clearly much better according to our metric, especially in so far as it seems to encourage the even distribution of all dialogue roles. This implies that all the participants in the collaboration will have an opportunity to practise and observe all of the dialogue roles that are available, and by doing so, if these roles have been chosen to reflect underlying cognitive processes which are pedagogically interesting, the participants should have the opportunity to practise, observe and improve their ability to execute those underlying processes.

It has been our goal to find such a cognitive environment. Having done so it is necessary to reflect on how this environment relates to a realistic situation with human collaborators. It was previously noted that the human participants would need some additional assistance to allow them to keep track of what everybody had said. (This is common in most meetings, and often some such device, like paper and pencil, is encouraged in educational collaboration). They also need to be encouraged to speak their mind, ask all their questions, say everything they can about a problem, with, perhaps little regard for their partners. In another respect, they must of course take careful note of everything their partners say, such that they can respond at some point. This satisfies the "multi" constraints. Finally the *Swap* constraints imply that participants should keep asking questions, if that is what they start doing; keep making statements about what is known about the problem; keep proposing deductions, suggesting things to do next. Participants should continue concentrating on one "role" until the beginning of a new "dialogue episode". The beginning of a new dialogue game has been used as such a marker. The key is to guarantee that these events happen frequently enough that participants do not get frustrated and bored by being captured in one role for too long a time.

Of course it is necessary to re-emphasise that this is the finding of a simulator which is built in a cognitively plausible manner, but has necessarily simplified many issues. The results of simulated model can do no more than suggest ways in which others may take this research further, having decided upon their pedagogic requirements, and the dialogue roles that they hope will fulfill these.

An alternative approach to the *Swap* form of role swapping, as has been mentioned previously, is the *Polite* mode. Here, rather than everybody swapping roles at the beginning of dialogue episodes, participants who finish dialogue episodes agree to drop their roles, allowing somebody else to take the floor. This may, in some situations, be an easier form of dialogue to explain and encourage in participants. Simply, having led the discussion about a specific topic, a participant should allow their partner to lead the next. This behaviour can be combined with the *Multi* behaviour previously examined (*Polite* is very similar to *Swap* so it is not presented here).

The findings, shown in Table 5, for this mode of collaboration are similar to those of *MultiSwap* collaboration looked at above. None of the roles are significantly split or negatively correlated. The mean number of interesting utterances received by one partner from the other in this case has risen to 33.9 (s=8.41). The weighted standard deviation of this population and the population of *Free* collaborative partners (s=1.63) is 8.57 (2 d.p.). The difference in the mean is 9, which is just 1.05 SD. This is still not significant at the 1% level, indeed it would be expected in 29.38% of normally distributed cases which had similar means. Little can be said about the increase in the level of interest seen, except to note its increase, and to note that it is slightly above that for *MultiSwap*.

There is then very little to choose between the *MultiSwap* environment and the *MultiPolite* environment. Both yield good collaboration as measured by our metric. The decision about which to use may rest on the ease

Table 4: Results for *MultiSwap* environment (**Bold** entries statistically significant)

with which the various different behaviours demanded by the collaborative environment can be taught to the participants or engineered into the environment in which they are collaborating.

Discussion

Clarissa agents simulate a form of collaboration. They offer a test-bench for investigating collaborative activity. Various different policies for collaboration have been, and others could be, examined with Clarissa. Different opinions about what makes for good collaboration can be used to investigate a variety of different collaborative situations. The notion that good collaboration is characterised by an even distribution of roles has been adopted and some hypotheses about collaboration have been evaluated given the starting point that even role distribution is important. The following results have been found:

- The best collaborative environment found involves participants having the ability to communicate in a non-normal way, and having some form of aide-memoire which would allow this abnormal communication to be effective. This finding was not predicted.
- Socially "normal" role usage is not conducive to educationally beneficial collaboration. One agent takes control of the conversation, and the social norms are such that the agent remains in control. This problem seems to be addressed by the multi-role distributions. Allowing participants to adopt the same roles at the same time is not socially normal, but seems to have a very significant effect on the quality of collaboration.

In the best form of collaboration that has been found, the environment involved participants swapping roles frequently. They can be instructed to do so either when they finish, or start, a new dialogue episode. The simplest instruction may be "if you have been dominating the discussion, when you come to the end of a topic, allow somebody else to take the lead". Clarissa has given interesting results that can be taken further.

Abstract

We are witnessing the emergence of a new technology for dynamically creating stories tailored to the interests of particular readers. *Narrative prose generators* offer much promise for literacy education, but designing them for maximal effectiveness requires us to understand their effect on readers. This article describes the evaluation of STORYBOOK, an implemented narrative prose generation system that produces original fairy tales in the Little Red Riding Hood domain. STORYBOOK creates two to three pages of text consistently represented at the deep linguistic structure level. Because of this, we can formally evaluate multiple versions of a single story and be assured that the content is identical across all versions. We produced five such versions of two separate stories which were compared by a pool of twenty upper division students in English and analyzed with an ANOVA test. While the results are most informative for designers of narrative prose generators, it provides important baselines for research into natural language systems in general.

Introduction

The emerging technology of narrative prose generation, which dynamically creates stories tailored to the interests of particular readers, offers great promise for literacy education. However, to design effective narrative prose generation software for literacy education, it is important to understand how students perceive texts created by these algorithms. Do the results of studies based on human-produced texts apply? How does computer control of minute aspects of text production affect readers? Do readers have quantitative reactions to fundamental alterations in texts as we expect they would?

As a result of recent work in formally evaluated language generation technology (Smith & Hipp 1994; Robin & McKeown 1995; Allen *et al.* 1996; Callaway & Lester 1997; Lester & Porter 1997; Young 1999), we are seeing an increased awareness of the issues involved in successfully generating texts dynamically for specific target audiences. However, these systems are focused more towards task effectiveness evaluations or explanation generation and are not suitable for the significant difficulties in creating literary narratives. And while there exist story generation systems capable of producing narratives (Meehan 1976; Lebowitz 1985; Lang 1997), none of these systems has been formally evaluated by readers. Furthermore, various formal studies on reading comprehension (Kintsch & Keenan 1973; Graesser, Millis & Zwaan 1997; Hoover 1997) have focused on mechanical aspects such as reading rate, and did not have access to computational mechanisms for producing the texts they studied.

To study the changes in perceived text quality stemming from alterations to the underlying text generation architecture, we conducted a formal study gauging the satisfaction of subjects reading narratives. The study involved the following:

- A consistent representation mechanism which allows for the representation of characters, props, locations, actions and descriptions found in a narrative environment. Holding these entities constant for the duration of an experiment ensures that the stories seen by the study participants will have identical plots and details except for the variations cued from the experiment's parameters.

- A story generation mechanism that, when given the story representation and the experimental parameters, can produce a specified set of narratives. Our story generator, named STORYBOOK, creates narratives in the Little Red Riding Hood fairy tale domain. These narratives can be tailored to produce a variety of grammatical, lexical, and propositional effects.

- A pool of readers familiar with narratives and the writing process itself. Thus we conducted a study involving 20 upper division undergraduate students majoring in English or Communication. Each student read two distinct Little Red Riding Hood stories averaging two hours per student.

There are two primary types of comparisons upon which an evaluation of a text-producing system can focus: human text *vs.* computer text and computer text *vs.* computer text. Although there are a number of pre-existing Little Red Riding Hood texts available for comparison via the World Wide Web, formally comparing such narratives with those produced by computer presents a difficult problem: there is no known objective metric for quantitatively evaluating narrative prose in terms of how it performs *as a story*. Simple metrics exist for evaluation at the sentence level (*e.g.*, number of words, depth of embedding, *etc.*), but a narrative *per se* cannot be considered to be just a collection of sentences

that are not related to each other. In addition, because narrative is not a "deductive" domain, it cannot be evaluated in terms of *correctness* by a panel of human judges. To overcome these problems, we instead opted for a computer *vs.* computer style of evaluation that investigates whether certain architectural elements are necessary or useful when generating narrative prose.

To study the effects of different textual effects upon the readers, we implemented five versions of the STORYBOOK story generator (Callaway & Lester 2001). Because a fully interleaved experiment would have required an excessive amount of time, we required each student to compare two versions of each story rather than all five versions. Each story was identical in plot, content, and form, but differed in terms of propositions per sentence, grammatical fluency, or choice of lexical forms. The results of the study show that the participants were highly discriminative of the texts which they read, preferring some versions over others. The readers most strongly dispreferred narratives lacking important grammatical structures and greatly dispreferred those with a small number of propositions per sentence. These results have important implications for the design of literacy software.

The STORYBOOK Narrative Prose Generator

STORYBOOK is a narrative prose generator that produces narratives in the Little Red Riding Hood domain. To write stories, STORYBOOK takes a narrative plan consisting of the actors, scenes, props and temporally ordered events and descriptions as input from a narrative planner. It then evolves that narrative plan into the final text seen by the reader using a sequence of architectural components:

- *Discourse History*: When populating a story with information from a conceptual network, noun phrases must be marked for indefiniteness if they have not yet been mentioned in the story or if they are not visually available references to the character or narrator in focus. Furthermore, frequently repeating noun phrases can be pronominalized to avoid sentences like "Grandmother knew that Grandmother had asked Grandmother's daughter to send some cakes to Grandmother" rather than "Grandmother knew she had asked her daughter to send her some cakes." A discourse history tracks noun phrase concepts and allows them to be marked for definiteness or pronominalization.

- *Sentence Planner*: A sentence planner maps characters, props, locations, actions and descriptions to concrete grammatical structures in a sentential specification. Thus in the example just mentioned, "grandmother" is mapped to the main subject while "know" is mapped to the main verb, etc.

- *Revision*: Because narrative planners create their content as a series of single proposition sentences, a revision component is usually introduced to *aggregate* those small sentences (protosentences) into larger multi-proposition sentences. It is usually assumed that these larger sentences will be more readable and less choppy or visually jarring. For example, "The wolf saw her" and "She was walking down the path" might be aggregated to produce "The wolf saw her walking down the path."

- *Lexical Choice*: Narrative planners also tend to create sentences that frequently repeat the same lexical items due to efficiency concerns. To combat this, a lexical choice component performs local search to determine when one lexical item can be replaced by another. Thus instead of character dialogue where characters always introduce utterances with "said", that lexical item can be replaced by "mentioned", "whispered", "replied", etc.

- *Surface Realizer*: Once the lexical and structural content of a set of sentences has been determined, they must be converted to text. This is accomplished by checking to make sure that each sentence is grammatical, imposes linear constraints, and adds morphological changes as necessary. The result is text which can be sent to a word processor, a web browser, or saved as a text file.

The existence of these architectural modules allowed us to conduct an *architectural ablation* experiment. By selectively removing a component, the resulting text of a story will be changed in some way. The sentence planner and surface realizer are vital components; without them text cannot be produced at all. However, removing the other elements will result in text that we expect to be degraded in some fashion. Thus without the discourse history, the system will be unable to produce pronouns in a reliable way or appropriately mark nouns for definiteness. Without the revision component, the system will produce a minimal number of propositions per sentence due to the lack of clause aggregation. Finally, removing the lexical choice module will result in a decrease in the variability of the lexical forms of verbs or nouns.

Given these three architectural modules, there are 2^3 or 8 possible pairwise comparisons between the presence or absence of each component when used to produce a narrative:

1. All three components are used.
2. Only the revision module is unused.
3. Only the lexical choice module is unused.
4. Only the discourse history module is unused.
5. Only the revision module is used.
6. Only the lexical choice module is used.
7. Only the discourse history module is used.
8. None of the three components are used.

Due to the constraints on the logistics of the evaluation process, we decided to utilize only five of those pairwise comparisons: the two all-or-none approaches and the

three approaches where one specific architectural module is ablated. The remaining three unused approaches would evaluate the enhancement that each module adds to the whole rather than what is missing when each is removed. We contend this approach leads to a slightly more effective comparison, because as more modules are removed from the generation process, the resulting prose becomes progressively less desirable and thus unwanted effects from the absence of multiple architectural modules might overlap and affect a test subject's experience in ways that could not be teased apart when analyzing the data.

The ablation of these architectural modules can have a significant impact in text quality, even over very small text segments, as is shown in the following excerpts:

- Complete (Version A), with revision, lexical choice, and discourse history all turned on:

  She had not gone far when she met a wolf.

  "Hello," greeted the wolf, who was a cunning looking creature. He asked, "Where are you going?"

  "I am going to my grandmother's house," she replied.

- No Revision (Version B), with lexical choice and discourse history turned on:

  She had not gone far. She met a wolf.

  "Hello," greeted the wolf. The wolf was a cunning looking creature. He asked, "Where are you going?"

  "I am going to my grandmother's house," she replied.

- No Lexical Choice (Version C), with revision and discourse history turned on:

  She had not gone far when she met a wolf.

  "Hello," said the wolf, who was a cunning looking creature. He said, "Where are you going?"

  "I am going to my grandmother's house," she said.

- No Discourse History (Version D), with revision and lexical choice turned on:

  Little Red Riding Hood had not gone far when Little Red Riding Hood met the wolf.

  "Hello," greeted the wolf, who was the cunning looking creature. The wolf asked, "Where is Little Red Riding Hood going?"

  "Little Red Riding Hood is going to Little Red Riding Hood's grandmother's house," replied Little Red Riding Hood.

- Empty (Version E), with revision, lexical choice, and discourse history all turned off:

  Little Red Riding Hood had not gone far. Little Red Riding Hood met the wolf.

  "Hello," said the wolf. The wolf was the cunning looking creature. The wolf said, "Where is Little Red Riding Hood going?"

  "Little Red Riding Hood is going to Little Red Riding Hood's grandmother's house," said Little Red Riding Hood.

1. On an absolute scale of how good fairy tales should be in general, evaluate the story on an A–F scale (A, B, C, D, F).
2. Style: Did the author use a writing style appropriate for fairy tales?
3. Grammaticality: How would you grade the syntactic quality of the story?
4. Flow: How well did the sentences flow from one to the next?
5. Diction: How interesting or appropriate were the author's word choices?
6. Readability: How hard was it to read the prose?
7. Logicality: Did the story omit crucial information or seem out of order?
8. Detail: Did the story have the right amount of detail, or too much or too little?
9. Believability: Did the story's characters behave as you would expect?

Figure 1: Grading factors presented to readers

Evaluation Methodology

To test the StoryBook system, we created a modestly sized narrative planner (implemented as a finite state automaton containing approximately 200 states), enough to produce two stories comprising two and three pages respectively. Furthermore, we fixed the content of those stories and ran five different versions of StoryBook on each one: (A) all three components working, (B) revision turned off, (C) lexical choice turned off, (D) the discourse history turned off, and finally (E) a version with all three components turned off. This resulted in ten total narratives which we presented to our test subjects using the grading factors found in Figure 1. While versions were different in the sense that certain modules were either ablated or not, the two stories differ because they were created from two different finite state automata. Thus story #1 potentially has different characters, different events and properties, and different props than story #2 has.

A total of twenty students were selected from North Carolina State University's Departments of English and

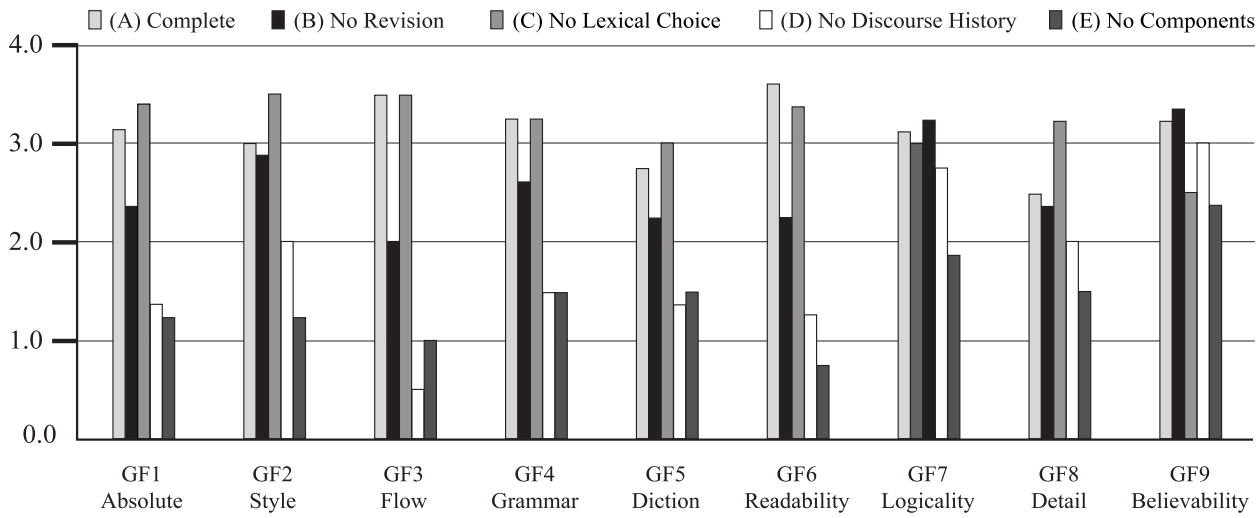

Figure 2: Means for Story #2: 4.0 scale, 8 evaluations per Version × Grading Factor × Story

Communication via first-come first-serve email notices. All of the students were registered in upper division or graduate courses in those departments. Each subject was asked to read the directions and ask for clarifications before the evaluation proceeded and was randomly assigned their evaluation task. Subjects were not informed prior to their completion of the questionnaire that the narratives were produced by computer program. Subjects were paid $25.00 for their participation.

Because each subject compared two versions of story #1 to each other and two versions of story #2 to each other, every subject saw a total of four narratives. To prevent subjects from evaluating the same types of stories in succession, we devised the following policy:

1. Each subject read four distinct story versions out of the total of five, two from each story (*e.g.*, subject #1 read versions A and B from story #1, and versions D and E from story #2). No subject read the same version twice.

2. Each version was read by the same total number of subjects (*i.e.*, each version of every story was read by 8 separate subjects).

3. Each pairwise comparison of different versions was read by two separate subjects (*e.g.*, subjects #1 and #11 both read versions A and B of story #1 and versions D and E of story #2).

4. For each pair of students reading the same two versions, the narratives were presented in opposite order (*e.g.*, subject #1 read version A first and then version B, while subject #11 read version B first followed by version A).

5. Students were randomly assigned narrative versions on a first-come first-serve basis; all students performed their evaluations within 3 hours of each other at a single location.

Subjects graded each narrative following the instructions according to an A–F scale, which we then converted to a quantified scale where A = 4.0, B = 3.0, C = 2.0, D = 1.0, and F = 0.0. The resulting scores were then tallied and averaged. The means for both stories are shown in Figure 2.

To determine the quantitative significance of the results, we performed an ANOVA test over both stories. The analysis was conducted for three independent variables (test subject, story, and version) and nine grading factors (labelled GF1 – GF9, as described in Figure 1). Because not all possible grading combinations were performed (only 80 observations, or 20 x 2 x 2, out of a possible 200, or 20 x 2 x 5, due to crossover and time constraints), we performed the mixed procedure analysis. Interactions between variables were only significant for grading factor #9 at 0.0300 for story∗version.

The results of the ANOVA analysis point to three significant classes of narratives due to the architectural design of the narrative prose generator. Table 1 indicates that the most preferred narrative class, consisting of versions A & C, were not significantly different from each other overall while they did differ significantly from all other versions (although there were similarities in particular grading factors such as GF2, *style*, between versions A & B). Interestingly, the affinity for versions A & C is strongly correlated for story #2 (Figure 2) but only weakly for story #1. A two-tailed paired t-test evaluating this difference illustrated that versions A & B were not significantly different when only story #1 was considered, but were significantly different in story #2. The opposite was true for versions A & C when the scores for each story were compared individually, even though the combined scores indicated versions A & C were not significantly different overall.

Discussion

Indisputably, versions D & E form the least preferred narrative class, differing quite significantly from all other versions while not differing significantly from each other. Because the architectural commonality between these two versions was the lack of a discourse history (corresponding to a lack of grammatical conformity to the expected norm, especially lack of appropriate pronominalization) while versions A, B, and C all utilized a discourse history, we conclude that this architectural component is extremely important in the design of a narrative prose generator and that any symbolic pipelined narrative prose generation system will suffer tremendous degradation in prose quality if a discourse history component is not present. In addition, we conclude that in future ablation experiments, if there is no other methodology for introducing pronominalizations, it is not even desirable to include the discourse history module as one of the components available for ablation. Effects of pronominalization and topicalization were previously studied by Hoover (1997) although that work focused on recall rates while we concentrate on expressed preferences.

As predicted in advance, the full version (Version A) scored quite well while versions lacking a discourse history (Versions D & E) scored quite poorly. A surprise in the results of the analysis was the mild preference subjects had for the version missing the lexical choice component (Version C) over the full-fledged version. While related work on word choice in spontaneous dialogues has concluded that dialogue participants tend to converge onto a limited set of words (Brennan 1996), fictional narrative by and large does not reflect the spontaneity and task-orientation reflected in such dialogues.

Upon analysis of the comments in the evaluations specifically comparing versions A & C, it became clear that one principal reason was the test subjects' belief that the increased lexical variation might prove too difficult for children to read (even though we provided no indication that the target audience was children) and thus Version A compared less favorably to Version C due to the more complex and varied words it contained. It is not clear whether a lexical choice component would play a much more significant role in subject matter where the audience was more mature.

The fact that Version B scored less favorably compared to Versions A and C indicates that revision is an important aspect of narrative prose generation. Test subjects frequently commented that Version B was "very choppy" or "didn't seem to have good grammar". These comments can be accounted for by the two main functions of the revision component: joining small sentences together and combining sentences with repetitive phrases together while deleting the repetitions. This is related to previous work in reading comprehension on propositional content. Such research (Kintsch & Keenan, 1973) has shown that reading rate increases as the number of propositions per sentence increases. Here, however, we have shown that a larger number of propositions per sentence is preferred more than a small number of propositions per sentence, although there would certainly be an upper limit.

Another important note is that there is a difference among the grading factors themselves. Grading factors 2-7 (style, flow, grammar, diction, readability and logicality) directly relate to elements governed by the parameters and rules of the various architectural components of the narrative prose generator. However, grading factors #8 and #9 (detail and believability) are more closely related to the content of the plot line, and as such could be expected to remain relatively constant since the content of the narratives was held constant across all versions of each story. Given that the perceptions of the test subjects might have "carried over" from their responses to previous questions, a future evaluation might randomize the order in which these questions are asked to see if this effect persists.

Finally, there appears to be a link between the appeal of the story content itself and the increase in the absolute (GF #1) and total means for versions A, B, and C. Story #1 is a "classic" Brothers' Grimm fairy tale in the sense that it typically has a gruesome ending that serves as a behavioral warning to young children. Thus our story #1 ends with the wolf devouring Little Red Riding Hood

and her grandmother. More modern stories have happier endings, however, and this is reflected in our story #2 which ends with a woodcutter killing the wolf and extracting the unharmed Little Red Riding Hood and her grandmother from the wolf's stomach. A large number of our test subjects, worried about the potential impact on children, complained about the "horrible" ending of story #1 in their written comments and this reader bias appears to have affected the overall grading scores.

Future Work

The existence of a computational system for generating complete narratives while providing access to the fundamental linguistic structure offers superb opportunities for future experimentation. Very fine-grained manipulation of texts becomes possible on a large scale; for example, within the discourse history, it is possible to run ablation experiments involving subject pronouns vs. object pronouns, correct vs. incorrect reflexive pronouns, random vs. ambient definite noun phrase marking, among many others.

Acknowledgements

The authors wish to thank Joy Smith of NC State University for her help with the statistical analysis and the anonymous reviewers for their extremely helpful comments. Support for this work was provided by the IntelliMedia Initiative of North Carolina State University.

Abstract

This paper presents an Artificial Life and Neural Network (ALNN) model for the evolution of syntax. The simulation methodology provides a unifying approach for the study of the evolution of language and its interaction with other behavioral and neural factors. The model uses an object manipulation task to simulate the evolution of language based on a simple verb-noun rule. The analyses of results focus on the interaction between language and other non-linguistic abilities, and on the neural control of linguistic abilities. The model shows that the beneficial effects of language on non-linguistic behavior are explained by the emergence of distinct internal representation patterns for the processing of verbs and nouns.

Modeling the Evolution of Language

The recent development of computational evolutionary models (Wiles & Hallinan, in press) has contributed to the rebirth of interest in the origin and evolution of language. Computational models can directly simulate the evolution of communication and the emergence of language in populations of interacting organisms (Cangelosi & Parisi, in press; Dessalles & Ghadakpour, 2000; Steels, 1997). Various simulation approaches are used such as communication between rule-based agents (Kirby, 1999), recurrent neural networks (Batali, 1994; Ellefson & Christiansen, 2000), robotics (Kaplan, 2000; Steels & Vogt, 1997), and internet agents (Steels & Kaplan, 1999).

Artificial Life Neural Networks (ALNN) are neural networks controlling the behavior of organisms that live in an environment and are members of evolving populations of organisms. ALNN models have been used to simulate the evolution of language (Cangelosi & Parisi, 1998; Cangelosi, 1999; Cangelosi & Harnad, in press; Parisi, 1997). For example, in Cangelosi and Parisi's (1998) model organisms evolve a shared lexicon for naming different types of foods. Communication signals are processed by neural networks with genetically inherited connection weights and the signals evolve at the population level using a genetic algorithm with no changes during an individual's lifetime.

ALNN models provide a unifying methodological and theoretical framework for cognitive modeling because of the use of both evolutionary and connectionist techniques and the interaction of the organisms with a simulated ecology (Parisi, 1997). All behavioral abilities (e.g., sensorimotor skills, perception, categorization, language) are controlled by the same neural network. This unified framework permits the study of various factors affecting language evolution, such as the differences between genetic and learned communication systems, the adaptive role of both simple and compositional languages, the neural control of language, the reciprocal influences between language and cognition.

Emergence of compositional languages: verbs and nouns

The evolutionary emergence of messages that combine two linguistic signals has been studied with ALNN models. In Cangelosi and Parisi's (1998) model, organisms communicate using simple signals that are genetically inherited. In an extension of the model, word combination and language learning were introduced to simulate the emergence of compositional languages (Cangelosi, 1999; in press). The organisms' neural networks had two linguistic winner-takes-all output clusters so that two "words" were simultaneously uttered to name foods (different types of mushrooms). Parents acted as linguistic teachers of their offspring. Children learned to name foods by imitating their parents' descriptions using an error backpropagation algorithm.

The simulation results showed that about 60% of the populations evolved optimal languages, i.e., languages in which each category of food was correctly identified and named. In the remaining populations, only one category out of six was misclassified. Evolved languages were classified into three types: (1) Single-

word, where the units in only one cluster are enough to differentiate all mushrooms; (2) Word-combination, where symbols from both clusters are needed to discriminate mushrooms; (3) Verb-Noun, where the units in one cluster are systematically associated with high-order categories (e.g., "verbs" for approaching/avoiding) and the other cluster is used for differentiating sub-categories (e.g., "nouns" for mushrooms of different color).

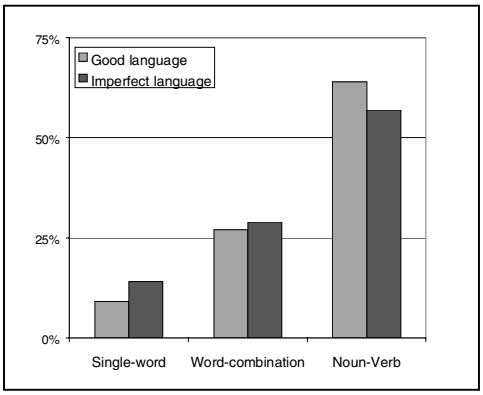

Figure 1: Distribution of languages in the 18 simulations with communication (at generation 400).

The distribution of language types (Figure 1) showed that there is a strong evolutionary tendency to evolve compositional languages, where the syntactic structure of messages reflects the hierarchical classification of mushrooms. In fact, the most frequent (e.g., 64% of good languages) combinatorial structure is that of predicate-argument, resembling a "verb-noun" sentence.

Behavioral and Neural Factors in the Evolution and Acquisition of Language and Syntax

We will now focus on some issues about the acquisition and use of language, and on their relations with language evolution studies. These issues regard the interaction between language and other behavioral abilities, the stages of the acquisition and evolution of syntax, and the organization of neural representations in language processing. The first issue is quite an important and old one: How does language affect, and how is it affected by, other cognitive and behavioral abilities? Various language origin theories stress the importance of pre-existing sensorimotor knowledge for effective evolution of linguistic skills. For example, Rizzolatti and Arbib (1998) proposed a motor theory of language evolution based on imitation skills. Steels (2000) showed how his robotics models of language evolution support this theory. In Cangelosi and Parisi's (1998) ALNN model, they showed how language evolution relies on the evolution of basic cognitive abilities such as categorization. The dependence of language on previous sensorimotor skills, and the effects of language on this behavior will be looked at in the models presented here.

Researchers interested in both the evolution and the acquisition of language, are primarily concerned with the early stages of the development of linguistic abilities. In particular they focus on the transition from a non-linguistic stage where sensorimotor abilities dominate to a phase in which language and other high order cognitive skills emerge and take control of cognitive development. Although little empirical evidence is available for language evolution, data on language acquisition strongly support the conclusion that children learn nouns before verbs (Brooks & Tomasello, 1999). They handle nouns at around 18 months, while verbs are acquired later, from around 24 months. Verbs seem to follow a more gradual acquisition pattern, passing through an intermediate stage called "verb islands" (Tomasello, 1992). We will use data from our simulations to look for similar learning patterns in language evolution.

The investigation of the neural control of nouns vs verbs has been the focus of some interesting neuropsychological and brain imaging studies. For example, Caramazza and Hillis (1991) looked at the brain representation of noun and verbs in patients with brain lesions. Martin, Haxby, Lalonde, Wiggs & Ungerleider (1995) used PET to show that cortical sensory areas are active when the color word of an object is retrieved, while motor areas are involved in the processing of action words. ALNNs permit the investigation of internal representations involved in the processing of different syntactic classes such as nouns and verbs.

In the next section we will describe a new ALNN model of the evolution of syntax, specifically the verb-noun syntactic rule. This simulation will be use to study in detail the interaction between linguistic abilities and other behavioral and neural factors.

Evolution of Verb-Noun Languages

The ALNN model described in Cangelosi, 1999 (cf. also Cangelosi, in press) showed a significant tendency to evolve compositional languages made up of verb-noun messages. To study the differences between verbs and nouns and how verb-noun languages affect and are affected by other behavioral, cognitive, and neural factors, a new model with a pre-defined compositional language will be used. The language includes four simple linguistic signals (words), two nouns and two verbs. Nouns are defined as linguistic signals that covary with the visual input. Verbs are defined as linguistic signals that covary with the action of the organism. Messages can include only a noun or only a verb or they can be a combination of a noun and a verb.

The Model

The task used in the simulation is an object manipulation task (Schlesinger & Barto, 1999). At any given time the organism is grasping an object with its hand and it either pulls the object toward itself or it pushes the object away from itself. Two different objects are used, a vertical bar (object A) and a horizontal bar (object B). The object is perceived through a retina of 5x5=25 cells corresponding to 25 visual input units. The object occupies either three vertical cells or three horizontal cells in one of 9 possible locations in the retina. Hence, an object is encoded as a pattern of 25 bits with three 1s and twenty-two 0s. In addition to this visual input from the retina the organism's neural network receives a proprioceptive input encoding the current position of the organism's two-segment arm. This input is encoded in 4 input units, with units encoding proprioceptive information about the two pairs of muscles (extensor and contractor) of each of the two arm segments.

In the simulations with language the neural network includes 4 more input units encoding linguistic signals. Four linguistic signals are used, two nouns and two verbs, and they are localistically encoded in the 4 linguistic input units One noun designates the vertical object and a different noun designates the horizontal object. One verb designates the action of pushing and the other verb the action of pulling the object. In different occasions the organism can perceive only a noun or only a verb or both a noun and a verb.
There are two layers of hidden units that receive information from the input units and pass it to the 4 output units (Figure 2). The output units control the extension/contraction of the four arm muscles.

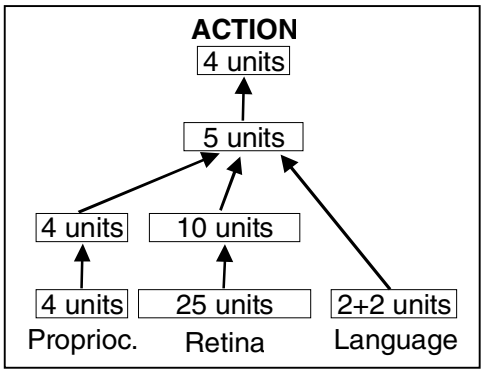

Figure 2 – The organism's neural network for the object manipulation task

The connection weights allowing the neural network to appropriately manipulate the two objects are developed using a genetic algorithm. At the beginning of a simulation 80 genotypes are randomly generated each encoding the connection weights of a single individual. These 80 individuals constitute the first generation. The 20 best individuals are selected for reproduction, with each individual generating 4 offspring with the same genotype (connection weights) of its single parent except for the addition of some random changes to some of the weights (random mutations). The process is repeated for 2000 generations.

Three experimental conditions were used. In the first condition, called "No-Language", an organism lives for a single epoch consisting of a total of 360 input/output mappings or moves (2 object types x 9 positions x 20 moves per task). Only the retina and the proprioceptive information are provided as input to the network. When the organism sees object A, it always has to push it away from itself; when it sees object B, it has to pull it towards itself. The fitness formula computes the total number of tasks successfully completed.

The second experimental condition is called "Late-Language". At generation 1000 a copy of the populations of the No-Language condition is made. From this generation onwards the organisms have a longer lifetime and they are exposed to language. Ten new epochs with language are added to an individual's lifetime, which therefore now includes 11 epochs, 10 with language and 1 without language. In 5 of the linguistic epochs an individual receives both the linguistic input and the retina and proprioceptive inputs, whereas in the remaining 5 epochs only the linguistic input and the proprioceptive input are present and the retina input is shut off. The 5 linguistic epochs are as follows: (1) add noun of the object, (2) add verb corresponding to the default action (push object A or pull object B), (3) add verb for opposite action (pull object A or push object B), (4) add both noun and default verb, and (5) add both noun and opposite verb. The various epochs are experienced by an organism in a random sequence. The same fitness formula is used as in the No-language case except that in the epochs when the opposite verb is used, the organism's action must reflect what the verb says, not what the object type would suggest by default.

In the third experimental condition, "Early-Language", organisms are exposed to all 11 epochs from the beginning of the simulation, i.e., from the first generation. For each condition, 20 replications of the simulations were run.

Results and Discussion

The average performance of the organism in the three simulations is reported in Figure 3. For the two linguistic conditions, only the curve of the performance in the epoch with no linguistic input is reported, to allow a direct comparison among the three conditions. The No-language fitness curve grows until it stabilizes at around 15.8 successfully completed epochs. In the

Late-Language condition, at generation 1001 the population goes through a significant drop in performance. This appears to be due to the fact that the linguistic input reaches the hidden units through random weights that disturb the previous good performance. However, the behavior gradually improves and from around generation 1400 Late-Language organisms outperform No-Language organisms. The final number of successful tasks is 16.6 for the Late-Language condition. In contrast with this, the performance of the Early-Language population is less good than that of both the No-Language and the Late-Language populations (14.4).

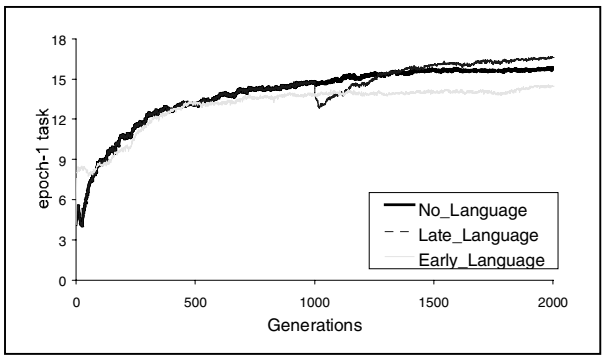

Figure 3 – Performance in epoch 1 (task without linguistic input) in the three experimental conditions

These results suggest an interesting hypothesis on language evolution and the interaction between linguistic and cognitive skills. To be adaptive language must be introduced at a later stage, after the cognitive abilities upon which it will be grounded have fully evolved. In this condition language has a beneficial influence on nonlinguistic behavior. If the evolutionary scenario involves both the practical task of pushing or pulling objects and the processing of linguistic signals from the beginning, it is more difficult to evolve populations with optimal performance in the practical task. Notice that if language is introduced later so that it can exploit the already existing (nonlinguistic) cognitive skills, the beneficial effects of language on nonlinguistic performance are observed not only when language is used together with nonlinguistic input (the language epochs) but also when there is no language and the organism is responding only to nonlinguistic input.

We will now focus on the Late-Language simulation to better understand why language has beneficial effects on nonlinguistic behavior and to analyze the differences between the two different classes of linguistic signals: nouns and verbs.

The 11 epochs of the Late-Language simulation can be grouped into 4 categories: (1) No-language, (2) Noun-only (the 2 epochs with and without retina input), (3) Verb-only (the four epochs with/without retina and with default/opposite verbs), and (4) Verb+Noun (the four epochs with/without retina and with default/opposite verbs).

Figure 4 shows the average performance for the three linguistic categories (categories 2-4) from generation 1000 to generation 1300. In the early generations, right after language has been introduced (from generation 1000 to generation 1100) the organisms' performance in the Noun-only epochs is higher than that of Verb-only and of Noun+Verb. Organisms learn to use nouns earlier than verbs to benefit their nonlinguistic performance. However, 100 generations later the disadvantage of the verb epochs disappears. Indeed, the performance for Verb-only and Verb+Noun epochs becomes stably better than that of Noun-only epochs.

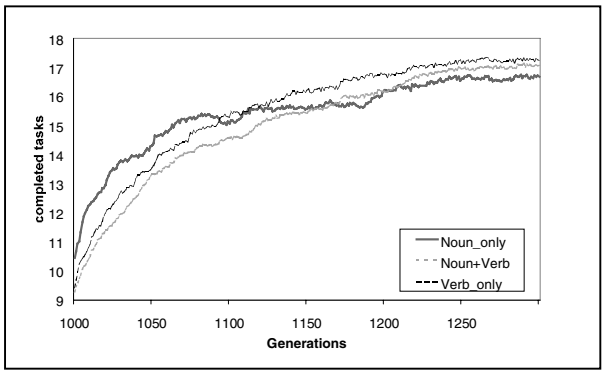

Figure 4 – Evolution of noun and verb use in the Late-Language simulation

The earlier advantage of nouns vs verbs can be explained by the fact that in the Noun-only epochs the task is consistent with what has been already learned without language up to generation 1000. Given this consistency with prelinguistic experience, nouns are easier to learn and they can benefit nonlinguistic performance earlier than verbs. On the contrary, with verbs organisms must learn to ignore some of the previously learned knowledge. When an opposite verb asks the organism to produce a new behavior (e.g., pull object A instead of pushing it, as previously learned) this is initially difficult to learn. Therefore, verbs can acquire an adaptive advantage only in later stages of language acquisition, when noun use has reached a good level of performance and stabilization and the individual can understand the more flexible nature of verbs, which can typically be predicated of a variety of arguments. This hypothesis could also explain the different stages of acquisition of nouns and verbs in children (Tomasello & Brooks, 1999). Verbs need a stable class of nouns to fully develop the potential and flexibility of their predicate-argument structure.

The Late-Language simulation can also be used to look at some aspects of the neural processing of language. To this purpose we analyzed the activation patterns in the second layer of hidden units (Figure 2), where sensory (retina+proprioception) and linguistic information come together and they both can have a role in determining the organism's motor behavior encoded in the output units. We used the activation patterns observed in these hidden units in the first cycle of each of the 18 motor tasks (9 for object A and 9 for object B). Each activation pattern can be represented as a point in the activation hyperspace of the hidden layer, with the 9 points corresponding to object A making up a "cloud" of points and the 9 points of object B making up another "cloud". We measured both the Euclidean distance between the centers of the two clouds and the size of each cloud as the average distance of the 9 points from the center of the cloud. (The points corresponding to objects/positions incorrectly handled were excluded from these calculations. On average, only 0.25 objects per epoch were misclassified.) The idea is that the successful accomplishment of the task requires that the different input patterns corresponding to the same object in different positions be internally represented as similarly as possible (small clouds) while the input patterns corresponding to the two different objects be represented as differently as possible (great distance between the two clouds).

The between-cloud distances and the sizes of the two clouds were computed for all 11 epochs. Then the data were averaged over the 4 categories of epochs: No-Language, Noun-only, Verb-only, and Noun+Verb. Figure 5 reports the average withn- and between-cloud distances at generation 2000. The between-cloud distances show a progressive increase from the No-language to the linguistic conditions. In an ANOVA test, these differences are statistically significant, except between the pair Verb-Only and Noun+Verb. A similar, but inverted, pattern of results is found for cloud size. The average size of a cloud decreases from the No-language to the linguistic conditions.

That language optimizes the representation of categories (i.e. increasing between-category distances and decreasing within-category sizes) has already been shown in other models (Cangelosi & Harnad, in press). What this model shows for the first time is that there are significant differences also between the three linguistic conditions, in particular between nouns and verbs. When the network is processing verbs, the size and distance of clouds is even better than when it is processing nouns.

How can we explain that verbs have even greater beneficial effects on nonverbal behavior than nouns? As we have shown, the beneficial effect of linguistic signals on nonlinguistic performance is due to the fact that linguistic signals induce better internal representations of reality. In our model, reality is internally represented in the neural network as the activation patterns observed in the higher layer of hidden units. The addition of language increases the distance between the two clouds of points (activation patterns) representing the two objects and decreases the size of the two clouds of points each representing one object. The language-modified clouds make it easier for the organism to select the appropriate action in response to the input. However, what is critical in internally representing reality is not to faithfully reflect the properties of the input but rather to prepare the motor output with which the organism must respond to the input. If the organism must be able to respond to the same object in different occasions with two different actions (push or pull) verbs are better than nouns in shaping the internal representations because while nouns covary with objects verbs covary with actions.

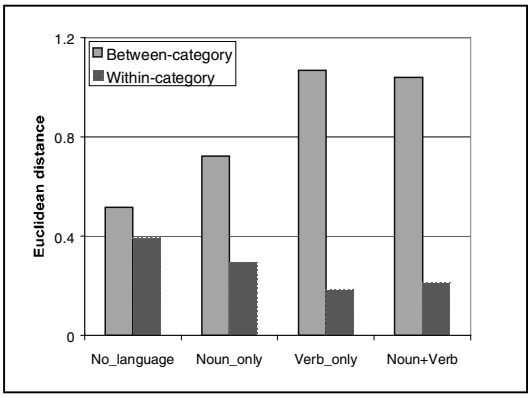

Figure 5 – Inter- and intra-categorical distances for the hidden representations at generation 2000.

Conclusion

The present model focuses on the evolution of an innate language understanding ability for a language made up of nouns and verbs. Notwithstanding its obvious limitations, the models sheds some light on the reciprocal influences between language and nonlinguistic cognition, on the differences between nouns and verbs, and on the internal organization of neural networks that use language in an ecological context. Language has a beneficial effect on nonlinguistic cognition if it emerges on already existing basis of nonlinguistic skills, but not if it evolves together with them. The basis for this beneficial influence of language on behavior appears to be that language produces better internal representations of reality. That is, more similar representations of different situations that must be responded to with the same action, and more different internal representations of similar situations that must be responded to with different behaviors. Furthermore, verbs have a more beneficial effect on behavior than nouns because verbs,

by their nature, tend to covary with the organism's actions while nouns tend to covary with the objects of reality that may be responded to with different actions in different occasions.

In this paper we have also done some comparisons between the computational model of language evolution and the literature on children's language acquisition and on neural processing of verbs and nouns. We are currently working on an extension of the object manipulation model to understand better the relations between language processing and sensorimotor knowledge (Martin et al, 1995). All in all, we believe this is a fruitful approach to the investigation of various adaptive, behavioral, and neural factors involved in the origin and evolution of language.

Abstract

We describe a computational model of the acquisition of early grammatical constructions that exploits two essential features of the human grammar learner: significant prior conceptual and lexical knowledge, and sensitivity to the statistical properties of the input data. Such principles are shown to be useful and necessary for learning the structured mappings between form and meaning needed to represent phrasal and clausal constructions. We describe an algorithm based on Bayesian model merging that can induce a set of grammatical constructions based on simpler previously learned constructions (in the base case, lexical constructions) in combination with new utterance-situation pairs. The resulting model shows how cognitive and computational considerations can intersect to produce a course of learning consistent with data from studies of child language acquisition.

Introduction

This paper describes a model of grammar learning in which linguistic representations are grounded both in the conceptual world of the learner and in the statistical properties of the input. Precocity on both fronts has previously been exploited in models of lexical acquisition; we focus here on the shift from single words to word combinations and investigate the extent to which larger phrasal and clausal constructions can be learned using principles similar to those employed in word learning. Our model makes strong assumptions about prior knowledge – both ontological and linguistic – on the part of the learner, taking as both inspiration and constraint the course of development observed in crosslinguistic studies of child language acquisition.

After describing our assumptions, we address the representational complexities associated with larger grammatical constructions. In the framework of Construction Grammar (Goldberg, 1995), these constructions can, like single-word constructions, be viewed as mappings between the two domains of *form* and *meaning*, where form typically refers to the speech or text stream and meaning refers to a rich conceptual ontology. In particular, they also involve relations among multiple entities in both form (e.g., multiple words and/or phonological units) and meaning (multiple participants in a scene), as well as mappings across relations in these two domains. We introduce a simple formalism capable of representing such relational constraints.

The remainder of the paper casts the learning problem in terms of two interacting processes, construction hypothesis and construction reorganization, and presents an algorithm based on Bayesian model merging (Stolcke, 1994) that attempts to induce the set of constructions that best fits previously seen data and generalizes to new data. We conclude by discussing some of the broader implications of the model for language learning and use.

Conceptual and lexical prerequisites

Children learning their earliest word combinations bring considerable prior knowledge to the task. Our model of grammar learning makes several assumptions intended to capture this knowledge, falling into two broad categories: representational requirements for ontological knowledge; and the ability to acquire lexical mappings.

Infants inhabit a dynamic world of continuous percepts, and how they process and represent these fluid sensations remains poorly understood. By the time they are learning grammar, however, they have amassed a substantial repertoire of concepts corresponding to people, objects, settings and actions (Bloom, 1973; Bloom, 2000). They are also competent event participants who have acquired richly structured knowledge about how different entites can interact (Tomasello, 1992; Slobin, 1985), as well as sophisticated pragmatic skills that allow them to determine referential intent (Bloom, 2000).

Few computational models of word learning have addressed the general problem of how such sensorimotor and social-cultural savvy is acquired. Several models, however, have tackled the simpler problem of how labels (either speech or text) become statistically associated with concepts in restricted semantic domains, such as spatial relations (Regier, 1996), objects and attributes (Roy and Pentland, 1998), and actions (Bailey et al., 1997; Siskind, 2000). Such models assume either explicitly or implicitly that lexical items can be represented as *maps* (i.e., bidirectional associations) between representations of *form* and *meaning* that are acquired on the basis of input associations.[1] Most of these also produce word senses whose meanings exhibit category and similarity

[1]Typically, supervised or unsupervised training is used to induce word categories from sensorimotor input, which is described using continuous or discrete features; models vary in the degree of inductive bias present in the input feature space.

effects like those known to be pervasive in human cognition (Lakoff, 1987): concepts cluster into categories with prototype structure and graded category membership.

For our current spotlight on the acquisition of grammatical structures, we will make a similar set of simplifying assumptions. We do not attempt to model the complex reasoning and inference processes needed to infer the appropriate intended meaning of an utterance in context; rather, we take as input a representation of the inferred meaning in a given situational context. We also assume that lexical maps like those produced by the word-learning models described above are available as input to the grammar-learning process.

For present purposes, the precise variant of word learning is not at issue, as long as several representational requirements are met. Lexical maps should facilitate the identification of similar concepts and provide some basis for generalization. They must also be able to capture the kinds of event-based knowledge mentioned above: the meanings of many early words and constructions involve multiple entities interacting within the context of some unified event (Bloom, 1973) or basic scene (Slobin, 1985). Fortunately, these representational demands have long been recognized in the context of adult constructions, and semantic descriptions based on *frames* relating various participant *roles* have been developed by, e.g., the Berkeley FrameNet project (Baker et al., 1998). Frame-based representations can capture the relational structure of many concepts, including not only early sensorimotor knowledge but also aspects of the surrounding social and cultural context.

It will be convenient to represent frames in terms of individual role bindings: Throw.thrower:*Human* and Throw.throwee:*Object* together bind a Throw frame with a *Human* thrower acting on an *Object* throwee. Note that although this representation highlights relational structure and obscures lower-level features of the underlying concepts, both aspects of conceptual knowledge will be crucial to our approach to language learning.

In the current model, ontological knowledge is represented with an inheritance hierarchy in which frames are represented as feature structures (i.e., attribute-value matrices) and role bindings are handled by unification. Our initial set of constructions contains a number of lexical form-meaning maps, where for simplicity we further constrain these to be mappings from orthographic forms to feature-structure meanings, as in Bailey (1997).

We now turn to the representationally more complex case of grammatical constructions, before addressing how such constructions are learned.

Grammatical Constructions

We base our representations of grammatical knowledge on ideas from Construction Grammar (Goldberg, 1995) and Cognitive Grammar (Langacker, 1987). In these approaches, larger phrasal and clausal units are, like lexical constructions, pairings of form and meaning. A key observation in the Construction Grammar tradition is that the meaning of a sentence may not be strictly predictable from the meaning of its parts; the syntactic pattern itself may also contribute a particular conceptual framing. For example, the CAUSED-MOTION construction underlying *Pat sneezed the napkin off the table* imposes a causative reading on the typically non-causative verb *sneeze*, and the need for an agentive recipient in the DITRANSITIVE construction renders *Harry kicked the door the ball* somewhat anomalous.

On this account, syntactic patterns are inextricably linked with meaning, and grammaticality judgments are rightly influenced by semantic and pragmatic factors. The interpretation and acceptability of an utterance thus depends not only on well-formedness conditions but also on the structure of the language user's conceptual ontology and on the situational and discourse context.

The main representational complexity introduced with these multiword constructions is the possibility of structure in the form pole. As mentioned above, although individual lexical items can evoke complex frames with multiple participant roles (e.g., *bye-bye*, *baseball*), the actual mapping between the form and meaning pole is necessarily straightforward. With multiple form units available, however, additional structures arise, both within the form pole itself and, more significantly, in the *relational correlations* between the form and meaning poles.[2] That is, a multiword construction may involve a more complex, *structured map* between its form and meaning poles, with maps between form and meaning relations whose arguments are also mapped.

In addition to the sound patterns of individual words, the form pole includes intonational contours, morphological inflections and word order. As with single words, the meaning pole encompasses the much larger set of frame-based conceptual knowledge. The constructional mapping between the two domains typically consists of a set of form relations (such as word order) corresponding to a set of meaning relations (such as role-filler bindings).

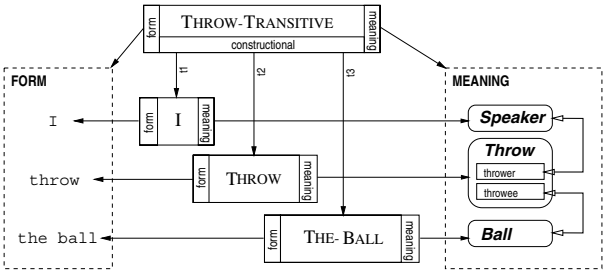

Figure 1: A constructional analysis of the sentence, *I throw the ball*, with form elements at left, meaning elements at right and some constituent constructions linking the two domains in the center.

As an example, Figure 1 gives an iconic representation of some of the possible constructions involved in an analy-

[2] See Gasser and Colunga (2000) for arguments that the ability to represent relational correlations underlies infants' reputed aptitude for statistically driven learning of concrete and abstract patterns.

sis of *I throw the ball*. The lexical constructions for I, THROW and THE-BALL[3] all have simple poles of both form and meaning. But besides the individual words and concepts involved in the utterance, we have several word order relationships (not explicitly shown in the diagram) that can be detected in the form domain, and bindings between the roles associated with Throw and other semantic entities (as denoted by the double-headed arrows within the meaning domain). Finally, the larger clausal construction (in this case, a verb-specific one) has constituent constructions, each of which is filled by a different lexical construction.[4] Crucially, the clausal construction serves to associate the specified form relations with the specified meaning relations, where the arguments of these relations are already linked by existing (lexical) maps. For example, the fact that the I construction's form pole comes *before* the THROW construction's form pole means that the meaning pole of I (i.e., the speaker in the situation) fills the thrower role in the Throw frame.

A more formal representation of the THROW-TRANSITIVE construction is given in Figure 2. For current purposes, it is sufficient to note that this representation captures the constituent constructions, as well as constraints on its formal, semantic and constructional elements. Each constituent has an alias used locally to refer to it, and subscripts f and m are used to denote the constituent's form and meaning poles, respectively. A designation constraint (in Langacker's (1987) sense) specifies a meaning type for the overall construction.

construction THROW-TRANSITIVE
  constituents:
    construct t1 **of meaning type** *Human*
    construct t2 **of type** THROW
    construct t3 **of meaning type** *Object*
  formal constraints:
    $t1_f$ *before* $t2_f$
    $t2_f$ *before* $t3_f$
  semantic constraints:
    $t2_m$.thrower $\longleftrightarrow$ $t1_m$
    $t2_m$.throwee $\longleftrightarrow$ $t3_m$
designates $t2_m$

Figure 2: Formal representation of the THROW-TRANSITIVE construction, with separate blocks listing constituent constructions, formal constraints (e.g., word order) and semantic constraints (role bindings).

Although this brief discussion necessarily fails to do justice to Construction Grammar and related work, we hope that it nevertheless conveys the essential representational demands on the structures to be learned.

[3]The definite determiner *the* explicitly depends on a representation of the situational and discourse context that supports reference resolution. For simplicity, we will ignore the internal structure of "the ball" and treat it as an unstructured unit.

[4]This example, like the rest of those in the paper, is based on utterances from the CHILDES corpus (MacWhinney, 1991) of child-language interaction.

Learning Constructions

We can now specify our construction learning task: Given an initial set of constructions C and a sequence of new training examples, find the best set of constructions C' to fit the seen data and generalize to new data. In accord with our discussion of conceptual prerequisites, a training example is taken to consist of an utterance paired with a representation of a situation, where the former is a sequence of familiar and novel forms, and the latter a set of frame-based conceptual entities and role bindings representing the corresponding scene.

Previous work on Bayesian model merging (Stolcke, 1994; Bailey et al., 1997) provides a suitable starting point. In that framework, training data is first incorporated, with each example stored as an independent model. Similar models are then merged (and thereby generalized); the resulting drop in likelihood is balanced against an increase in the prior. Merging continues until the posterior probability of the model given the data decreases. In the case of probabilistic grammars (Stolcke and Omohundro, 1994), structural priors favor grammars with shorter descriptions, and likelihood is based on the probability of generating the data using the grammar.

We apply a similar strategy to our current task by casting it as a search through the space of possible grammars (or sets of constructions), where the grammars are evaluated using Bayesian criteria. The operations on the set of constructions (merging and composition, described below as **reorganization** processes) extend previous operations to handle relational structures. Similarly, the evaluation criteria need not change significantly for the construction learning case: structural priors favor grammars with fewer, more general constructions that compactly encode seen data; this measure combats the inevitable corresponding drop in the likelihood of generating the seen data using the grammar. Again, the learning algorithm attempts to maximize the posterior probability of the set of constructions given the data.[5]

The main complication requiring a departure from previous work is the need to hypothesize structured maps between form and meaning like those described in the previous section. Essentially, incorporating new data involves both the **analysis** of an utterance according to known constructions and the **hypothesis** of a new construction to account for any new mappings present in the data. These processes, described below, are based on the assumption that the learner expects correlations between what is heard (the utterance) and what is perceived (the situation).[6] Some of these correlations have already been encoded and thus accounted for by previ-

[5]Model merging conducts a best-first search through the hypothesis space based on available merges. It is thus is not guaranteed to find the best model, which would require searching through an exponential number of possible grammars.

[6]The task as defined here casts the learner as primarily comprehending (and not producing) grammatical utterances. The current model does not address production-based means of hypothesizing and reinforcing constructions, which would be included in a more complete model.

ously learned constructions; the tendency to try to account for the remaining ones leads to the formation of new constructions. In other words, what is learned depends directly on what remains to be explained. The identification of the mappings between an utterance and a situation that are predicted by known constructions can be seen as a precursor to language comprehension, in which the same mappings actively evoke meanings not present in the situation. Both require the learner to have an analysis procedure that determines which constructions are potentially relevant, given the utterance, and, by checking their constraints in context, finds the best-fitting subset of those.

Once the predictable mappings have been explained away, the learner must have a procedure for determining which new mappings may best account for new data. The mappings we target here are, as described in the previous section, relational. It is important to note that a relational mapping must hold across arguments that are themselves *constructionally correlated*. That is, mappings between arguments must be in place before higher-order mappings can be acquired. Thus the primary candidates for relational mappings will be relations over elements whose form-meaning mapping has already been established. This requirement may also be viewed as narrowing the search space to those relations that are deemed *relevant* to the current situation, as indicated by their connection to already recognized forms and their mapped meanings.

Details of these procedures are best illustrated by example. Consider the utterance U_1 = "you throw a ball" spoken to a child throwing a ball. The situation S consists of entities S_e and relations S_r; the latter includes role bindings between pairs of entities, as well as attributes of individual entities. In this case, S_e includes the child, the thrown ball and the throwing action, as well as potentially many other entities, such as other objects in the immediate context or the parent making the statement: S_e = {Self,Ball,Block,Throw,Mother,...}. Relational bindings include those encoded by the Throw frame, as well as other properties and relations: S_r = {Throw.thrower:Self, Throw.throwee:Ball, Ball.Color:Yellow, ...}.

In the following sections we describe what the learner might do upon encountering this example, given an existing set of constructions C that has lexical entries for BALL,THROW,BLOCK,YOU,SHE, etc., as well as a two-word THROW-BALL construction associating the `before(throw,ball)` word-order constraint with the binding of Ball to the throwee role of the Throw frame.

Construction analysis and hypothesis

Given this information, the analysis algorithm in Figure 3 first extracts the set F_{known} = {you,throw,ball}, which serves to cue constructions whose form pole includes or may be instantiated by any of these units. In this case, C_{cued} = {YOU,THROW,BALL,THROW-BALL}. Next, the constraints specified by these constructions must be matched against the input utterance and situation. The form constraints for all the lexical constructions are trivially satisfied, and in this case each also happens to map to a meaning element present in S.[7] Checking the form and meaning constraints of the THROW-BALL construction is also trivial: all relations of interest are directly available in the input utterance and situation.[8]

Analyze utterance. Given utterance U in situation S and current constructions C, produce best-fitting analysis A:

1. Extract the set F_{known} of familiar form units from U, and use them to cue the set C_{cued} of constructions.
2. Find the best-fit analysis $A = < C_A, F_A, M_A >$, where C_A is the best-fitting subset of C_{cued} for utterance U in situation S, F_A is the set of form units and relations in U used in C_A, and M_A is the set of meaning elements and bindings in S accounted for by C_A.

   A has associated cost $Cost_A$ providing a quantitative measure of how well A accounts for U in S.
3. Reward constructions in C_A; penalize cued but unused constructions, i.e., those in $C_{cued} \setminus C_A$.

Figure 3: Construction analysis.

In the eventual best-fitting analysis A, the constructions used are C_A ={YOU,THROW,BALL,THROW-BALL}, which cover the forms and form relations in F_A = {you,throw,ball,before(throw,ball)} and map the meanings and meaning relations in M_A = {Self,Throw,Ball,Throw.throwee:Ball}. (Remaining unused in this analysis is the form a.)

We proceed with our example by applying the procedure shown in Figure 4 to hypothesize a new construction. All form relations and meaning bindings, respectively, that are *relevant* to the form and meaning entities involved in the analysis are extracted as, respectively, F_{rel} = {before(you,throw), before(throw,ball), before(you,ball)} and M_{rel} = {Throw.thrower:Self, Throw.throwee:Ball}; the *remainder* of these not used in the analysis are F_{rem} = {before(you,throw), before(you,ball)} and M_{rem} = {Throw.thrower:Self}. The potential construction C_{pot} derived by replacing terms with constructional references is made up of form pole {before(YOU_f,THROW_f),before(YOU_f,BALL_f)} and meaning pole {THROW_m.thrower:YOU_m}. The final

[7] We assume the YOU construction is a context-dependent construction that in this situation maps to the child (Self).

[8] The analysis algorithm can be viewed as a version of parsing allowing both form and meaning constraints. More sophisticated techniques are needed for the many complications that arise in adult language – category constraints on roles may apply only weakly, or may be overridden by the use of metaphor or context. For the cases relevant here, however, we assume that constraints are simple and few enough that exhaustive search should suffice, so we omit the details about how cueing constructions, checking constraints and finding the best-fitting analysis proceed.

construction C_{U_1} is obtained by retaining only those relations in C_{pot} that hold over correlated arguments:

$(\{\texttt{before}(\texttt{YOU}_f,\texttt{THROW}_f)\}, \{\texttt{THROW}_m.\texttt{thrower:YOU}_m\})$

Hypothesize construction. Given analysis A of utterance U in situation S, hypothesize new construction C_U linking correlated but unused form and meaning relations:

1. Find the set F_{rel} of form relations in U that hold between the forms in the analysis F_A, and the set M_{rel} of meaning relations in S that hold between the mapped meaning elements in M_A.
2. Find the set $F_{rem} = F_{rel} \setminus F_A$ of relevant form relations that remain unused in A, and the set $M_{rem} = M_{rel} \setminus M_A$ of relevant meaning relations that remain unmapped in A. Create a potential construction C_{pot} = (F_{rem},M_{rem}), replacing terms with references to constructions in C_A where possible.
3. Create a new construction C_U consisting of pairs of form-meaning relations from C_{pot} whose arguments are constructionally related.
4. Reanalyze utterance using $C \cup \{C_U\}$, producing a new analysis A' with cost $Cost_{A'}$. Incorporate C_U into C if $Cost_A - Cost_{A'} \geq MinImprovement$; else put C_U in pool of potential constructions.
5. If U contains any unknown form units or relations, add (U,S) to the pool of unexplained data.

Figure 4: Construction hypothesis.

At this point, the utility of C_{U_1} can be evaluated by reanalyzing U_1 to ensure a minimum reduction of the analysis cost. As noted in Step 4 of Figure 4, a construction not meeting this criterion is held back from incorporation into C. It is possible, however, that further examples will render it useful, so it is maintained as a candidate construction. Similarly, Step 5 is concerned with maintaining a pool of examples involving unexplained form elements, such as the unfamiliar article a in this example. Further examples involving similar units may together lead to the correct generalization, through the reorganization process to which we now turn.

Reorganizing constructions

The analysis-hypothesis process just described provides the basis for incorporating new examples into the set of constructions. A separate process that takes place in parallel is the data-driven, bottom-up reorganization of the set of constructions based on similarities among and co-occurrences of multiple constructions. Figure 5 gives a high-level description of this process; we refrain from delving into too much detail here, since these processes are closely related to those described for other generalization problems (Stolcke, 1994; Bailey et al., 1997).

Continuing our example, let us assume that the utterance U_2 = "she's throwing a frisbee" is later encountered in conjunction with an appropriate scene, with similar results: in this case, both the unfamiliar inflections and the article are ignored; the meanings are mapped; and constraints with appropriate correlations are found, resulting in the hypothesis of the construction C_{U_2}:

Reorganize constructions. Reorganize C to consolidate similar and co-occurring constructions:

1. Find potential construction pairs to consolidate.
   - **Merge** constructions involving correlated relational mappings over one or more pairs of similar constituents, basing similarity judgments and type generalizations on the conceptual ontology.
   - **Compose** frequently co-occurring constructions with compatible constraints.
2. Evaluate how possible merge/compose operations affect the posterior probability of C on seen data, performing operations on a greedy, best-first basis.

Figure 5: Construction reorganization.

$(\{\texttt{before}(\texttt{SHE}_f,\texttt{THROW}_f)\}, \{\texttt{THROW}_m.\texttt{thrower:SHE}_m\})$

C_{U_1} and C_{U_2} bear some obvious similarities: both constructions involve the same form relations and meaning bindings, which hold of the same constituent construction THROW. Moreover, the other constituent is filled in the two cases by SHE and YOU. As emphasized in our discussion of conceptual representations, a key requirement is that the meaning poles of these two constructions reflect their high degree of similarity.[9] The overall similarity between the two constructions can lead to a merge of the constructional constituents, resulting in the merged construction:

$(\{\texttt{before}(\mathbf{h}_f,\texttt{THROW}_f)\},\{\texttt{THROW}_m.\texttt{thrower:}\mathbf{h}_m\})$

where $\mathbf{h}$ is a variable over a construction constrained to have a *Human* meaning pole (where *Human* is a generalization over the two merged constituents). A similar process, given appropriate data, could produce the generalized mapping:

$(\{\texttt{before}(\texttt{THROW}_f,\mathbf{o}_f)\},\{\texttt{THROW}_m.\texttt{throwee:}\mathbf{o}_m\})$

where $\mathbf{o}$ is constrained to have an Object meaning pole.[10]

Besides merging based on similarity, constructions may also be composed based on co-occurrence. For example, the generalized *Human*-THROW and THROW-*Object* constructions just described are likely to occur in many analyses in which they share the THROW constituent. Since they have compatible constraints in both form and meaning (in the latter case even based on the same conceptual Throw frame), repeated co-occurrence eventually leads to the formation of a larger construction that includes all three constituents:

[9] The precise manner by which this is indicated is not at issue. For instance, a type hierarchy could measure the distance between the two concepts, while a feature-based representation might look for common featural descriptions.

[10] Although not further discussed here, examples with unexplained forms (such as the a in U_1 and U_2) may also undergo merging, leading to the emergence of common meanings.

$$(\{\texttt{before}(\mathbf{h}_f,\texttt{THROW}_f),\texttt{before}(\texttt{THROW}_f,\mathbf{o}_f)\},$$
$$\{\texttt{THROW}_m.\texttt{thrower}{:}\mathbf{h}_m,\texttt{THROW}_m.\texttt{throwee}{:}\mathbf{o}_m\})$$

Note that both generalization operations we describe are, like the hypothesis procedure, merely means of finding potential constructions, and are subject to the evaluation criteria mentioned earlier.

Discussion

We have described a model of the acquisition of grammatical constructions that attempts to capture insights from child language using the formal tools of machine learning. Methods previously applied to word learning are extended to handle grammatical constructions, which are claimed to require new representational and algorithmic machinery.

The model is compatible to the extent possible with evidence from child language acquisition. In particular, the tight integration proposed between comprehension and learning is consistent with usage-based theories of language acquisition: new constructions are hypothesized to capture form-meaning correlations not covered by known constructions, in a manner akin to some of Slobin's (1985) Operating Principles for mapping. The data-driven progression from lexically specific to more abstract constructions is also consistent with Tomasello's (1992) observation that the earliest verb-argument constructions are lexically specific and give way only later to more general argument structure constructions.

More broadly, since the algorithm produces constructions based on any utterance-situation pair and existing set of constructions represented as described above, it can apply equally well for more advanced stages of language development, when the learner has more sophisticated meaning representations and more complex constructions. The potential continuity between early language acquisition and lifelong constructional reorganization offers hope for the modeling of adaptive language understanding systems, human and otherwise.

Abstract

The acquisition of infant causal perception has been the center of considerable debate, and some have attributed this phenomenon to an innate causal module. Recent studies, however, suggest that causal knowledge may develop in infants through experience with the environment. We present a computational model of causal knowledge acquisition built using the Constructivist Learning Architecture, a hierarchical self-organizing system. This system does a remarkably good job of developing causal perception from a component view to a holistic view in a way that mirrors data from habituation studies with human infants.

Causal Perception in Infants

Causal perception has been the focus of philosophical inquiry for centuries, but it received its first notable psychological investigation by Michotte (1963). He presented adults with a scene in which one billiard ball struck another stationary ball, resulting in the launching of the stationary ball, and the halting of the moving ball. The subjects, naturally, described this scene as a "causal" event. But by manipulating the launching event (along spatial or temporal dimensions), Michotte could affect a subjects' likeliness of perceiving causality. One can alter the *spatial* component of the event by introducing a gap between the two balls, so that agent and the object never actually touch. Also, one can alter the *temporal* component by introducing a delay between the moment of contact and the moment of launching. As these components deviated from zero gap and zero delay, adult subjects were less likely to classify the event as "causal." These events are illustrated in Figure 1.

Since then, researchers have combined these events with habituation techniques to demonstrate the presence of causal perception in infants. One such study, by Leslie (1984), was able to demonstrate 6 1/2-month-old infants' ability to discriminate between different launching events. Leslie further demonstrated that infants' responses were based, in part, on the causality of the event. For example, infants habituated to a causal event would dishabituate to a non-causal event (e.g. from direct to gap), or vice versa. But infants would not dishabituate to the same degree if the causality remained constant between events (e.g. from delay to delay+gap). Leslie then claimed that these results, since they came from such young infants, were the product of an innate "causal module".

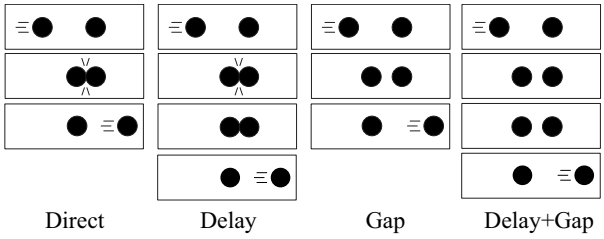

Figure 1: Four different launching events.

More recent studies, though, have cast doubt on a nativist view of causal perception. Cohen and Amsel (1998) performed a similar experiment on 6 1/4-month-old infants, and re-affirmed their ability to discriminate causal events from non-causal events. But they then ran the same experiment on 5 1/2-month-old and 4-month-old infants and found that these younger infants were not able to discriminate between launching events strictly on the basis of causality. Rather, infants responded to the spatial and temporal *components* of the event. Unlike the older infants, younger infants would respond to the introduction or removal or either a delay or a gap, regardless of how this change impacted the causality of the event.

Cohen and Amsel (1998) posited that these results indicated a developmental component to causal perception. It is this progression from component to high-level concept that we are interested in modeling. The development of causality is just one instance of a more general part-to-whole progression that can be seen in a variety of cognitive developmental domains. Cohen (1998) pointed out numerous studies of developmental

cognition that fit this general framework, and proposed an *information processing* approach to cognitive development as an alternative to nativism. Rather than being born with a set of innate perceptual modules, infants start with very low-level perceptual capabilities. This approach is summarized by the following set of propositions (Cohen & Cashon, 2000):

1. Perceptual/cognitive development follows a set of domain-general information processing principles.
2. Information in the environment can be processed at a number of different levels of organization.
3. Higher (more holistic) levels can be defined in terms of the types of relations among lower (parts) levels.
4. Development involves progressing to higher and higher levels.
5. There is a bias to initiate processing at the highest level available.
6. If an information overload occurs (such as when movement is added or when the task involves forming a category), the optimal strategy is to fall back to a lower level of processing.

At the very least, long term development appears to play an important role in the perception of high-level concepts such as causality, regardless of the concept's origin. There are countless learning systems which model knowledge acquisition. But we know of no such model that conforms to the six propositions of developmental information processing described above. There are also very few computational models of infant cognitive development that differentiate between long-term learning and short-term habituation, let alone use one to determine the other. One example in the language development domain has recently reported by Schafer and Mareschal (2001).

Constructivist Learning Architecture

The Constructivist Learning Architecture (CLA) (Chaput, 2001) is a hierarchical self-organizing system designed to generate concepts at multiple levels of abstraction through the organization of sensory input. Using the six propositions of cognitive development listed above as a design specification, CLA was built to learn hierarchical knowledge structures through observation, and use those structures to produce the kind of short-term habituation effects that infants exhibit throughout their development.

The information processing approach to cognitive development described above does not mention any kind of corrective feedback, and thus suggests an unsupervised learning system. For this reason, CLA uses one such system, the Self-Organizing Map (Kohonen, 1997), as a building block. The Self-Organizing Map (SOM) is a two-dimensional matrix of nodes, each of which stores a feature vector. As stimuli are repeatedly presented to the SOM (as feature vectors), the SOM adjusts the feature vectors of its nodes to represent the observed stimuli. A trained SOM exhibits the following attributes: 1) the feature vectors of nodes in a SOM reflect the stimuli presented to the SOM (*environmental representation*); 2) nodes which are close to each other in the network have similar feature vectors (*similarity topography*); and 3) stimuli which occur more often will be represented by a larger number of nodes (*frequency effect*).

But although the SOM performs the kind of unsupervised category formation that appears to be at work in cognitive development, it does not by itself form the kind of hierarchical knowledge representation suggested by the information processing approach.

CLA achieves this hierarchical representation by connecting multiple SOMs into a hierarchy. Like a regular SOM, the lowest layer of CLA (Level 1) receives raw input from the environment. When a stimulus is introduced, each node in the Level 1 layer receives an activation, A, which is in proportion to how close the stimulus is to the nodes' representation. (This is determined using a Euclidean distance metric.) These activation values are then collected for the layer into a corresponding matrix of activation values, or an *activation matrix*. This activation matrix then becomes the input vector to the layer directly above. This process then repeats for as many layers as are contained in the whole system. For an illustration, see Figure 2.

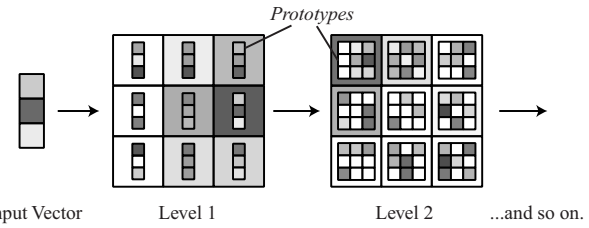

Figure 2: The first two layers of an example CLA. The darkness of each cell represents its level of activation.

Of course, two SOMs connected in this fashion can learn no more or less than a single SOM would. But the stratification of the SOMs allows for processing to occur at intermediate stages. There are three types of intermediate processing that are relevant to the present discussion: activation decay, activation blurring, and multi-modal layers. *Activation Decay* allows the activation of a given node to decay over time, rather than reset at each time step. This is useful as a rudimentary representation of time and sequence. *Activation Blurring* will "blur" the activation matrix by applying a Gaussian filter to the matrix. This has the effect of spreading the activation of a given node to

surrounding nodes, which is particularly useful given the SOM's similarity topography feature. Finally, a layer can receive input from two or more lower-level layers. We call these layers *Multi-Modal Layers*.

The result is a system that will have the information processing properties listed above, which we address one by one. First, CLA is not designed for any particular domain, but is a domain-general learning architecture that can readily be applied to any number of areas in cognitive development. Second, when a stimulus is introduced to the system, it will create activation patterns at multiple layers, which are actually different levels of organization; processing of these patterns can occur at any of these layers. Third, because each layer is organizing activation patterns of the layer beneath it, higher-level representations can be defined in terms of the types of relations among lower-level representations.

Fourth, learning in CLA involves progressing to higher and higher levels. When CLA is learning, each layer is trying to build categories out of the activation patterns of the layer beneath it. While one layer is organizing, all the layers above it cannot form stable categories because the underlying activation patterns are unorganized. Only when a layer "settles" into a coherent organization can the layers above it organize. The result is a progression from level to level.

Propositions 5 and 6 involve the resulting behavior of the system, rather than its organization. This paper does not address these propositions directly, but we do consider their ramifications in the discussion section.

Experiment: Learning a Causal Event

We conducted an experiment designed to show whether CLA could model the data produced by human infant subjects in the Cohen and Amsel (1998) study, given the same experiment design and starting set of assumptions. Specifically, we are looking to see if our model exhibits the part-to-whole progression demonstrated in infants between 4 and 6.25 months.

Design

Cohen and Amsel (1998) posit that infants are able to perceive the spatial and temporal components of a launching event before they perceive its causality. For this reason, we present the launching events to the learning system by means of two input vectors. The first input vector (the "movement vector") reported the magnitude of the movement of each of the two balls with two rows of nodes. By ignoring the position of each ball, this layer would use activation decay to represent the temporal information of the launching event and exclude the spatial information. The movement vector represented the movement of each ball, with each ball represented in its own row. The element of the row corresponding to the amount of absolute change in position, scaled to the width of the input vector, was set to 1.0. So, elements ~~to~~ on the right side of the vector represent rapid movement, while the left most element would represent no movement. These values decay over time.

Figure 3, for example, shows the state where the first ball (represented in the top row) is now stationary, but was recently moving; while the second ball (represented in the bottom row) is now moving, but was recently stationary. This state occurs in a direct launching event shortly after a collision.

Figure 3: The movement input vector. The decay is shown by a decrease in brightness (or change in color from yellow to red).

The second input vector (the "position vector") reported the position of the balls on the table. The position was represented by a 20 element vector. (The vector only had one row of nodes because the collisions presented were always horizontal.) The positions of the balls on the table were scaled to the 20 element vector, and the element nearest to each ball's position was set to 1.0. Complimentary to the movement vector, the position vector reports the spatial information and excludes the temporal information.

Figure 4: The position input vector.

In Figure four, we see the state where the two balls are close, but not touching. Like Figure 3, this state occurs in a launching event shortly after a collision.

Receiving each input vector was a 5-by-5 node layer to observe it. The "movement layer" organized activation patterns in the movement vector, while the "position layer" organized activation patterns in the position vector. These Level 1 layers would learn the independent spatial and temporal features of the launching event.

Finally, there was a Level 2 layer (the "Top Layer"), which observed *both* bottom-level layers. This layer, 6-by-6 nodes, would learn the combination of activation patterns in the Level 1 layers. Thus, it should discover the combination of spatio-temporal events that comprise each of the events.

The movement vector had an activation decay of 0.25, so that the movement layer could learn the temporal attributes of the ball movements. All other layers had an activation decay of 1.0 (instant decay). Similarly, the position vector had its blurring set to 0.6 to let it see proximal ball positions as similar (that is, having a ball at position 3 is very similar to having a ball at position 4, but very different from having a ball at position 17). All other layers had their blurring set to 0.0 (that is, turned off).

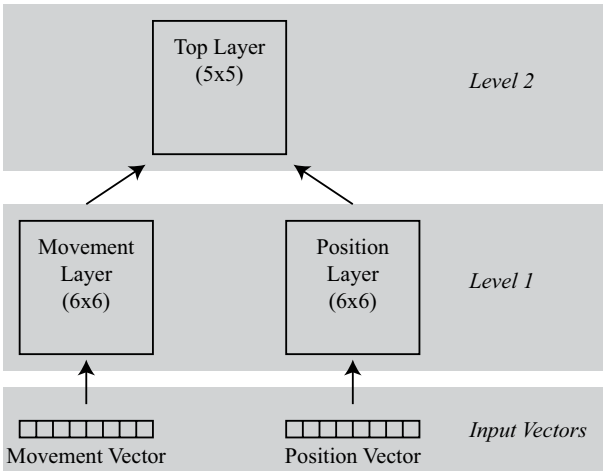

Figure 5: A schematic of the CLA used in the causality experiment.

To generate the launching events, we used a simulated "pool table" written for this experiment. This pool table is used for both the long-term training of the learning system as well as the short-term habituation studies. A simple algorithm was used to represent the state of the pool table through the two input vectors.

For long-term training (meant to represent an infant's long-term experience with the world), the learning system was presented with 2500 complete launching events. The type of launching event presented to the learning system was chosen using a probability meant to approximate roughly the nature of the real world: a direct launching event had a 0.85 probability of being chosen, while delay, gap, and delay+gap events each had a probability of 0.05. The presentation of a complete launching event constituted a single training cycle. The learning rates and neighborhoods of each SOM in the CLA system were decreased as training progressed. (Learning rate decreased from 0.1 to 0.0 over 1000 cycles, and the neighborhood from 1.0 to 0.0 in the same time frame.) This is the customary training procedure when using SOMs.

In order to simulate the changes during the short-term habituation trials, a "familiarity" variable F was associated with each node. Remember that we associate an activation A with each node. Familiarity for each node always approached the node's activation by some rate using the formula $F=F+r(A-F)$, where r is the rate of approach. We then determined an output O for each node using the formula $O=A^{(1.0-(A-F))}$. Recalling that both F and A are between 0.0 and 1.0, the result is that output levels are amplified, relative to raw activation, as activation differs from the familiarized level. (See Figure 6 for a graphical representation of these values.) The output for each node in a layer was summed to create a Layer Output. This was then averaged across the duration of the event, giving us a Mean Layer Output. Dishabituation was measured as *change* in Mean Layer Output.

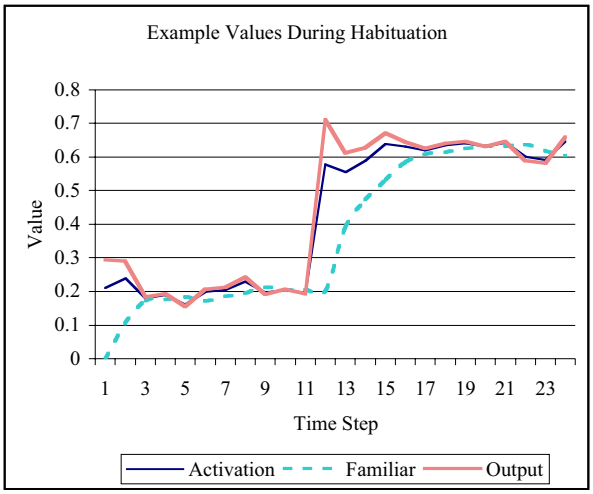

Figure 6: Example values of Activation, Familiarization and Output for a single node during the habituation trials. An event change at time step 12 is represented by a jump in activation.

For each habituation trial, the network was exposed to five repetitions of the habituation event, and then exposed to the test event. A complete habituation experiment consists of 16 parts: four habituation events by four test events. Familiarity levels were cleared for all nodes before each part of the habituation experiment. In all, 12 "simulated infants" were fully trained and tested.

Results

Because of the nature of the events we are dealing with, the difference between a delay event and a gap event should be the same as the difference between a direct event and a delay+gap event. This is because both pairs involve equal changes along the spatial *and* temporal axes. (See Figure 7.)

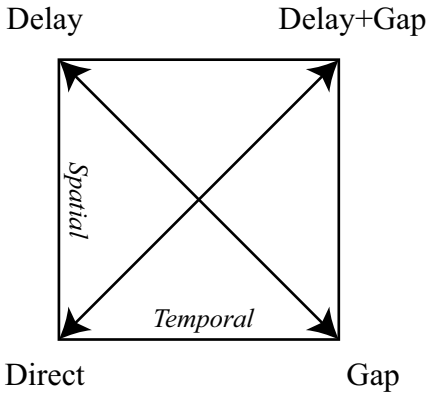

Figure 7: Launching events along spatial and temporal axes. Events at opposite corners involve both a spatial and temporal change of equal amounts and, thus, should be equivalent given a component model.

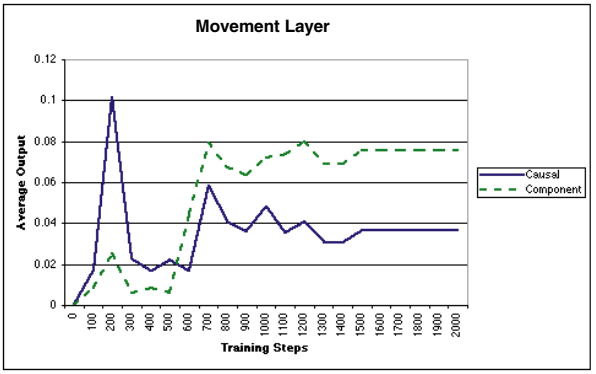
We averaged the dishabituation levels for delay-to-gap trials with gap-to-delay trials, and compared them to the average of direct-to-delay+gap trials and delay+gap-to-direct trials. We did an analysis of variance on both of the Level 1 layers and found that, in fact, both showed a significantly greater response to delay-gap changes, $F(1,11) = 243.3$, $p < .0001$ and $F(1,11) = 34.4$, $p < .0001$ for the movement and position layers, respectively.

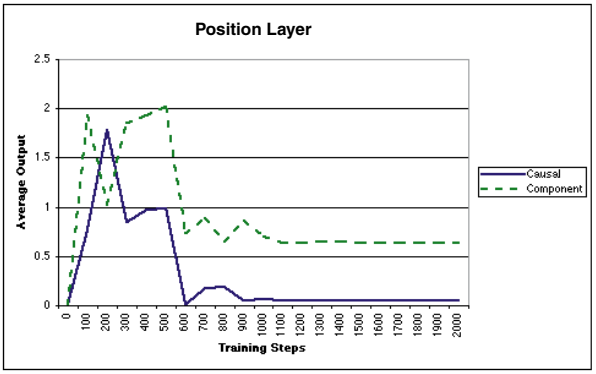
This odd disparity comes about because we have designed each of the Level 1 layers to train on one component exclusively, to the exclusion of the other. For example, the movement layer, which is sensitive to temporal differences, is *insensitive* to spatial differences, so that a direct event and a gap event look nearly identical. For this reason, we would expect this layer to see the direct event and the delay+gap event as similar, since the direct event looks like a gap event, and the delay+gap event also has a gap. The converse is true for the position layer. Thus, we would expect these two layers to respond more to the delay-to-gap change.

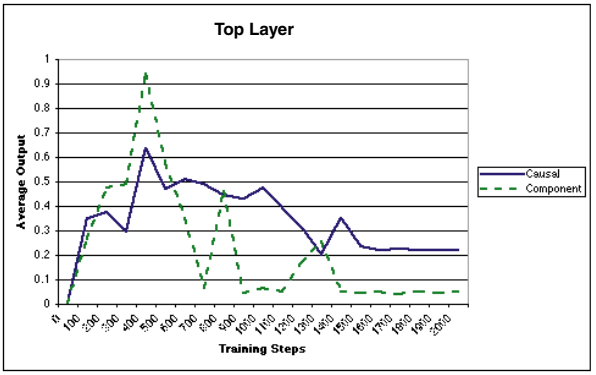
We verified that this difference was the result of the exclusivity of the input by comparing the average of trials where there was strictly a spatial change to the average of trials where there was strictly a temporal change. There was a significantly greater response to temporal changes than spatial changes in the movement layer, $F(2,22) = 4.1$, $p < .05$. And, conversely, there was a significantly greater response to spatial changes in the position layer, $F(2,22) = 123.2$, $p < .0001$.

Having verified that our Level 1 layers were operating according to our expectations, we then wanted to see if the Top Layer was responding to the components of the events or to their causality. We ran an analysis of variance on the same two event types as above: direct-delay+gap and delay-gap. Without the component exclusivity present in the Level 1 layers, the difference between these two conditions should be the same. However, there was a significantly greater response to the direct-delay+gap change than to the delay–gap change, $F(2,22) = 15.3$, $p < .0001$. This shows a clear preference on the basis of causality rather than just the independent components.

We can see, too, that this difference in processing has a developmental or long-term experiential component. Figure 8a and 8b shows the preference for a component model of causality settling in the two Level 1 layers after about 800 training cycles. Figure 8c shows that the Top Layer does not settle on a causal model until about 1500 cycles. As mentioned earlier, this is because of the nature of CLA: the lower levels must settle before the higher levels can.







Figures 8a, 8b and 8c: The acquisition of a component model vs. a causal model in different layers over time.

Discussion

Our CLA system has created a hierarchical knowledge structure that can produce habituation results compatible with those from similar studies with human infants. These results are consistent with those of Cohen and Amsel (1998) as well as Leslie (1986). Contrary to Leslie's conclusions, however, our model does not rely on a causality module.

That is not to say, of course, that our model has *nothing* built in to it. CLA is not *tabula rasa.* Unlike a modularist view, though, the innate attributes of CLA are domain general information processing principles. More generally, CLA has innate processes, rather than specific innate knowledge of abstract concepts.

CLA also relies on the vast majority of direct events in the world compared to non-direct events. We believe that infants also rely on this arrangement. CLA is guided by the nature of the environment to develop a causal model because there are simply more direct events in the environment. We can imagine an alternate universe which contained more delay events than any other kind, and our model would predict that development in this kind of environment would result in a drastically different world view.

One might ask what the point of having a stratified representation of causality might be, when it might be possible to achieve this same learning with a monolithic system. As previously stated, our hierarchical approach has the effect of producing the stages in development that we see in infants. But more than just fitting the experimental data, a hierarchical representation makes it possible to address the last two information processing principles described above. Cohen and Cashon (2000), and others, have observed hierarchical knowledge processing in infants, both in terms of perceptual preference and in handling cognitive overload. CLA's hierarchical design makes such processing possible, where a monolithic system would not. We intend to use CLA for robotic control, and we feel that principles five and six can be used with CLA's knowledge hierarchy to give certain layers priority over others. Also, we plan to test proposition six by overloading our system and seeing if it produces the "fall back" phenomenon that has been demonstrated in infants.

Conclusion

Although there are several connectionist models of infant development, CLA is the first to use hierarchical representation and differentiate between long-term and short-experience. These are important factors in cognitive development, and are often not given much weight even in *real* infant habituation experiments. The information processing approach to cognitive development has been applied to infant cognition with considerable success. We feel that a computational model which uses this approach holds promise for modeling the acquisition of a variety of domains within infant, child, and even adult cognition.

Abstract

Some effort has been made to examine why people often do not adopt efficient strategies, however little attempt has been made to determine the conditions that support strategy generation. This study examines how practice may lead to efficient strategy generation, through perceptual noticing and the elaboration of a device representation. Forty-three participants were required to complete drawing tasks in MS PowerPoint, for which there are a number of possible strategies that share the same component operators, and yet vary in efficiency. Merely by practicing a component of a less efficient strategy, a more efficient strategy was generated earlier on in the experiment. Further, the efficiency of the strategy used at test was correlated with device knowledge. It is proposed that through practice a user's device representation becomes elaborated, and this in turn leads to strategy generation. The possibility of a perceptual noticing mechanism for problem solving was also investigated, however providing strong perceptual groupings did not aid strategy generation.

Introduction

A reliable finding in experimental psychology is that practice on a task leads to faster and less erroneous performance of that task. In the 1920s Snoddy (1926, as cited in Anderson, 1995) graphed learning data and demonstrated that a power function characterises the rate of improvement in the performance of a task. This means that with practice the speed at which people complete a task increases with diminishing returns (Newell and Rosenbloom, 1981).

A growing body of evidence suggests that power law learning occurs within strategy, and not with regards to the task as a whole (Rickard, 1997; Delaney, Reder, Staszewski and Ritter, 1998). Compton and Logan (1991) suggest that improvement in the performance speed of a task is often due to the adoption of more refined and effective strategies.

However, there appears to be evidence that people do not adopt efficient strategies as rapidly as might be expected. Early explanations for this failure centred around the Einstellung effect, where prior experience results in a reluctance to investigate alternative procedures for a novel task (Luchins, 1942). Inefficient use of a device was also investigated using the ACT theory of skill acquisition (Anderson, 1982) where procedures that hinder completion of a task are discarded upon detection, however procedures that are sufficient and yet inefficient are less easily identified and so are maintained. In considering the problem of inefficient device use, Carroll and Rosson (1987) suggest that people are trapped by a production paradox, meaning that users are so focused on completing tasks, that they are unlikely to take time out to learn about a device. Paradoxically, if time were spent learning about the device, performance might be improved in the long term.

More recent evidence suggests that even people who are very skilled at a set of tasks are also not likely to operate as efficiently as might be expected (Nilsen et al., 1993; Nilsen, Jong, Olson and Polson, 1992). For example Young and MacLean (1988) found users do not always choose the faster method when presented with several different routines. Bhavnani and John (1997) observed that even after several years of experience and formal training in a particular CAD package, many users had not adopted efficient strategies. Further, the use of inefficient strategies impacted upon completion times and caused an increase in low level error. Bhavnani, John and Flemming (1999) highlight the difficulty of moving from "sufficient use to a more efficient use of computer applications" (p.183). The reason for this inefficiency, they suggest, is not related to the standard of interface design or experience with the package, but to strategic knowledge. Once participants received both traditional command based training ('learning to do') and strategic knowledge training ('learning to see' or recognize opportunities for efficient strategies to be used), it was found that most tasks were performed using efficient strategies (Bhavnani et al., 1999; Bhavnani, in press). However, the relative success of those who received strategic knowledge training should not be too surprising, as during the extensive training stages participants were explicitly taught each strategy. The tests therefore are more of an ability to recall and apply efficient strategies to novel situations, rather than strategy generation per se.

Some would argue that the use of strategies, that on the surface appear inefficient, could actually be rational.

Potential costs associated with strategy generation, such as time spent exploring the device and searching through problem space, could outweigh the benefits that a possible new strategy may deliver. It may therefore be rational to maintain sufficient, yet inefficient procedures. For example with regards to choice between strategies, Young and MacLean (1988) found that where the effort of using a strategy is perceived to be high, people are prepared to 'trade off' the possible benefits of using that strategy. Users choose to continue with a method that is easier to implement, yet results in a slower task completion time.

Early attempts at investigating strategy change by Anzai and Simon (1979) found that participants spontaneously advanced through several strategies when solving the Tower of Hanoi task. Their explanations for efficiency gaining strategy changes included both mechanisms that perform modifications on existing procedures to make them more efficient (such as the identification and removal of redundant steps), and also a mechanism for perceptual noticing. In the Tower of Hanoi, this perceptual noticing mechanism identifies that the problem can be restructured in terms of pyramids.

Recent attempts to model strategy generation and change include Shrager and Siegler's (1998) SCADS simulation. Mechanisms for strategy generation and change proposed by Crowley, Shrager and Siegler (1997) were used to simulate children's use of addition strategies. Shrager and Siegler's (1998) model represents a significant step forward in understanding. However, due to the focus of the model, the reasons that people fail to apply the hypothesised mechanisms for strategy generation are not considered.

The study reported provides evidence for the conditions that support strategy generation. While some effort has been spent examining the failure of people to use optimal strategies, little evidence exists about how and when people generate new strategies. Crowley et al. (1997) suggest that during practice people make a method more efficient by identifying and eliminating redundant sub-procedures. However it is possible that practice results in efficient performance through other mechanisms such as perceptual noticing of task related features and elaboration of the user's device representation. Perceptual noticing may involve both noticing the structure of the task and the structure of objects to which operators are applied. Known operators could, as a result, be applied more efficiently. Practice may also allow elaboration of the device model through incidental learning, and this in turn may permit a more comprehensive, high quality search for efficient procedures.

The task used in the experiment is a computer-based drawing task, similar to that used by Bhavnani et al. (1999), and was selected for its ecological validity. The task provides a rich domain for studying strategy change as the basic fence, copy and paste operations can be embedded within a range of relatively sophisticated strategies for complex drawings. For example, people asked to draw a series of repeated items may use the recursive multiple-item-copy (MIC) strategy. This is where a single item is copied, then the resulting pair, and then all of the objects are copied again. The number of objects increases exponentially.

Also, following the proposal of a perceptual noticing mechanism by Anzai and Simon (1979), the task was either presented with a strong pattern that contained groupings useful to the development of the efficient strategy, or with no groupings. A mechanism for perceptual noticing should lead the user to be more likely to generate a multiple item copy strategy where groupings allude to the strategy.

The study is designed to determine whether merely practicing known procedures makes the generation of efficient strategies more likely. The importance of a mental representation of both the device and task, and their development through practice, will be examined. It is hypothesised that practice on the components of a non-optimal strategy can establish the prerequisites, through elaboration of the device representation, for the generation of a new strategy.

Method

Participants

Forty-three regular computer users, first and second year psychology undergraduates ranging in age from 18 to 32, took part in the experiment for course credit. All participants were given 2 hours of course credits to take part in the study, no matter how long they took (the average time taken was approximately 1 1/2 hours), in order to encourage efficient completion of the tasks.

Design

The study involved two between subjects manipulations. Although all of the participants knew the component procedures necessary for the efficient strategy to be used, the manner in which they were practiced varied. Practice trials involved different objects, same objects or same objects with space between them (see Table 1). The second manipulation was the pattern of the test item. In order to use MIC it was hypothesized that a participant must make certain perceptual groupings. Where there was a patterned test item, the objects were arranged so that the groupings necessary to use MIC were already present (Figure 1).

Procedure and Materials

The participants completed an informed consent form and a brief questionnaire to determine prior experience

with Microsoft PowerPoint, as well as other software packages with drawing functions. The tuition phase was then completed, which ensured that the participants mastered basic drawing skills (such as drawing, moving and altering shapes, and selection of single items by fencing), and were also made aware of the existence of some functions, including copy and paste. The participants were informed that they should only use functions identified in the tutorial stage. These included fencing, copying and pasting, but, for example, excluded duplication and grouping.

After the tuition phase the participants completed an open-ended questionnaire designed to assess knowledge about the device. Ten questions relevant to the key concepts particular to the MIC strategy were included. Five questions related to fencing multiple objects with space between them and five related to the manipulation of multiple objects. The participants were then given the same pre-test version of the test stimuli and asked to complete the drawing in as few moves as possible. The pre-test item consisted of eight equally spaced two-item objects (P- in Figure 1). If a participant completed the pre-test using any form of MIC (see Table 2) they were excluded from the analysis.

The main series of items were then presented. Each participant carried out four practice trials (see Table 1), filled in the device representation questionnaire (same as before), and then completed a saturation trial. The saturation trial involved drawing one shape, fencing it and using copy and paste to create another identical shape. This was designed to make sure all participants had fence, copy and paste functions readily available to them in memory. Half of the participants were then presented with a patterned test trial (P+) and half were presented with a non-patterned test trial (P-).

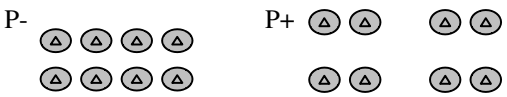

Figure 1: Non-patterned and patterned test trials

Four practice trials, the device representation questionnaire, saturation trial and test stage were repeated four times. All participants received exactly the same instructions and drew the same stimuli, except for the type of practice trials and the pattern of the test trials. Therefore each group had the same opportunity (in five test trials) to use the efficient strategy.

Table 1 shows examples of the practice tasks. The different practice trials allowed differential experience with the operators fence, copy and paste. All the participants used the operators in the saturation trial, yet in the practice trials they were used in different ways.

Table 1: Practice trials

Practice group	Explanation
1: Different objects 	Participants drew each shape one-by-one, as it was not possible to use fence, copy and paste.
2: Same objects 	The participants drew the first two shapes that constitute the first object, and used fence, copy and paste to complete the task.
3: Same objects with space 	Participants drew the two shapes on the left and used fence, copy and paste to complete the drawing.

If participants had not used the exponential MIC strategy during the first five test trials they were given five more opportunities to do so. They were instructed to complete the task as efficiently as they could, minimising the number of steps taken to complete the task.

Microsoft PowerPoint '97 was used to carry out the drawing tasks, these were all video recorded.

Coding of Strategies

There are at least seven strategies that can be used to complete the task with the functions made available to the participants (those identified in the tuition phase). Multiple Items Copy (MIC) is the most efficient manner of performing the task. This strategy involves fencing (as depicted in Figure 2), where all objects within the fence become selected, and the manipulation of more than one object at a time.

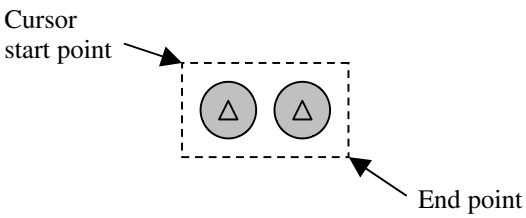

Figure 2: Fencing, by using the mouse to click and drag from the start point and releasing at the end point

There are some key concepts that must be understood before each strategy (see Table 2) can be used. Each practice group differs in their experience of these concepts. Firstly it must be appreciated that copy and paste can be used on a single item once it is selected, this being a central concept for the use of Element Copy strategy. All practice groups experience this through the saturation trial. Secondly it must be understood (to use DAC and MIC) that more than one item may be

selected by using a fence, and that copy and paste can be performed on all selected items at once. Only the two 'same objects' practice groups (2 & 3) experienced this. Finally, to use MIC it must be appreciated that items with space between them can be selected by using a fence, and that all selected items can then be manipulated together. Only the 'same objects with space' practice group experienced this.

Table 2: Possible strategies for completion of the task, result of GOMS analysis and points awarded

Strategy name, points for use and GOMS analysis result	Classification requirements and Example 
Element-by-element (EBE) 1 *153s*	Each two item picture is drawn element by element (a square would be drawn and then a triangle, process repeated 7 times).
Division (D) 2 *133s*	All of the first shape are drawn and then all of the other shape (all the squares drawn, then all triangles).
Element copy (EC) 3 *101s*	Copy and paste are used on single shapes (one square would be drawn, copied and pasted 7 times, and then the same for the triangle).
Detail Aggregate Copy (DAC) 4 *64s*	All the details are completed in the first object, then it is fenced, copied and pasted seven times (a house would be drawn and then fenced, copied and pasted 7 times).
Multiple Items Copy (MIC_1) 5 *53s*	As with DAC, but once the first 4 copies are in place, they are all fenced, copied and pasted to make 8.
Multiple Items Copy (MIC_2) 6 *50s*	As with DAC, but once the 2nd copy is in place, both are fenced, copied and pasted to make 4, pasted again to make 6, and pasted again to make 8.
Exponential MIC (MIC_{exp}) 7 *47s*	As with DAC, but once the second copy is in place both are fenced, copied and pasted to make 4. The 4 are then fenced, copied and pasted to make 8.

A GOMS analysis was carried out to determine the efficiency of each strategy. Points for each strategy are allocated on the basis of this analysis (see Table 2). Where available the moves were assigned the length of time specified by Olson and Olson (1990). Times for moves not covered in the literature were determined from an observational pilot study. The seven strategies were classified on a seven-point scale with 1 being the least efficient and 7 being the most efficient strategy.

Results

Seven of the forty-three participants used a form of MIC during the pre-test stage, and so were excluded from the analysis, leaving thirty-six. All participants were experienced users of at least one Microsoft package, yet inexperienced with Microsoft PowerPoint.

At the pre-test stage of the experiment there were no between group differences in time taken to perform the task, strategy used and device knowledge. An overall speed up in the performance of the task was observed, and by the fifth trial a main effect of practice on completion time was approaching significance [$F(2,30)=3.082$, $p=0.06$, $MSE=405.3$] (different objects $M=69$s, same objects $M=56$s, and same objects with space $M=49$s,).

Best Strategy Used at Test

Participants were given a strategy score ranging from one (inefficient strategy) to seven (efficient strategy) for each of the five test trials (see Table 2), and for the second set of test trials undertaken at the end of the experiment (in the event that MIC was not used earlier). A between subjects three by two ANOVA found a significant main effect of practice on the best strategy used at test [$F(2,30)=7.784$, $p<0.01$, $MSE=1.6$]. No main effect of pattern was found.

A Tukey HSD test confirmed a significant difference between the different ($M=4.4$) and same ($M=5.9$) objects conditions ($p<0.05$) and between the different and same objects with space ($M=6.3$) conditions ($p<0.01$). The difference between the two same objects conditions did not reach significance. The same pattern of significant results was found when considering the best strategy used over all ten test trials.

Strategy Use Score

For each participant the sum of strategy scores over the five test trials was taken as the strategy use score, and was essentially a measure of overall efficiency. A two by three between subjects ANOVA was performed on the data, and as before a significant main effect of practice was found [$F(2,30)=6.405$, $p<0.01$, $MSE=20.6$].

A Tukey test confirmed a significant difference between the different ($M=20.2$) and same objects ($M=25.0$) conditions ($p<0.05$) and between the different and same objects with space ($M=26.5$) conditions ($p<0.01$). The two same objects conditions were not significantly different.

Discovery Trial

A significant main effect of practice (but not pattern) was found for the trial (1-10) upon which one form of MIC was first used by a participant (those that did not use MIC at any time in the experiment were given a

score of 10), $F(2,30)=13.826$, $p<0.001$, $MSE=3.7$. A Tukey test found significant differences between the different ($M=6.9$) and same objects ($M=3.5$) conditions ($p<0.001$), and between the different and same objects with space ($M=3.2$) conditions ($p<0.001$).

There was no significant main effect of pattern, although a significant interaction (shown in Table 3) was found [$F(2,30)=6.337$, $p<0.01$] between pattern and practice. Simple effects tests found practice had a significant effect where the test item was patterned [$F_A@b1(2,30)=19.400$, $p<0.01$], and pattern had a significant effect where practice trials involved drawing different objects [$F_B@a1(1,30)= 8.046$, $p<0.01$].

Table 3: The mean trial upon which MIC was first used

	Practice		
	Different Objects	*Same Objects*	*Same Objects with Space*
Patterned	8.5	2.8	2.2
Non-patterned	5.3	4.2	4.2

Device Representation and Strategy Generation

The device representation questionnaire (DRQ) provided a score, out of ten, that reflected the knowledge each participant had about the device. This measure was repeated throughout the experiment and was specific to aspects of the device central to a MIC strategy. A Spearman's non-parametric correlation between improvement in the performance of the task (difference in strategy score from test trial one to test trial five) and the improvement in DRQ score was significant ($r_s=0.384$, $p<0.05$).

A two by three between subjects ANOVA was conducted on the score for each DRQ. Before practice, scores on the DRQ did not differ between groups. Results for all DRQs administered after practice (DRQs 2-5) followed the same pattern, and so the scores were combined. No main effects of pattern and practice on DRQ score were found, however interactions between practice and pattern were significant [$F(2,30)=7.312$, $p<0.005$, $MSE=3.3$] (see Table 4).

Table 4: Average score for DRQs 2-5

	Practice		
	Different Objects	*Same Objects*	*Same Objects with Space*
Patterned	5.8	7.9	8.9
Non-patterned	8.2	6.1	5.6

Simple effects tests revealed that practice had an effect where the test item was patterned [$F_A@b1(2,30)= 4.793$, $p<0.05$]. Pattern was found to have an effect on device representation where different objects were drawn at practice [$F_B@a1(1,30)=5.340$, $p<0.05$] and where objects drawn at practice were the same with space between them [$F_B@a3(1,30)=8.005$, $p<0.01$].

The questionnaire measured understanding of two concepts central to the use of MIC. Firstly, that multiple objects with space between them can be selected at the same time by using a fence, and secondly that multiple objects can be manipulated simultaneously once selected. For each of these concepts there were five questions. The trial upon which participants reached a good understanding of these concepts was taken to be when they answered four or all five of these questions correctly. An ANOVA revealed an interaction between practice and pattern for the trial upon which participants reached a good understanding of both fencing [$F(2,30)=3.451$, $p<0.05$, $MSE=1.8$] and manipulating objects [$F(2,30)=6.843$, $p<0.005$, $MSE=1.1$]. Simple effects tests found the same pattern of significant results for manipulating objects as were found on the overall DRQ results (Table 4). Further analyses found that a good understanding of fencing was reached significantly earlier on than a good understanding of manipulating objects [$t(35)=7.402$, $p<0.001$].

Discussion

As expected, practice resulted in the more efficient performance of the task. Those in groups where practice involved the selection and manipulation of more than one item performed the task more efficiently overall, generated more efficient strategies, and did so earlier on in the experiment. Although all groups used fence, copy and paste, the manner in which they were experienced influenced strategy generation. Most importantly, repeated use of the component parts of the less superior strategy proved useful for the generation of the new strategy (MIC). In addition, the more participants understood about the device, the better the strategy that was used at test.

For the copy paste task described, the results imply that people acquired information about the device through the repeated practice of a known method. Initially a good understanding of the fence operator was gained, and then an elaborated model of manipulating multiple objects. Participants learned more than was required to merely reduce the performance time of the method, as the knowledge acquired correlated with the efficiency of the strategy generated. This finding has implications for models of practice that assume people merely re-code previously stored information. Neither Anderson's compilation (1982), nor Rosenbloom and Newell's (1986) chunking model predict the results reported here. Both models explain how an existing strategy becomes more efficient, and thus effect a speed-up, rather than how information, acquired through practice, supports strategy change. Logan's (1988) instance-based model also fails to predict the

results reported here, as an increase in the number of instances of a strategy in memory can only support shift from algorithm to memory-based processing, not the kind of strategy change reported here. The results also have implications for models of strategy change. In Shrager and Siegler's (1998) model the role of new information acquired through repeated practice is not considered as a precursor to strategy change.

Also in contrast to Anzai and Simon (1979), providing the perceptual groupings that must be made in order to use the efficient strategy had no effect on strategy generation. However, groupings did have an effect on strategy generation depending upon the practice experienced. An explanation for this interaction may be that those in the different objects group, where efficient strategies were not readily available, had a relatively high workload. Constructing the pattern may have added to the high workload of the group, and so the perceptual noticing mechanism could not make use of the pattern, and in turn the use of the efficient strategy was not prompted. Alternatively, the pattern may only be useful for generating MIC if concepts central to DAC are known, without this the pattern may serve as a distraction. Similar explanations could be offered for the interaction between pattern and practice for the amount learned about the device.

In summary, the evidence reported here suggests that repeated practice of a known method can facilitate the generation of new strategies. A possible reason for this is that practice results in the elaboration of the user's device representation, which in turn supports strategy generation. These results challenge models of learning through practice that merely increase the efficiency of existing methods, and models of strategy change that fail to account for the role of practice.

A Potential Limitation of Embedded-Teaching for Formal Learning

Mei Chen (MeiChen@Vax2.Concordia.Ca)

Abstract

This paper presents a study that investigated the effects of two forms of "embedded teaching" on students' formal learning of high-school-level algebra. The term "embedded teaching" here refers to the presentation modes in which algebraic concepts, procedures, strategies, and principles are taught within the context of solving specific problems. Two forms of "embedded teaching" (i.e., program control, and learner-control) were compared to a conventional presentation mode in which various forms of algebraic representations were taught as a coherent system before students were introduced to problems. The three instructional modes were implemented in three versions of a computer algebra tutor. Three groups of high-school students (N=27) were randomly assigned to one of the three experimental conditions. Pre- and posttests were administered to measure changes in students' ability to construct different forms of algebraic representations, and their ability to make estimates using these different representations. A multivariate analysis of the pre- and posttest results indicates that overall student performance in all three conditions improved significantly on the two measures used (F (2, 23) = 46.6, p < 0.01). However, students in the conventional teaching condition achieved higher posttest scores (group mean = 86, and 93 on the measures of students' ability to construct algebraic representations and their ability to make estimates, respectively) than students in the two embedded-teaching conditions did (group mean for the two measures = 65 and 57 for the program-controlled condition; and group mean = 67, 59 for learner-controlled condition, respectively). Furthermore, all students in the conventional teaching condition completed the posttest successfully, compared to only 56% of students did so in each of the two embedded teaching conditions. Despite an overall disadvantage, 3 out of 9 students in each of the two embedded-teaching conditions received perfect scores whereas only 1 student in the conventional teaching condition did so. It seems that the conventional presentation mode provided an instructional context that enabled the majority of students to succeed whereas the embedded-teaching modes offered the conditions for certain students to reach their greatest potential but left others far behind.

This paper presents a study that investigated the effects of two presentation modes of "embedded teaching" on students' formal learning of high-school-level algebra. The term "embedded teaching" can be defined broadly or narrowly, depending on the purpose of the study. In the broad sense, most situated approaches that emphasize the learning of domain knowledge through expert-like activities and authentic problem solving in rich social, cultural and functional contexts can be thought as "embedded teaching." For example, the cognitive apprenticeship model (e.g., Collins, Brown, & Norman, 1989), problem-based learning (e.g., Barrows, & Tamblyn, 1980), goal-based scenarios (Collins, 1994; Schank, 1995), and case-based reasoning (Schank, 1995; Kolodner, 1994) can be all considered as "embedded teaching" (Hmelo, & Narayanan 1995). Although they can be characterized in many different ways and a wide array of features can be identified, situated approaches typically (a) focus on ill-defined, authentic problem solving tasks; (b) embed the learning of domain knowledge within a rich social and cultural context; (c) organize learning content and activities around problems or cases. Consequently, concepts, procedures, strategies, and principles are taught within the context of solving specific problems, as opposed to being taught as a coherent symbol system independently. Studies of "embedded teaching" in the past have often focused on the central role that social and cultural context played in learning, thus reflecting research traditions in anthropology and sociology.

The examination of social context is necessary for forming theories and good practice of situated learning. However, the focus of the study presented in this paper was placed on investigating the effects of "embedded teaching" from an instructional design perspective. That is, "embedded teaching" is defined as a narrow term that signifies the instructional techniques by which concepts, procedures, strategies, and principles are taught within a specific problem-solving context. The "embedded teaching" examined in this study represents merely an instructional feature but not the social and cultural characteristics of the situated learning approaches described above. The exclusive focus on the instructional feature of the "embeddedness" of the situated approaches in a study is justified for the following two reasons. First, as human beings and life-long learners, we have to complete a large part of our learning under solitary conditions due to the many practical limitations of getting together and learning with other people. Therefore, it is important to investigate what characteristics of instructional applications can effectively support the development of the individual knowledge in situations where rich social interaction and resources are lacking. Secondly, there is a formal system of symbols, or a structured body of scientific knowledge in a formal knowledge domain such as mathematics, physics, or chemistry. Therefore,

it is necessary to find out whether teaching concepts, procedures, strategies, and principles within the context of solving specific problems is more effective than teaching such knowledge as a coherent, representational system before introducing students to problems, as teachers often do in classroom teaching. The answer to this question is needed in order to design instructional applications, especially computer tutoring systems that effective foster individual learning in formal knowledge domains.

The Theoretical Background

A primary focus of analysis in cognitive science over the past three decades has been the processing structures of the brain and the symbolic representations of mind (Norman, 1993). Norman further characterizes such a research paradigm as studies of *symbolic representations* (Norman, 1993). Cognitive researchers have shown that structured, principle-based knowledge representation is a function of expertise (Chi, Feltovich, & Glaser, 1981). Therefore, one important goal of instruction is to help students form coherent and structured knowledge representations of the domain being studied (Glaser, 1989). Although they specify neither the elements of which instruction should be composed, nor the sequence in which the different instructional elements should be arranged, some cognitive theories seem to support an instructional approach by which the knowledge elements are structured and coherent, preferably proceeding from a declarative stage to a procedural stage. Kintsch's Construction-Integration (CI) model of discourse comprehension (Kintsch, 1988, 1998) and Anderson's ACT-R theory of cognitive skills represent two central tenet of this research paradigm.

It is apparent that Kintsch's CI model is a cognitive model of discourse comprehension rather than an instructional model, however, this model explains the ways that the mental representations are constructed when learning from text. According to Kintsch, comprehension (i.e., an important form of learning) is an interactive process between the learning materials and the mental models that learners formed on the basis of their prior knowledge. Kintsch suggests that the process of building a coherent mental representation from text depends on the learner's ability to recognize the structure of the text (Kintsch, 1998). Many studies have shown that the structural features of a text (e.g. coherence, the use of the outlines, headings) can help learners identify the structure of the text thus having a significant impact on learners' memory, comprehension, problem solving, and transfer (Kintsch, 1997, in Kintsch 1998; Mayer, 1989; 1997). It is postulated that the structural features of a text may enable learners to form a coherent knowledge representation of the material to be studied, the coherent representation formed, in turn, can guide the processes of selecting, interpreting, organizing, and integrating the subsequent information to be studied (Mayer, 1989). As a result, the structure feature of text can has impact on learning, especially for learners who lack prior knowledge of the domain (Kintsch, 1997, in Kintsch 1998).

Furthermore, Anderson's ACT-R theory asserts that the acquisition of cognitive skills proceeds from a declarative stage to a procedural stage (Anderson, 1983, 1993). Although both Kintsch and Anderson state that learning should be embedded in the context of meaningful activities, their theories seem to support a pedagogical approach in which learning proceeds from instruction that focus on the structured knowledge representations, to problem-solving activities that emphasize the use of the knowledge learned — a method that is frequently employed by teachers in their classroom teaching.

In contrast to the emphasis on the structured knowledge representations and rigid instructional sequence, situated learning approaches give great importance to the functional use of knowledge thereby the learning materials and activities are organized around problems or cases. The theoretical assumption underlying such approaches can be refered to as situated theory. From the situated perspective, thinking, knowing, and learning are situated within a particular context of intentions, social partners, and tools (Resnick, Levine, & Teasley, 1991; Greeno, 1997). Therefore, internal cognitive activities such as perceiving, understanding, remembering and reasoning are shaped and given significance within the context of activities (Greeno, Collins, & Resnick, 1996). The situative view challenges standard pedagogical practice for paying too little attention to the processes employed by experts to solve complex, realistic problems (Collins et al., 1989; Resnick et al., 1991). Situative theorists criticize learning opportunities provided to students within the scope of typical school activities as mostly involving memorization of factual knowledge and the rote manipulation of symbols and equations. As a result, the kind of knowledge that students acquire in conventional teaching often remains "inert" and can't be applied to other relevant problem-solving situations (Collins et al., 1989; Resnick et al., 1991). It is asserted that "embedded teaching" can facilitate students' development of problem-solving skills and reasoning strategies more effectively. It can also enhance students' conceptual understanding because knowledge is immediately used within a relevant context (Collins et al., 1989). A variety of pedagogical approaches that have been developed emphasize such situative nature of learning and cognition (e.g., Collins et al., 1989; Collins, 1994; CTGV, 1993; Schank, 1995; Kolodner, 1994).

An interesting phenomenon occurred in the debate over symbolic representations versus situated action is that, as Norman points out, the cognitive and situative researchers find different sets of observations to be

interesting and important (Norman, 1993). The same statement may also apply to the argument over conventional school teaching versus situated approaches to learning. Conventional teaching normally focuses on the understanding of symbolic representations and the command of symbolic manipulations whereas situated approaches typically places their focus on the development of students' ability to formulate and solve ill-structured, authentic problems. It is important to keep in mind that, in a knowledge domain such as mathematics, physics, or chemistry, there is a formal system of symbols, or a structured body of scientific knowledge. Therefore, an expert model of knowledge in such domains may consist not only of the strategies that are used in expert-like performance, but also of structured, principle-based knowledge representations of symbolic systems. Correspondingly, students should be encouraged and required to develop the full range of knowledge and skills in the domain, including the ability to understand the symbol systems correctly and manipulate symbols intelligently, the ability to communicate ideas scientifically, the ability to formulate and solve ill-structured problems proficiently and, ultimately, the ability to participate in expert practice in the real world. Therefore, an important question concerning "embedded teaching" is to understand whether it is indeed a more effective technique than the conventional method for teaching formal knowledge. The study presented in the paper attempts to find out whether the embedded teaching as a presentation mode is more effective than conventional teaching for computer-assisted learning of high-school-level algebra.

Methods

This study compared the effects of two presentation modes of "embedded teaching" (i.e., program control, and learner-control) to that of a conventional presentation mode. The three experimental modes were implemented in three versions of a computer tutor that was designed to teach linear functions to grade ninth students. Several features of the computer tutor are important for interpreting the results of the study. First, a cognitive task analysis was conducted to identify the specific elements of knowledge that students need in order to (a) construct multiple forms of algebraic representations (i.e., tables of values, graphs, and equations), and (b) make estimates using such representations (e.g., finding the price of ordering a given number of music CDs based on the relations expressed in a graph of linear functions). Second, the computer tutor employed a basic instructional model that consisted of instruction, demonstration, and practice. In addition, everyday-life scenarios were incorporated into the instruction, demonstration, and practice whenever possible, to help students make connections between their knowledge of the everyday life and the formal algebraic representational system that they were to learn. Furthermore, various media formats (text, graphics, and animations) were combined to describe some complex concepts, principles, and procedures. Finally, all three versions of the computer tutor utilized the same instructional materials, practice exercises, and media formats, varying only in terms of the "embeddedness" and "learner control". The following is a brief description of these conditions.

The first version of the tutor was designed as a base line for making the comparison (Condition 1). In this version, the computer tutor first presented instruction about the different forms of algebraic representations, explaining what are tables of values, graphs, or equations, and the relationship between the different forms of representations. After the instruction, the computer tutor then provided examples illustrating how to construct each of the different forms of algebraic representations and how to convert these representations from one form to another.

Two forms of "embedded teaching" were examined: a program-control instruction (Condition 2), and learner-control instruction (Condition 3). Both conditions presented the instruction about the different forms of algebraic representations (i.e., what are tables of values, graphs, or equations) within the context of constructing these representations. Because it was the instructional designer of the computer tutor who decided the occasions to introduce the relevant algebraic concepts and principles, students had to follow a fixed sequence imposed by the computer tutor in the program-controlled instruction (Condition 2). The ways that the computer tutor presented various types of algebraic knowledge might not meet the needs of individual students. Therefore, a learner-controlled hypermedia environment (Condition 3) was developed to enable students themselves to determine what, and when to consult a particular type of knowledge. In the learner-controlled hypermedia environment, students engaged directly in problem-solving activities without receiving any prior instruction or demonstration, but they could receive relevant instructions and demonstrations using hyperlinks. It is necessary to indicate that for both Condition 2 and 3, the instruction on algebraic representations was broken into small independent chunks to enable the computer tutor or students to access the relevant knowledge elements in the context of solving specific problems. This might create stronger links between particular knowledge chunks and their applications, but weaker links between the different forms of algebraic representations.

All three conditions included a practice session in which two problems similar to the one used in the demonstration were presented. Students could check their answers, or get the correct answers if them failed to provide the correct answers.

Participants

A public English school in suburban Montreal was

selected as the setting of the experiment. An effort was made to recruit as many participants as possible. As a result, two types of students constituted the sample pool for the experiment: (a) ninth graders in a below-average class, who had just finished learning linear functions one week prior to the pretest, but who had difficulties in math classes; and (b) eighth-graders from two regular math classes who had some knowledge of algebra, but hadn't explicitly learned about linear functions. A pretest was administered to assess the prior knowledge that students had on linear functions. Twenty-seven students who scored under 60 on a scale of 100 were selected to participate in the experiment.

Procedures

The twenty-seven students were divided into three groups based upon their pre-test scores, the grades and gender were balanced in each group. Each group was then randomly assigned to one of the three experimental conditions. Some adjustments were made to accommodate the schedules of the participants. The experiment consisted of two 45-minute learning sessions over a two-week period in the school computer lab. The algebra tutoring program was used as the sole source of instruction and each student learned alone with one version of the computer program. Instruction on the use of a particular version of computer program was presented by the computer at the beginning of the learning sessions. In order to understand types of learning activities in which students engaged, student-computer interaction was recorded during the experiment. To conclude the experiment, a posttest was administered one week after the last learning session. The posttest consisted of (a) two word problems to assess students' algebraic skills and the transfer of such skills, and (b) questions designed to assess students' understanding of algebraic concepts and rules. After students had completed the posttest, they were asked to complete an attitude questionnaire concerning their learning experience with the computer tutor. In addition, three students who received the best posttest scores were interviewed one week after the posttest. They were asked first to orally answer some structured questions in attempt to understand their conceptual knowledge, problem-solving and reasoning strategies, then to translate the algebraic representations from one form to the other in "backward" fashion in order to determine whether student performance was based on the execution of a set of "rote" procedures or on the understanding of the algebraic relations.

Results

The independent variable of this study is the presentation modes: two forms of "embedded teaching" were compared to a conventional teaching mode. The dependent variables include the pretest and posttest measures that reflect the development of students' algebraic knowledge and skills: (a) the measure on the ability to construct different forms of algebraic representations; and (b) the measure on the ability to make estimates using the relationships expressed by such representations. In addition, several other dependent variables were measured in the posttest but not in the pretest: (c) the measure of the transfer of algebraic knowledge and skills to the solution of a problem in an unfamiliar situation, (d) the measure of understanding of the relationships between different forms of algebraic representations by asking students to construct the various forms of algebraic representations that they had learned in "backward" fashion, and (e) the assessment of students' conceptual understanding of the key algebra concepts and principles by asking them to fill in the answers to some conceptual questions. In addition, students offered their opinions about their learning experience by answering an attitude questionnaire.

Two types of "process" data were also collected to determine how the three different teaching modes affected students' learning of well-structured algebraic tasks: (a) the "dribble" file recordings of the history of student-computer interaction; and (b) the explanations that the selected students provided in response to structured interview questions.

The data-analysis strategy consists of two steps: The first step is comparing the learning outcome measures to determine whether the three different presentation modes have different effects on students' learning outcomes. A multivariate analysis (MANOVA) is employed to analyze the pre- and posttest scores on students' ability to construct different forms of algebraic representations and their ability to make estimates using these representations. This is followed by a qualitative analysis of the learning process measures to understand what may have contributed to the effects observed. The results of this study were reported in details elsewhere (Chen, 2000). This paper only highlights the findings concerning the following questions:

(1) did the three versions of computer tutor improve student performance on well-structured algebraic tasks?

The population mean scores on the measure of students' ability to construct algebraic representations was raised from 22.5 to 72 on a scale of 100. Similarly, the population mean score on the measure of students ability to make estimates using these representations was raised from 27.1 to 70. Table 1 presents the pre- and post-test scores of these two variables for all three conditions. A multivariate analysis (MANOVA) of the pre- and posttest scores indicates a significant overall effect on the two measures used ($F(2, 23) = 46.6$, $p < 0.01$). Therefore, it seems that students improved not only their ability to construct algebraic representations, but also their ability to make estimates using the different forms of algebraic representations. However, it

Table 1: The pre- and post-test scores of two measures of students' algebraic abilities (N=27).

Presentation Modes	Constructing Representa-tions		Making Estimates	
	Pre-test	Post-test	Pre-test	Post-test
C1: Conventional	17.9	86.4	25.9	92.6
C2: Program-control	29.8	64.8	33.3	57.4
C3: Learner-control	19.9	67.3	22.2	59.3
M	*22.5*	*72.8*	*27.1*	*70*
SD	*21.4*	*31.6*	*33.4*	*37.2*

should be noticed that the standard deviations are considerably large in both the pre- and post-test scores (SDs range from 21 to 37), reflecting big individual differences in the participants' initial algebraic abilities, as well as the improvement of such abilities.

(2) Did "embedded teaching" modes promote better learning outcomes than conventional teaching?

The MANOVA rejects the hypothesis of no difference between the conventional teaching mode and the program-controlled embedded-teaching mode on students ability to construct algebraic representations and their ability to make estimates using these representations ($F(2, 23) = 3.7$, $p < 0.05$). Similarly, the hypothesis of no difference between the conventional teaching and the learner-controlled embedded-teaching on the same two dependent variables is rejected ($F(2, 23) = 4.1$, $p < 0.05$). Therefore, students' learning outcomes in the embedded teaching modes differ significantly from that in the conventional teaching mode. However, contradicting the hypothesis that the embedded teaching is more effective than conventional teaching, this study reveals that students produced better learning outcomes in the conventional teaching mode. Students in conventional teaching mode also showed superiority in terms of their performance on transfer task, and measure on conceptual understanding. It is important to indicate that all students in the conventional teaching condition (including those who had difficulty in the regular math classroom) successfully passed the posttest, whereas only 56% of students passed the post-test in the other two conditions. However, three out of nine students in each of the embedded teaching modes received the perfect scores whereas only one out of nine students in the conventional teaching mode was able to do so. It seems that the conventional teaching provides an instructional context that enables the majority of students to succeed whereas the embedded-teaching conditions offer the conditions for certain students to reach their greatest potential.

(3) Did "learner-controlled" instruction enhance student learning in a "embedded-teaching" mode?

No difference is found between the learner-controlled and the program-controlled embedded-teaching modes on the measures of students' ability to construct algebraic representations and their ability to make accurate estimates ($F(2, 23) = 0.46$, $p > 0.05$). Thus, the level of student control (i.e., being able to determine whether or when to consult the different types of knowledge available) did not influence students' learning outcomes. However, the examination of student-computer interaction reveals what differentiates the high achievers from the low achievers is the navigation strategies that they employed when they were given control over the navigation paths. The high achievers tended to complete each topic that they reviewed whereas the low achievers tended to switch from topic to topic, indicating a lack of mindful engagement.

(4) What factors may have contributed to different learning outcomes observed?

The analysis of the interview protocol reveals that the strategies that students employed to solve problems are linked to the types of conceptual understanding that they developed. The interview also indicates that successful task performance is associated with conceptual knowledge that is retrievable and, more importantly, that is coupled with appropriate reasoning strategies.

The examination of student-computer interaction and students' self-reports indicates that students' posttest performance relates to neither the amount of time that students spent on tasks, nor to the amount of instructional materials that they reviewed. However, the navigation strategies that students used in the learner-controlled condition seem to relate to the outcomes of learning. The surfer's strategy (i.e., switching from topic to topic without completion) is directly linked to poor posttest performance. The "learning curve" derived from the dribble file recordings further indicates that (a) significant learning had took place through instruction and demonstration and, (b) a certain amount of learning took place through practice, however, the role of practice was not as predominant as what is usually believed. The questionnaire and interview data indicate that student attitudes toward their learning with the computer tutor program are very positive, irrespective of the teaching conditions. Therefore, the superior posttest performance of the students who learned under the conventional teaching condition seem primarily due to the characteristics of this presentation mode rather than any other factor.

Discussion

This section will discuss briefly two important findings of this study. First, this study shows that students' algebraic knowledge and skills have improved significantly over time. Such a finding suggests that

computer-based learning environments that employ an adequate instructional model, incorporate authentic problem scenarios, provide rich learning activities, and use multimedia to illustrate abstract concepts and procedures, can effectively enhance student learning of algebra. Second, this study indicates that students in the conventional teaching condition generally learned better than students in both program-controlled and learner-controlled embedded teaching conditions did. It is speculated that the conventional teaching condition may enable the majority of students to develop a coherent mental model of the algebraic representations. The coherent knowledge representations that students developed, in turn, may help them better interpret the goals and functions of the subsequent procedures and effectively direct their attention to the key task elements in the step-by-step demonstration performed by the tutor, as well as in their own problem-solving exercises. Furthermore, this study shows that significant learning had taken place through instruction and demonstration prior to the practice of the exercises. The findings of this study seem to support the notion that learning is a sense making process that involves construction and integration of mental representation of the materials being studied, as explained by Kintsch's CI model (Kintsch, 1989, 1998). The findings of this study suggest that instructional designers need to consider the coherence of the symbolic representations when applying "embedded teaching" and "learning by doing" principles to design instruction applications for formal learning. This study also showed that the percentage of students who received perfect posttest scores is higher in the embedded teaching conditions than that in the conventional teaching condition. It seems that the problem-solving context and the higher level of learner control enables some students to reach their greatest potential. Therefore, problem-solving context may indeed more effectively facilitate the development of conceptual understanding, problem-solving skills, and reasoning strategies for some students. In addition, some students are able to focus on their own weaknesses when they have control over what to learn.

Some limitations of this study include the use of a small sample of the participants and a lack of aptitude and learning strategy measures prior to the experiment. A further direction of this research is to incorporate other features of successful "embedded teaching" approaches (e.g., using diversified and contrasting cases to enable students to generate the "rules of thumb") into the computer algebra tutors described here to investigate how these features can support both collaborative inquires and individual learning. The goal is to understand the pedagogical requirements for implementing particular instructional approaches and to explore their limitations and strengths for teaching in a given domain. The findings of such studies will certainly have important implications for the development of instructional theories and applications. However, precautions are in order when discussing the pedagogical approaches taken by teachers in classroom situations. This is because good teachers adjust their teaching techniques according to their assessment of students and their monitoring of the on-going instructional processes—they rarely use an instructional technique exclusively even though they may firmly believe in a particular pedagogical approach .

Abstract

The effect of chunking in the process of drawing was investigated using a task domain consisting of simple hierarchically organized geometrical patterns, which participants learnt to draw. The study focused upon the latencies between drawing actions. A new technique for the identification of chunks was devised, based on patterns in the magnitudes of latency. The technique was significantly better than the use of a fixed latency threshold. It was discovered that there was a strong temporal signature of the underlying chunk structure and that effects of learning were evident.

Introduction

The concepts of chunking and the limited size of memory span, first proposed by Miller (1956), underlie many modern theories of human cognition. The phenomenon has been verified in many domains (Vicente, 1988), and at most levels of cognitive processing in both humans and nonverbal organisms (Terrance, 1991). Given the pivotal role of chunking it is, perhaps, surprising that there has been little research on the role of chunking in drawing. There has been some research on: low level motor behaviour constraints on drawing (Van Sommers, 1984), the functions of drawing in high level cognitive tasks such as design (Akin, 1986) and, drawing as a reflection of children's cognitive development (Goodnow & Levine, 1973). However, direct investigations of the role of chunking in the process of drawing are absent.

We are conducting studies that begin to address this deficiency in the understanding of this prominent human ability. Our approach is to have participants learn specially designed named geometric shapes, from verbal labels, which they then reproduced from memory – drawing out induced perceptual chunks. This paper focuses on whether chunks are apparent in temporal characteristics of drawing. Specifically, we have discovered that the absolute duration of pauses between drawing actions, the latencies, reflects the hierarchical structure of induced chunks and reveals the effect of learning by the composition of chunks. Further, we have found that local maxima in the latencies are better discriminators of boundaries between separate chunks than a fixed latency threshold.

Previous work on chunking and drawing will first be discussed to set the context for this work.

Chunking and Pausing Behaviour

The idea that latencies or pauses might be a means by which one can segment data in order to discriminate chunk boundaries, arises from research conducted by Chase and Simon (1973). They defined an operational method by which to characterize chunks. In recall and memory tasks the latency distributions for between-glance placements of chess pieces, which were taken to indicate boundaries between chunks, were significantly longer than within-glance placements, which were taken to indicate items within a chunk. Hence, items with pauses below a certain threshold could be considered as within a chunk and items with longer pauses above the threshold could be considered to be between chunks. The use of thresholds as one means to distinguish chunks has been supported by studies in domains such as: Chess (Chase & Simon, 1973; Gobet, 1998), Go (Rittman, 1976,1980), and electronic circuits (Egan & Schwartz 1979).

A significant pause can be defined as a latency greater than a static threshold typically within the range 2 to 5 seconds (Card, Moran, & Newell, 1983). Although, in studies of drawing, researchers have used pauses as low as 1 second to segment data into chunks (Akin, 1986; Ullman, 1990).

However, there are difficulties with the use of latency thresholds to differentiate chunk boundaries (Holden, 1992; Gobet, 1998). Firstly, there is no one threshold that holds across different task domains (Chase & Simon 1973; Egan & Schwartz, 1979; Akin, 1986; Ullman, 1990; Gobet & Simon, 1998). However, a threshold can be found by training participants in a domain and then testing them (Reitman, 1976). Secondly, it has been observed that when learning takes place, as in the transition from novice to expert, latency times for chunk boundaries decrease (Chase & Simon 1973; Reitman, 1976; Egan and Schwartz, 1979). Thresholds must be changed dynamically over time to cope with individual differences. Thirdly, for memories that are organized hierarchically (Palmer, 1977), the higher the chunk is in the hierarchy the more subchunks it contains and the longer it takes to recall (Reitman, 1976). A single threshold might elicit chunks at one level but not its subchunks or higher order chunks.

This paper proposes an alternative approach to thresholds for the identification of chunks using

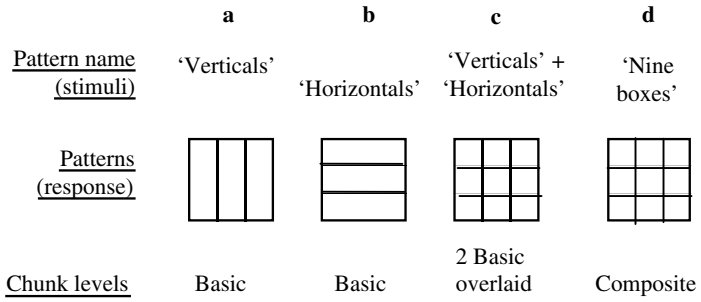

Figure 1. Examples of types of patterns from the shape drawing domain.

latencies between drawing actions. By focusing on patterns over successive latencies the new technique can overcome some of the limitations of fixed thresholds.

Here, we define latency for a particular element as the time between lifting the pen off the paper at the end of one element and the time at which the pen touches the paper again at the beginning of marking the current element. The same holds for mouse button up and down actions when dragging a line on a computer screen.

The Nature of Drawing

Intuitively and theoretically there are various reasons to believe that understanding the role of chunks in the process of drawing will be a challenge. First, consider the recall and the drawing of a perceptual chunk given a verbal label for that chunk. A succession of processes are involved, including: the recall of the chunk, the planning of the order in which to produce the elements of a chunk, the planning of where to draw each individual element, and, the execution of the motor actions to make a mark for the element. It seems likely that such a sequence of processes would hide any hierarchical organization of chunks in long-term memory. Second, it appears unlikely that these processes would occur in a strictly serial manner and they are likely to be interleaved to different extents. This will probably mask any attempt to analyze the underlying structure of chunks. Third, the process of planning might in itself interfere with the recall of chunks and so potentially prevent each chunk from being recalled in a single burst of activity (Reitman, 1976). One might reasonably assume that analysis of latencies within this area would reflect planning and action, rather than chunking. Fourth, the processes of mark making, including subjects sensitivity to methods of motor efficiencies (Akin, 1986), might interact with the recall of chunks. For example, the speed of making a mark may vary with the hierarchical chunk level of the current element being drawn and so interfere with the apparent recall latency of the next element.

Despite all these reasons, the experiment reported here demonstrates that the duration of pauses between the drawing of individual elements is highly indicative of the structure of chunks in memory. It appears that far from diluting any information about the underlying organization of chunks, the duration of latencies in the process of drawing seems to provide a temporal signature for perceptual chunks.

The next section presents the drawing domain and task used in the experiments. The following section describes the discovery of patterns in the latencies that were highly suggestive of a temporal signature of chunks. The experiment and results that demonstrate the reality of these patterns are then considered in turn. The implications of the findings are considered in the final discussion section.

Domain, Stimuli and Tasks

To study the behavioural manifestations of chunking in drawing a special 'shape' domain consisting of named geometric patterns was devised; examples are shown in Figure 1. Initially participants were taught six basic patterns, such as Figure 1a and 1b, and they drew several examples of them when given their names. They were then shown pairs of names of basic patterns to draw overlaid upon each other; Figure 1c. These composite patterns were then separately named; Figure 1d. The composite patterns consist of four lines and a typical drawing task involves drawing a sequence of different composite patterns in a row beside a written list of names.

Features of the design of the domain that make it highly suited to the study of chunking behaviour are: (1) the use of simple predefined shapes to make errors in recall or drawing easily identifiable, (2) the definition of a fixed hierarchy of patterns, with known nesting of levels and no overlapping of elements over chunks at the same level, (3) the participants learn the patterns, so the specific chunks and their organisation is known *a priori,* (4) verbal labels are used as stimuli to make participants recall the perceptual chunk from long-term memory, (5) the composite chunks consist of a small number of sub-chunks to keep demands on working memory low, (6) the outline square is drawn before each pattern to ensure drawing processes are fully engaged when the pattern is produced.

The domain has three chunk levels: (level 1) lines within chunks, (level 2) basic patterns, (level 3) composite patterns. Thus, every line was coded depending on the order in which they were drawn. The first and second drawn lines of a two line basic pattern were coded level 2 and 1, respectively. The code for the four lines of two basic patterns overlaid was 2-1-2-1, respectively. The four lines of a composite pattern were coded 3-1-2-1, respectively, on the assumption that the composite consisted of two sub-chunks.

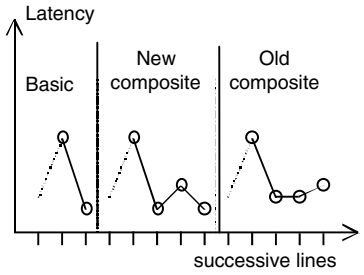

Figure 2. Temporal signature for different chunks

Motivating Observations and Hypotheses

The experiment reported below consists of two experiments (taken together here for the sake of brevity and coherence). The first was a pilot in which latency and other measures were examined in an exploratory manner. In graphs for various measures based on data from each individual participant on a single task (i.e., raw un-aggregated data), it was noticed that certain patterns of latencies appeared to be common and were related to the participants' induced chunks. Figure 2 illustrates the patterns found. Local maxima in latencies, *peaks*, tended to be associated with the first line of basic and composite chunks. A peak was operationally defined as any latency whose magnitude was at least 10% greater than the mean of the preceding and following latencies. With new just learnt composite chunks there were two peaks, matching the two sub-chunks, with the second peak being smaller. With old composites that had been drawn many times, and so learnt well, the second peak tended to disappear.

Although the patterns illustrated in Figure 2 were not universal they were sufficiently frequent to suggest that some temporal signature of chunks would be found by analyzing latencies. In particular, we propose three hypotheses: (H1) Peaks may be an effective way to discriminate chunks. Are peaks better than fixed latency thresholds for identifying chunk boundaries? (H2) Hierarchical chunk levels may be reflected in the absolute magnitude of latencies. (H3) The learning of chunks may be apparent in changes of latencies over time. Further, (H4) if the temporal signature of perceptual chunks is real then it should be apparent when different drawing media are used. The purpose of the experiment was to test these hypotheses.

Experiment

The first two hypotheses were tested by using the shapes domain described above. The third hypothesis concerning learning was tested by comparing performance over two successive sessions in which the same patterns were learnt and reinforced. The fourth hypothesis was tested by using two different drawing interfaces – pen and paper drawing versus keyboard and mouse driven on-screen computer drawing, henceforth *freehand* and *computer* groups, respectively.

The participants were unpaid volunteers, 4 male and 4 female aged 30-45. Equal numbers were assigned to the computer and freehand groups.

Apparatus

The computer drawing used a specially written program on a Macintosh G3 computer. To draw a line, participants first used the keyboard to select the type of line to be drawn (i.e. horizontal, vertical or diagonal) by pressing a key. The line was then drawn using a standard mouse dragging action, with the line "rubber banding" between the endpoints.

The freehand drawing used a high spatial and temporal resolution drawing tablet (Wacom UD tablet) connected to a PC computer running a specially written data capture and analysis program.

In both cases the computers recorded detailed spatial and temporal data to enable the drawn patterns to be identified and for the latencies to be found.

Procedure

Participants were tested individually and each completed two sessions. The participants were given a period of familiarization with the given drawing apparatus. In session 1, in order to learn the patterns participants completed drawings of several basic patterns. This was followed by a further 6 drawings of both and basic and composite patterns. In the session 2, there were 18 drawings consisting of multiple patterns. The stimuli were presented on printed sheets or by verbal instructions.

Results

Peaks versus thresholds: H1 and H4

Consider first the overall distributions of latencies for elements within chunks (level 1) and between chunks (levels 2 and 3). For data aggregated over participants in the same group and over all the tasks in each session, Table 1 shows various measures for these distributions. Between chunk latencies are greater than within chunk latencies, across session and interface type. All the distributions are skewed towards lower latency values. This pattern is similar to that found in other domains (e.g., Chase and Simon, 1973; Reitman, 1976; Egan and Schwartz, 1979), so it is appropriate to analyze this

domain using thresholds to identify chunk boundaries. As latency distributions were skewed, median latencies rather than the mean latencies were used in the analysis.

As expected, the median latencies were shorter for freehand drawing versus computer drawing because of the extra decisions and motor actions required with the computer drawing interface.

Table 1: Between and Within Chunk Latency Distributions (milliseconds)

	Group	Computer		Freehand	
	Session	1	2	1	2
Between Chunk	N	217	309	197	315
	Mean	1647	1188	2017	899
	Median	1347	931	989	620
	SD	1237	892	2985	1677
Within Chunk	N	214	325	186	286
	Mean	814	686	1113	413
	Median	681	665	475	389
	SD	958	340	3657	169

As the number of chunks is defined by the stimuli set an 'optimum threshold' can be set to distinguish chunk boundaries on an individual participant and session basis. The threshold is set so that the number of items above the threshold equals the number of known chunk items. Table 2 gives the thresholds found for each participant. Note the differences across sessions and the differences between individuals within sessions. As would be expected, the threshold for free hand is generally less than that for computer drawing.

Table 2: Optimal thresholds (milliseconds) for each participant

Computer sessions			Freehand session		
	1	2		1	2
P1	600	800	P5	400	400
P2	1400	800	P6	600	600
P3	1400	1200	P7	800	800
P4	1600	1200	P8	600	600

How do peaks compare with the use of latency thresholds as methods to discriminate chunks? Information theory (Wickens, 1993) provides a convenient way to measure how well each method performs by treating each as a system that is attempting to transmit information about items within chunks and items at the boundaries between chunks. By using conditional probabilities, information theory takes into account not only true positives and negatives (e.g., peak–>between chunks, ~peak–> within chunk) but also false positives and negatives (peak–>within chunk, ~peak–>between chunks). Using the optimal thresholds given above and the prior knowledge about which items were chunks or not, the correctness of each individual identification was determined. The same was done for peaks. Hence, the 'quality' (information transmission/channel capacity) of each method was computed (Wickens, 1993). The ideal quality, for all participants across the sessions, was almost unity because the numbers of within and between chunk items were nearly equal.

Table 3: Quality of chunk discrimination by the two methods (bits)

	Peaks		Threshold	
	Session 1	Session 2	Session 1	Session 2
Computer				
P1	0.628	0.444	0.398	0.247
P2	0.503	0.186	0.155	0.080
P3	0.306	0.195	0.261	0.092
P3	0.355	0.117	0.247	0.071
Freehand				
P5	0.460	0.595	0.133	0.274
P6	0.400	0.620	0.168	0.331
P7	0.671	0.622	0.321	0.205
P8	0.410	0.238	0.217	0.138

Table 3 shows that for each participant in each session under each drawing interface, the quality of the discrimination with peaks was better than that using fixed latency thresholds. Although there were just four participants in each group, two-tail t tests were performed to determine whether the peak method gave a significantly higher quality of discrimination than the threshold method. This was indeed the case for the freehand drawing in sessions 1 and 2 ($p=.005$ and $p=.02$, respectively) and computer drawing in session 2 ($p=.018$). For computer drawing in session 1 the difference was approaching significance ($p=.07$).

The results demonstrate: (H1) that peaks are a more effective way to discriminate chunk boundaries, and (H4) the temporal signature of perceptual chunks is apparent across different drawing media.

Chunking levels and learning: H2 & H3

Figures 3 and 4 show graphs of the median latencies against different chunk levels for each drawing interface and across each session. With one exception, for every participant in each session with both drawing interfaces, the median latencies increased with increasing chunk level. Using Page's test for ordered median alternatives as applied to the different levels of the chunk hierarchy (levels 1, 2, and 3) there was a significant increasing trend in the latencies for the computer drawing in both sessions; in both cases $L=56$, $p=.001$ ($n=4$, $k=3$). Similarly for Freehand drawing in session 1 $L=56$, $p=.001$ and session 2 $L=55$, $p=.01$ ($n=4$, $k=3$). The difference between the medians holds not only at the group levels but also at an individual level. Using the data for each participant, the Kruskal-

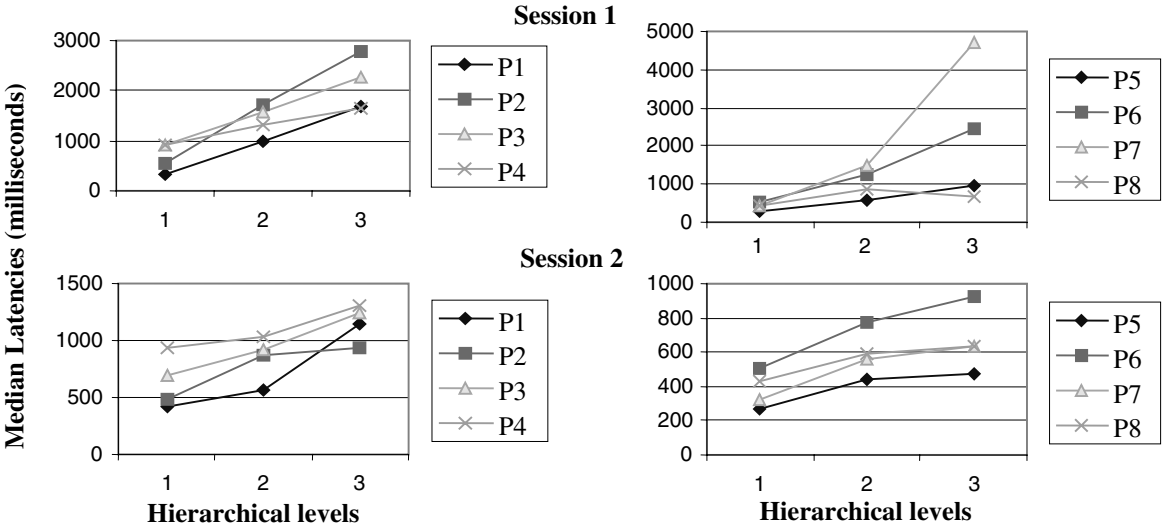

Figure 3: Computer drawing

Figure 4: Freehand drawing

Wallis-H test was used to test whether the latency distributions for the hierarchical levels were significantly different. As shown in Table 4, the results of the test for all participants were significant in both sessions and regardless of the mode of drawing. Comparing the graphs in Figures 3 and 4 across the two sessions for each mode of drawing, it is clear that the magnitudes of latencies drop. (Note that the latency scale ranges differ.)

The results demonstrate: (H2) that the magnitude of latencies reflect the hierarchical chunk level.

Table 4: Analysis of participants' latency distributions over the hierarchical levels; Kruskal-Wallis H

	P7	93	29.1^{+}	115	29.9^{+}

$^{+}p \leq .001$, df=2 in all cases

Table 5 presents median latencies for participants using each mode of drawing for each chunk hierarchy level and summarises the analysis. The latencies decreased over sessions regardless of the hierarchical level. The differences between participants performance over the two sessions was assessed by applying the Mann-Whitney U test (one-tailed); for the freehand drawing group the decrease in median latencies is significant at all chunk levels and for the computer drawing group the decrease is significant at chunk level-2 and level-3.

The results demonstrate: (H3) that the learning of chunks is apparent in the changes of latencies over time.

Discussion

A specially designed geometric shapes domain has been used to study chunking behaviour in drawing. Participants learnt named patterns that were assumed, reasonably, to have been stored in memory as induced perceptual chunks. The differences in the distributions of recall latencies for elements within chunks and those between chunks is similar to patterns of latency distributions found in other domains (e.g., Chase and Simon, 1973; Reitman, 1976; Frey, 1976; Egan and

Schwartz, 1979; Akin 1986; Ullman, 1990; Gobet, 1998). Similarly, optimal latency thresholds that could be used to identify chunks were found to vary with participants, depending on the nature of the drawing interface and on the effect of learning.

It was discovered that peaks (local maxima in latencies) were significantly better discriminators of chunks than fixed thresholds. The contrast between the approaches would be even starker, if, as would normally be the case, the number of chunks was not known *a priori* and used to set the optimal threshold. Peaks have the advantage that they use only local information about the relative magnitude of latencies to discriminate chunks. Whether the peaks method constitutes a general technique applicable beyond drawing awaits further studies in other domains.

It was found that in drawing there was a strong temporal signature of perceptual chunks in the latencies. The level of an element in the chunk hierarchy is reflected in the magnitude of the latency, the higher the level the longer the pause. The effect is sufficiently prominent to yield significant differences in individual participant data. The effect of learning is also evident in the changes in the absolute magnitude of latencies at specific chunk levels. The changes to the latencies appear to indicate when two chunks have been compiled into a single composite chunk.

These effects were consistent over the different modes of drawing, which suggests that the temporal signature reflects the structure of chunks in memory, and that the other processes of drawing, such as planning, are organized on the basis of the chunk structure. The process of drawing may magnify the effect of chunk structure rather than diminish or distort it. It seems plausible that the (sub) processes of drawing may operate in a largely serial fashion. Latencies between chunks may be longer than within chunk latencies because they encompass more sub-processes.

Further work is addressing the robustness and generalisability of the phenomena outlined in this paper. The temporal signature of chunking has been found to be apparent in other drawing domains, such as diagrammatic representations for problem solving (Lane, Cheng & Gobet, 2001).

Modeling Tonality: Applications to Music Cognition

Abstract

Processing musical information is a task many of us perform effortlessly, and often, unconsciously. In order to gain a better understanding of this basic human cognitive ability, we propose a mathematical model for tonality, the underlying principles for tonal music. The model simultaneously incorporates pitch, interval, chord and key relations. It generates spatial counterparts for these musical entities by aggregating musical information. The model also serves as a framework on which to design algorithms that can mimic the human ability to organize musical input. One such skill is the ability to determine the key of a musical passage. This is equivalent to being able to pick out the most stable pitch in the passage, also known as "doh" in *solfege*. We propose a computational algorithm that mimics this human ability, and compare its performance to previous models. The algorithm is shown to predict the correct key with high accuracy. The proposed computational model serves as a research and pedagogical tool for putting forth and testing hypotheses about human perception and cognition in music. By designing efficient algorithms that mimic human cognitive abilities, we gain a better understanding of what it is that the human mind can do.

Introduction

Music cognition is a complex task requiring the integration of information at many different levels. Nevertheless, processing musical information is an act with which we are all familiar. The mind is so adept at organizing and extracting meaningful patterns when listening to music that we are often not even aware of what it is that we do when comprehending music. Some of this unconscious activity includes determining the tonal center[1], the rhythm, and the phrase structure of the piece.

I illustrate our unconscious ability to process music by a short anecdote from my own experiences. In my first semester as a pianolab[2] instructor at MIT, I encountered a few students who had no prior musical background. I asked one such student, after he carefully traced out the melodic line for Yankee Doodle, "What is the key[3] of this piece?" He responded with a reasonable question: "What do you mean by key?" I began singing the piece and stopped mid-stream. I then asked the student if he could sing me the note on which the piece should end. Without hesitation, he sang the correct pitch[4], thereby successfully picking out the first degree, and most stable pitch, in the key. The success of this method raised more questions than it answered. What is it we know that causes us to hear one pitch as being more stable than others? How does the mind assess the function of this stable pitch over time as the music evolves?

Before we can study music cognition, we first need a representation for musical structure. In this paper, we propose a mathematical model for tonality, the underlying principles of tonal music. According to Bamberger (2000), "tonality and its internal logic frame the coherence among pitch relations in the music with which [we] are most familiar." The model uses spatial proximity to represent perceived distances between musical entities. The model simultaneously incorporates representations for pitch, interval, chord and key relations.

Using this model, we design a computational algorithm to mimic human decisions in determining keys. The process of key-finding precedes the evaluation of melodic and harmonic structure, and is a fundamental problem in music cognition. We relate this new representation to previous models by Longuet-Higgins & Steedman (1971) and Krumhansl & Schmuckler (1986). The computational algorithm is shown to identify keys at a high level of accuracy, and its performance is compared to that of the two previous models.

The Representation

Western tonal music is governed by a system of rules called *tonality*. The first part of the paper proposes a geometric representation, the Spiral Array model, that captures this system of relations among tonal elements. The Spiral Array model offers a parsimonious description of the inter-relations among tonal elements, and suggests

[1] The *tonal center*, also called the *tonic* of the key, is the pitch that attains greatest stability in a musical passage.

[2] A keyboard skills class for students enrolled in Music Fundamentals and Composition courses.

[3] Excerpted from the Oxford Dictionary of Music: A *key* implies adherence, in any passage, to the note-material of one of the major or minor scales. When the pitches in a scale are ordered, the first degree of the scale gives the scale its name. This is also the most stable pitch, known as the *tonic*.

[4] A *pitch* is a sound of some frequency. High frequency sounds produce a high pitch, and low frequency sounds produce a low pitch. This is distinct from a *note*, which is a symbol that represents two properties, pitch and duration.

new ways to re-conceptualize and reorganize musical information. A hierarchical model, the Spiral Array generates representations for pitches, intervals, chords and keys within a single spatial framework, thus allowing comparisons among elements from different hierarchical levels. The basic idea behind the Spiral Array is the representation of higher level tonal elements as aggregates of their lower level components.

Spatial analogues of physical and psychological phenomena are known to be powerful tools for solving abstract intellectual problems (Shepard, 1982). Some have argued that problems in music perception can be reduced to that of finding an optimal data representation (Tanguine, 1993). Shepard (1982) determined that "the cognitive representation of musical pitch must have properties of great regularity, symmetry, and transformational invariance." The model placed all twelve chromatic pitches equally over one full turn of a spiral, and highlighted pitch height relations. Further extensions to a double helix emphasized perfect fifth interval[5] relations, but did not account for major and minor third relations.

Applying multi-dimensional scaling techniques to experimental data, Krumhansl (1978,1990) mapped listener ratings of perceived relationships between probe tones and their contexts into space. The resulting cone (1978) places pitches in the tonic triad closest to each other, confirming the psychological importance of fifth and third interval relations, which form triads. Parncutt (1988) has also presented a psychoacoustical basis for the perception of triadic units.

Another representation that incorporates spatial counterparts for both perfect fifth and major/minor third relations is the *tonnetz*, otherwise known as the Harmonic Network. This model has been used by music theorists since Riemann (see, for example, Lewin, 1987; Cohn, 1998), who posited that tonality derives from the establishing of significant tonal relationships through chord functions. Cohn (1998) has traced the earliest version of this network to the 18th century mathematician Euler, and used the *tonnetz* representation to characterize different compositional styles, focussing on preferred chord transitions in the development sections. More recently, Krumhansl (1998) presented experimental support for the psychological reality of these neo-Riemannian transformations.

Our proposed Spiral Array model derives from a three-dimensional realization of the Harmonic Network, and takes into account the inherent spiral structure of the pitch relations. It is distinct from the Harmonic Network in that it assigns spatial representations for higher level musical entities in the same structure. The representations for intervals, chords and keys are constructed as mathematical aggregates of spatial representations of their component parts.

Like the models derived from multi-dimensional scaling, the Spiral Array model uses proximity to incorporate information about perceived relationships between tonal elements. Distances between tonal entities as represented spatially in the model correspond to perceived distances among sounding entities. Perceptually close intervals are defined following the principles of music theory. In accordance with the Harmonic Network, the Spiral Array assigns greatest prominence to perfect fifth and major/minor third interval relations, placing elements related by these intervals in proximity to each other.

In the calibration of the model, the parameter values that affect proximity relations are prescribed based on a few perceived relations among pitches, intervals, chords and keys. These proximity relations will be described in a later section.

The Spiral Array Model

As the name suggests, in the Spiral Array Model, pitches are represented by points on a spiral. Adjacent pitches are related by intervals of perfect fifths. Pitches are indexed by their number of perfect fifths from C, which has been chosen arbitrarily as the reference pitch. For example, D has index two because C to G is a perfect fifth, and G to D is another. $\mathbf{P}(\mathrm{k})$ denotes the point on the spiral representing a pitch of index k. Each pitch can be defined in terms of transformations from its previous neighbor - a rotation, and a vertical translation.

$$\mathbf{P}(\mathrm{k} \quad 1) \stackrel{\text{def}}{=} \mathbf{R}\ \mathbf{P}(\mathrm{k}) \quad \mathbf{h},$$

$$\text{where } \mathbf{R} = \begin{matrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{matrix} \quad \text{and } \mathbf{h} = \begin{matrix} 0 \\ 0 \\ \mathrm{h} \end{matrix}.$$

The pitch C is arbitrarity set at the point [0,1,0].

Since the spiral makes one full turn every four pitches to line up vertically above the starting pitch position. Positions representing pitches four indices, or a major third, apart are related by a simple vertical translation:

$$\mathbf{P}(\mathrm{k} \quad 4) = \mathbf{P}(\mathrm{k}) \quad 4\ \mathbf{h}.$$

For example, C and E are a major third apart, and E is positioned vertically above C.

At this point, we diverge from the original *tonnetz* to define chord and key representations in the three-dimensional model. The added complexity of the three-dimensional realization allows one to define representations off the grid, and *within* the spiral. A chord is the composite result, or effect, of its component pitches. A key is the effect of its defining chords. We propose that this effect can be represented spatially by a convex combination of its components.

[5] Excerpted from the Oxford Dictionary of Music, an *interval* is the distance between any two pitches expressed by a number. For example, C to G is a 5th, because if we proceed up the major scale of C, the fifth pitch is G. The 4th, 5th and octave are all called Perfect. The other intervals, measured from the first pitch, in the ascending major scale are all called Major. Any Major interval can be chromatically reduced by a semitone (distance of a half step) to become Minor. If any Perfect or Minor interval is so reduced, it becomes Diminished; if any Perfect or Major interval is increased by a semitone it becomes Augmented.

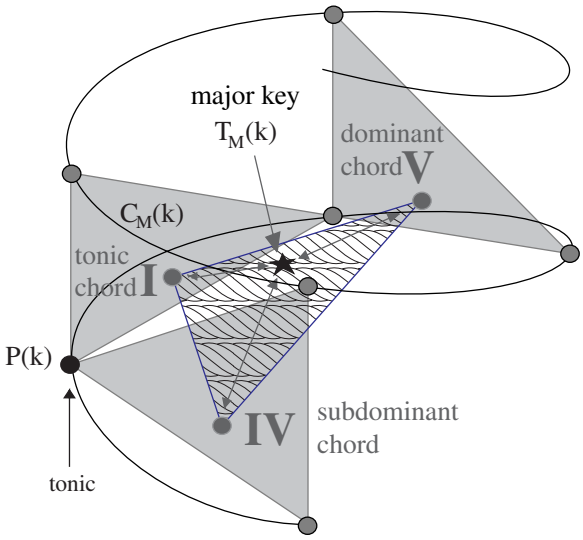

Figure 1: The Spiral Array Model.

Mathematically, the chord's representation is generated by a convex combination of its three component pitch positions. Geometrically, the chord representation resides strictly within the boundaries of the triangle outlined by the triad (see Figure 1). A chord is represented by a weighted average of its component pitch positions: the root **P**(k), the fifth **P**(k+1), and the third **P**(k+4) for major triads, and **P**(k−3) for minor triads:

The representation for a major triad is

$$\mathbf{C}_{\mathrm{M}}(\mathrm{k}) \stackrel{\text{def}}{=} w_1\ \mathbf{P}(\mathrm{k}) \quad w_2\ \mathbf{P}(\mathrm{k}\quad 1) \quad w_3\ \mathbf{P}(\mathrm{k}\quad 4),$$

$$\text{where} \qquad w_1 \quad w_2 \quad w_3 > 0 \text{ and } \sum_{i=1}^{3} w_i = 1.$$

The minor triad is generated by a similar combination,

$$\mathbf{C}_{\mathrm{m}}(\mathrm{k}) \stackrel{\text{def}}{=} u_1\ \mathbf{P}(\mathrm{k}) \quad u_2\ \mathbf{P}(\mathrm{k}\quad 1) \quad u_3\ \mathbf{P}(\mathrm{k}-3),$$

$$\text{where} \qquad u_1 \quad u_2 \quad u_3 > 0 \text{ and } \sum_{i=1}^{3} u_i = 1.$$

The weights, w_i and u_i, on the pitch positions represent the importance of the pitch to the generated chord. For longstanding psychological, physical and theoretical reasons, the root is deemed the most important, followed by the fifth, then the third. Correspondingly, the weights are constrained to be monotonically decreasing from the root, to the fifth, to the third. In order that spatial distance mirrors these relations, there are additional constraints on the aspect ratio h/r. These constraints are described in Chew (2000).

An important property of the Spiral Array is that representations of pitches in a given key occupy a compact neighborhood. Each major chord, together with its right and left neighbor major chords, combine to produce the effect of a major key. In music terminology, these chords are given names, with respect to the key, that reflect their function. The center chord is called the tonic chord (I)[6], the one to its right the dominant (V), and the one to its left the subdominant (IV). Hence, we represent the major key as a combination of its I, V and IV chords. For example, the representation of the C major key is generated by the C major, G major and F major chord representations. See Figure 1 for an example of a major key representation.

Mathematically, the representation for a major key, $\mathbf{T}_{\mathrm{M}}(\mathrm{k})$ is the weighted average of its tonic triad ($\mathbf{C}_{\mathrm{M}}(\mathrm{k})$), dominant triad ($\mathbf{C}_{\mathrm{M}}(\mathrm{k+1})$) and subdominant triad ($\mathbf{C}_{\mathrm{M}}(\mathrm{k}-1)$) representations. As before, the design objective is to have the weights correspond to each chord's significance in the key. Hence, the I chord is given the largest weight, followed by that of the V chord, then the IV chord:

$$\mathbf{T}_{\mathrm{M}}(\mathrm{k}) \stackrel{\text{def}}{=} \omega_1\ \mathbf{C}_{\mathrm{M}}(\mathrm{k}) \quad \omega_2\ \mathbf{C}_{\mathrm{M}}(\mathrm{k}\quad 1) \quad \omega_3\ \mathbf{C}_{\mathrm{M}}(\mathrm{k}-1),$$

$$\text{where} \qquad \omega_1 \quad \omega_2 \quad \omega_3 > 0 \text{ and } \sum_{i=1}^{3} \omega_i = 1.$$

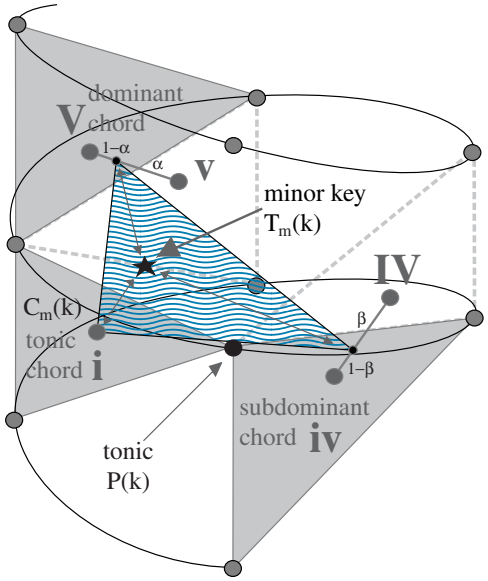

Figure 2: Geometric representation of a minor key, a composite of its tonic (i), dominants (V/v) and subdominant (iv/IV) chords.

The definition for the minor key is more complicated,

[6]We shall use roman numerals to denote chord function within a key. The number indicates the scale degree of the chord's root. For example, "I" represents the tonic chord. We adopt the convention of denoting major chords by upper case roman numerals, and minor chords by lower case ones. For example, a major chord with the tonic as root is "I" but a minor chord with the same root is "i".

but we will not go into the details at this time. It suffices to say that the center of effect for the minor key $\mathbf{T}_m(k)$ is modeled as a combination of the tonic $\mathbf{C}_m(k)$, the major and minor dominant triads $\mathbf{C}_M(k+1)$ and $\mathbf{C}_m(k+1)$, and the major and minor subdominant triad $\mathbf{C}_m(k-1)$ and $\mathbf{C}_M(k-1)$:

$$\begin{aligned}\mathbf{T}_m(k) \stackrel{\text{def}}{=} & \quad v_1 \ \mathbf{C}_m(k) \\ & v_2 \ \alpha \ \mathbf{C}_M(k \quad 1) \quad (1-\alpha) \ \mathbf{C}_m(k \quad 1) \\ & v_3 \ \beta \ \mathbf{C}_m(k-1) \quad (1-\beta) \ \mathbf{C}_M(k-1) \ , \\ \text{where} \quad & v_1 \quad v_2 \quad v_3 > 0 \text{ and } v_1 \quad v_2 \quad v_3 = 1, \\ \text{and} \quad & 0 \quad \alpha \quad 1, 0 \quad \beta \quad 1.\end{aligned}$$

See Figure 2 for the spatial representation of a minor key.

Properties of the Spiral Array Model

In the Spiral Array model, musical information is condensed, or aggregated, and represented by a single point. Proximity in the Spiral Array indicates some combination of the following: shared pitches, shared intervals, or tonal elements within a perfect fifth, major third or minor third interval of each other. This section summarizes the criteria for selecting the weights defined in the previous section so that relations between represented tonal entities have direct counterparts in the geometric structure. Details are given in Chew (2000). The criteria are summarized as follows:

1. Perceptually close intervals should be represented by shorter inter-pitch distances. For example, the closest distance between any two pitch positions denotes a perfect fifth relation; and, pitches a third apart are closer than those a second apart, etc.

2. Each chord representation is closest to its root, followed by the fifth, then the third; and, no other pitches are as close to the major chord center as its three constituent pitches.

3. The average position of two pitches an interval of a half step apart should be closest to the key related to the upper pitch; and, the average position of two pitches an interval of a perfect fourth apart should be closest to the key related to the upper pitch.

These preliminary criteria are subjective, and are by no means comprehensive. We found, through experiments, that by satisfying these few conditions, the model performed well when applied to the problem of key-finding (as described in the next sections). Thus, this could be reason to believe that with a few simple conditions, we might be able to capture the salient features in musical information in a way that concurs with listener perceptions.

Finding the Key of a Melody

The Spiral Array provided a framework on which to design viable and efficient computational algorithms for problems in the analysis and manipulation of musical information. Because the model condenses musical information to a spatial point, it allows for efficient and dynamic tracking of a streams of musical signals. Using the model, an algorithm is designed to determine the key of musical passages. We illustrate how the algorithm works by an example, "Simple Gifts". This algorithm is shown to perform better than existing ones when applied to the 24 fugue subjects in Book I of Bach's "Well-Tempered Clavier" (henceforth, referred to as the WTC). This algorithm exemplifies the concept of mapping musical information onto the Spiral Array.

Analyzing the key of a melody poses many challenges. Given a melody, one must make informed decisions about its key based on little information. Furthermore, there could be more than one equally valid answer, in which case a list for the most likely candidates for key would be more appropriate than one definite key. This section introduces the key-finding algorithm (CEG) based on the Spiral Array that returns a ranked list of possible keys. CEG is an acronym for *Center of Effect Generator*. The CEG algorithm is fundamental to the Spiral Array model and uses the model to reframe the problem of key recognition as a computationally simple one of finding a distance-minimizing representation.

In the Spiral Array, the collection of pitches in a given key defines a compact space. As pitches in a melody are sounded in sequence, the geometric shape defined by the pitch positions becomes increasingly more complex. Instead of using this complex shape to identify the key, *the algorithm collapses the pitch information down to a single point*, the center of effect (c.e.). In this manner, the pitches combine to create an object in space – a point which is the composite sum of the pitch positions.

Since keys are also defined as points in space, it is then simple to compute the distance between the c.e. and the key, and nearby keys, to determine which key is closest to the c.e. Thus the mathematical sum of pitches affords parsimonious descriptions of, and comparisons between, different pitch collections.

However, the CEG algorithm more than simply compares pitch collections. By definition, the key representations favor triadic pitch configurations, and also tonic-dominant and tonic-subdominant relationships. These representations incorporate different levels of hierarchical structure and relationships. Not all pitches are weighted equally; and, the key representation is a structured but nonlinear combination of its pitch collection. By comparing the c.e.'s to these key representations, we expect certain pitch relations to prevail.

An Example

The algorithm is best explained by an example. Consider the Shaker tune, used in Copland's symphonic suite "Appalachian Spring" (1945), shown in Figure 3.

At any point in time, the CEG method generates a c.e. from the given musical information that summarizes the tonal space generated by the pitches sounded. Define a step to be a pitch event. At each step, the pitches from the

Figure 3: "Simple Gifts".

beginning to the present is weighted (multiplied) by its duration, and the c.e. is generated by *aggregating* these weighted pitch positions.

If the i-th note is represented in the Spiral Array by pitch position p_i and has duration d_i, then the *aggregate* center at the i-th pitch event is defined as:

$$c_i \stackrel{\text{def}}{=} \sum_{j=1}^{i} d_i \;\; p_i.$$

The CEG method updates its decision with each note or pitch event. The distance from the key representations to c_i is calculated and ranked. The key that is closest is ranked first, next closest second, and so on.

Figure 4 plots the exact distances from the four closest keys (F major, C major, F minor and C minor), at each successive pitch event. Observe, in the graph, that F major quickly establishes itself as the closest key. However, between pitch events $i = 22$ to 24, C major (the dominant of F) vies with F major for preeminence. The melody dwells on the dominant key area at $i = 19$ to 24, outlining the C major triad from $i = 21$ to 24. This behavior in the model concurs with listener perception.

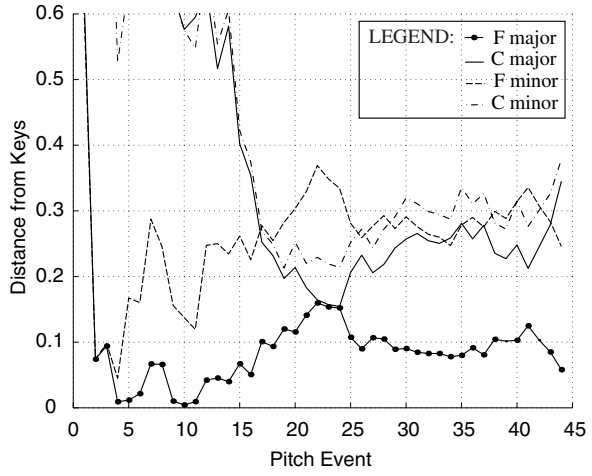

Figure 4: Distance to various keys as "Simple Gifts" unfolds.

Comparison to other Key-Finding Models

To validate the model, it was compared to Longuet-Higgins & Steedman 's Shape-Matching Algorithm (SMA) (1971) and to Krumhansl & Schmuckler's Probe Tone Profile Method (PTPM) (1986). Detailed discussions of each test run is documented in Chew (2000).

The tonic-dominant rule was devised for cases when the SMA algorithm failed to reach the desired conclusion by the end of the fugue theme. In such cases, the tonic-dominant rule derives the key from the first pitch which is assumed to be either the tonic or the dominant of the intended key. The † denotes cases when the tonic-dominant rule was applied. Numbers in brackets denote the average when considering only the fugue subjects in which the tonic-dominant rule was not applied by any of the three methods.

Table 1: Applying key-finding algorithm to Bach's fugue subjects in the WTC. (Numbers generated using h= $\overline{2\ 15}$ (r= 1), and weights across all hierarchies set to [0.516, 0.315, 0.168].)

Book I	Steps to key		
Fugue subj	CEG	PTPM	SMA
C major	2	2	16†[7]
C minor	5	5	5
C major	6	7	16
C minor	3	3	4
D major	2	2	15†
D minor	3	3	8
E major	2	6	11†
D minor	2	6	12†
E major	14	12†	11
E minor	3	2	7†
F major	4	10	6
F minor	3	15	4†
F major	3	2	8
F minor	7	18	5†
G major	2	2	15
G minor	3	3	4
A major	3	2	7†
G minor	5	5	5
A major	2	4	7
A minor	5	5	5
B major	4	4	14
B minor	2	3	6†
B major	2	11	11
B minor	3	3	7
Average	3.75 (3.57)	5.25 (4.79)	8.71 (8.21)

For the fugue subjects in Book I of the WTC, the CEG required on average 3.75 pitch events, the PTPM 5.25, and the SMA 8.71 to determine the correct key. Given a melody, a hypothesis of its key based on its first pitch is not a meaningful one. The reliability of a hypothesis based on two pitch events is still questionable. Hence, on average, the absolute minimum number of pitches re-

quired to form an opinion of the key is 3. The CEG algorithm required, on average, 3.75 steps to determine the key of the 24 fugue subjects. Based on the reasons stated, we claimed that the key-finding algorithm using the Spiral Array has an average performance that is close to optimal.

Comments

The approach detailed in this paper is computational, and mimics the manifestation of human music cognitive abilities. It proposes mathematical ways to aggregate and organize musical information. However, this does not imply that the computational algorithm describes how the human mind processes musical information. The fact that it performs well suggests that it should be considered as a method of modeling human cognition in music.

A computational model serves as a research and pedagogical tool for putting forth and testing hypotheses about human perception and cognition in music. For example, one can generate hypotheses about how humans perceive musical groupings, and implement this theory using the model.

In the melodies used for model validation, and in the "Simple Gifts" example, the aggregate points (c.e.'s) were generated cumulatively as the melodies unfolded. For lengthier examples, some decay of the information over time should be incorporated into the c.e.'s. This would be a way to model short-term memory in listening to music.

At present, the model ignores the dimension of pitch height. Clearly, pitches from different registers will generate different perceptions of relatedness. Future modifications could take into consideration the modeling of pitch height by weighting pitches from different registers differently.

The CEG algorithm currently proceeds sequentially forward through time, and cumulatively aggregates the information to produce a representation for the c.e. Cognitively, a human listener makes judgements about the key not only sequentially forward in time as the melody unfolds, but also retroactively after having gained some future information. A harmonic analysis algorithm proposed by Winograd (1968) proceeds backwards from the end of the piece; and, Temperley's (1999) extension of the Krumhansl-Schmuckler model employs dynamic programming, which also works backwards algorithmically. Future extensions of the Spiral Array Model might incorporate elements of both forward and retroactive decision-making.

By designing efficient algorithms that mimic human cognitive abilities, we gain a better understanding of what it is that the human mind can do. By studying the shortcomings of the algorithms, we can modify them, and in so doing, learn about the extent of human cognitive abilities. In the examples we discussed, the information was processed sequentially forward through time. In actual fact, the human listener can often retroactively change his or her decision about structural properties of the piece after having listened to more of the music. Attempts to model this would yield further insight as to the temporal nature of music cognition.

Causal Information as a Constraint on Similarity

Abstract

Considerable evidence indicates that causal information provides a vital constraint on conceptual representation and coherence. We investigated the role of causal information as a constraint on similarity, exploiting an asymmetry between predictive causal reasoning (given the cause, predict the effect) and diagnostic causal reasoning (given the effect, diagnose the cause). This asymmetry allowed us to isolate the effects of causal understanding from the effects of sharing non-causal features. We found that judged similarity between two objects that are identical except for one feature was affected by whether that feature was a competing potential cause of an effect or an effect of a common cause.

Causation Constrains Similarity

Any two objects have indefinitely many features in common. For example, Murphy and Medin (1985) pointed out that the number of features that plums and lawn mowers have in common is, in principle, infinite. Both weigh less than 1000 kg, and both are found on earth, in the solar system. Both cannot hear well, have an odor, are used by people, not by elephants, and so on. But despite these shared features people do not generally consider plums and lawnmowers to be similar. Intuitively, the features plums and lawnmowers have in common are not considered important. But what features are important? Why are some features important and not others? There must be criteria for constraining the sheer number of these features (Goodman, 1972; Medin, Goldstone, & Gentner, 1993). Previous researchers (e.g., Murphy & Medin, 1985) have suggested that features will be considered more important when they are diagnostic of causal function and part of a larger explanatory framework. Whether or not a feature is causal serves as a criterion by which people select important features and separate them from unimportant ones (Sloman, Love, & Ahn, 1998).

We propose a new paradigm to investigate the influence of causal knowledge on similarity and categorization. This paradigm provides an optimal way of equating the number of common and distinctive features between two objects across conditions: Equality is ensured because the stimuli were in fact identical across conditions. We use this paradigm to investigate the influence of causal knowledge as a constraint on similarity.

Experiment

To avoid confounding the effects of causal understanding with the effects of shared non-causal features, we utilized an asymmetry tested by Waldmann and Holyoak (1992). When a feature is identified as a cause, other potential causes are discounted (Morris & Larrick, 1995). Other potential causes (presented at the same time) are redundant to explain the effect and are assumed not to be causes after all. For example, if one notices a bowling ball moving, knowing that it was kicked is enough to explain the motion. There is no need to postulate another cause. By contrast, when a feature is identified as an effect, other potential effects are not discounted. For example, if one were to kick a bowling ball, the person might move the bowling ball and hurt his or her foot at the same time. The cause (the kick) would have two effects (the moving of the bowling ball and the pain in the foot). One would not assume the ball did not move simply because of the pain in the foot. The significance of this asymmetry for our current project is that it can be used to distinguish the influence of causal understanding from that of mere associations.

Two tasks were used in this experiment: first a training task and subsequently a similarity rating task. The purpose of the training task was to allow participants to learn a competing cause of an effect or an effect of a common cause. It used a two-phase blocking paradigm similar to that employed by Waldmann and Holyoak (1992). We trained participants by showing them the keys presented in Table 1. Half of the participants (predictive condition: identify features that predict an effect) were told that some of the keys could open any safe (target event in predictive condition), and they were asked to identify which features were responsible for this special ability. The other half of the participants (diagnostic condition: diagnose whether features were caused by the carving process) were told that some of the keys were carved by a special carving process (target event in diagnostic condition), and they

were asked to identify whether each feature was caused by the special carving process.

Participants saw two series of keys. In the first series, the keys were all missing a section. In the second series, this section was restored. The restoration provided an enabling condition (provided a location on which a feature could be located) for the existence of a redundant new feature that could be causally related to the target event. In the predictive condition, because old features were sufficient to explain the opening of safes, we predicted that this new, redundant feature would not be thought responsible for opening safes. By contrast, in the diagnostic condition, because a cause can have multiple effects, the new feature could very well be the result of the special carving process. We predicted that the carving process would be assumed to produce the redundant feature. Non-causal features would not produce this asymmetry.

We predicted that this causal knowledge would affect whether features are considered important in a similarity judgment. Consider a similarity judgment between a key that had the restored new feature and one that did not. If the old feature was sufficient to open safes, the key without the restored feature could open safes just as well as the key with this feature, the causal relations would not be altered, and the restored feature would not be important. By contrast, when the restored feature is the result of the carving process, the key with the restored feature received different treatment from the key without it, the causal relations would be altered, and the feature would be important.

Method

Participants

The participants were 298 students enrolled in an introductory psychology class at the University of California, Los Angeles, and 106 travelers waiting to board airplanes at Los Angeles International Airport (LAX). The students participated as part of a class exercise. The travelers participated voluntarily. Of these 404 participants, 5 failed to answer critical questions, leaving 399 responses for analysis.

Materials

As shown in Table 1, we created pictures of keys with features attached. To parallel Waldmann and Holyoak's (1992) disease symptoms, these keys had four features that we manipulated during the training phase as follows. One feature was constantly present (the t-shape on the left, called Cue C for *Constant*) and was not correlated with the target event. Another feature was present half of the time (the b-shape on the middle left, called Cue U for *Uncorrelated*) and also was not correlated with the target event. The L-shape on the middle right (called Cue P for *Predictor*) was a perfect deterministic predictor of the target event. The k-shape on the right (called Cue R for *Redundant*) was not presented at all during the first series and was only presented in the presence of Cue P during the second series. Within the second series, Cue R was a perfect predictor of the target event but only provided redundant information after Cue P.

1st Series (missing section)	2nd Series (restored section)	Target Event Occurs?
		
		No
		Yes
		No
		Yes

Table 1: Key stimuli. The top key is a blank used as an initial illustration for participants. Cues C (t-shape on the left) and U (b-shape on the middle left) were not correlated with the target event. Cues P (L-shape on the middle right) and R (k-shape on the right) were correlated with the target event, but Cue R only provided redundant information.

We prepared two three-page booklets, one booklet for the predictive condition and another for the diagnostic condition. The first page was used to present the first series of keys and to elicit the causal inferences that participants first made. The second page was used to present the restored feature in the second series of keys and to elicit the causal inferences participants made after this item was restored. The third page was used to collect similarity judgments.

At the top of the first page, participants were told that some of the keys they would see either could open any safe (predictive condition) or were caused by a special carving process (diagnostic condition). It was necessary to explain why Cue R was missing from this first page. To do so, participants in both conditions were told that the keys for the first page were carved from blanks with a missing notch that looked like the first key in the left column of Table 1. In the middle of the booklets' first page a two-column table was used to present the keys. The left-hand column was labeled "Keys" and presented the four keys in the bottom four rows of the left column in Table 1. The right-hand column was used to indicate whether the target event occurred for each key.

In the predictive condition, the right-hand column asked, "Will this key open any safe?" In the diagnostic condition, it asked, "Is this key carved by the special process?" The word "Yes" was used to indicate that the target event occurred and the word "No" was used to

indicate that the target event did not occur. At the bottom of the first page, participants were asked questions on their understanding of the causal relations. In the predictive condition, participants indicated whether they thought each of the three features, Cues C, U, and P respectively, caused safes to open by circling the word "yes" or the word "no." In the diagnostic condition, they likewise indicated whether they thought the carving process caused each of the three features.

The second page resembled the first, except that the keys on the middle column of Table 1 replaced those on the left. The first key in the middle column of Table 1 replaced the first key in the left-hand column as the blank. The keys in the bottom four rows on the right replaced the keys in the bottom four rows on the left as the keys causally related to the target event. Participants were asked to indicate whether they thought each of the four features, Cues C, U, P, and R, respectively, was causally related to the target event.

The final page was used to collect similarity judgments. Seven-point scales were provided, with "1" labeled "not at all similar;" and "7" labeled "very similar." Participants compared a key containing all four features to a key that lacked Cue R. In the predictive condition, since Cue P would be sufficient to open safes, judged similarity between the two keys would be high— both keys could open safes. By contrast, in the diagnostic condition, since Cue R was caused by the carving process, judged similarity between the two keys would be low—the keys received different treatments. Participants likewise judged the similarity between a key containing all four features to one that lacked Cue P. This similarity serves as a baseline for evaluating the importance of Cue R, to reduce noise in the analyses.

Procedure

The introductory psychology students received our materials within a larger packet of materials. The packets were randomly assigned and completed within the classroom. The travelers were approached by the experimenter and asked to participate. After agreeing to participate, participants were randomly given a booklet. Participants were given pencils and instructed to follow the instructions inside the booklet. After participants had finished, the experimenter returned to collect the booklets.

Results and Discussion

The results of the training task mirrored the basic findings of Waldmann and Holyoak (1992). We divided participants into those who showed a coherent pattern of responses that indicates blocking (judged Cues C, U and R non-causal and Cue P causal) and those who showed other patterns. A blocking pattern of responses was observed for 12.5% of the participants in the predictive condition and only 4.7% of the participants in the diagnostic condition. This difference was significant, X^2 (1, n=399) = 6.13, $p < .025$. Only a minority of the participants in both conditions, however, showed this pattern. Questioning participants afterwards revealed that many based their judgments solely on the information provided on the second page, the page on which P and R both predicted the target event Many thought the second page represented a separate updated scenario. This misunderstanding likely explains why the majority of participants in both conditions judged Cue R to be causal.

To measure the importance of Cue R (relative to Cue P) in similarity judgments, we subtracted judged similarity between a key containing all four features and one that lacked Cue R from judged similarity between a key containing all four features and one that lacked Cue P. Positive scores indicated that Cue P was more important than Cue R and vice versa. As predicted, participants (n = 198) in the predictive condition judged the relative importance of Cue P to Cue R (M = 1.45) higher than participants (n = 201) in the diagnostic condition (M = 0.99), $t(397) = 2.27$, $p < .025$.

Because the size of this effect was relatively small and large numbers of participants misunderstood the task, we analyzed the relative importance of Cue P and Cue R conditionalized on causal response patterns. We divided participants into 3 groups: those who showed a coherent pattern of responses that indicates blocking (judged Cues C, U, and R non-causal and Cue P causal), those who showed a coherent pattern of responses that indicates "no blocking" (judged Cues C and U non-causal and Cues P and R causal), and those who showed other patterns. Of the participants in the predictive condition, those who showed blocking (n = 22) judged the relative importance of Cue P to Cue R (M = 2.64) greater than those who showed "no blocking" (n = 118, M = 1.28), $t(138) = 2.71$, $p < .01$. [Note: Of the participants in the diagnostic condition, the very few (n = 9) who showed blocking also judged the relative importance of Cue P to Cue R (M = 2.33) greater than those who showed "no blocking" (n = 134, M = 0.80), $t(141) = 2.81$, $p < .01$.] Most important for our hypothesis, those participants in the predictive condition who showed the blocking pattern judged the relative importance of Cue P to Cue R (M = 2.64) much higher than participants in the diagnostic condition (M = 0.99), $t(221) = 3.89$, $p < .001$, and even higher yet than participants in the diagnostic condition who did not show blocking (M = 0.8), $t(154) = 4.83$, $p < .0001$. We also replicated these results in another experiment (not reported here). It is notable that we obtained these results from a simple paper-pencil task with participants who were probably unmotivated or unable to pay close attention to the instructions or answer the questions carefully. It is likely that the differences will be enhanced under more controlled conditions, providing a means for future

studies to isolate the effects of causal understanding from the effects of mere associations.

Conclusions

The importance of causal information in category formation and conceptual coherence has been emphasized by a number of researchers (e.g., Lien & Cheng, 2000; Murphy & Medin, 1985). The results reported here extend this research to similarity judgments among novel stimuli and provide a paradigm to study this effect. A two-phase blocking paradigm such as the one used by Waldmann and Holyoak (1992) can be used to isolate the effects of causal understanding from the effects of mere association. We found that different causal schemas applied to the same correlational data affected rated similarity of novel stimuli. Of course, causality is not the only mechanism that constrains similarity. Analogical processes and higher-order relations are also responsible for providing constraints (Medin, Goldstone, & Gentner, 1993).

Why should causal information be so important? People need to discover causal relations because only such relations allow the prediction of the consequences of interventions. This constraint makes discovery of causal features vital for understanding the world and for predicting future events. Having a notion of similarity that reflects the causal relations in the world is critical for inductive inference.

Hemispheric lateralisation of the word length effect in Chinese character recognition

Yu-Ju Chou (sallyc@cogsci.ed.ac.uk)
Richard Shillcock (rcs@cogsci.ed.ac.uk)
Division of Informatics, University of Edinburgh,
2 Buccleuch Place, Edinburgh, EH8 9LW UK

Abstract

In the last decade, researchers of hemispheric superiority have become increasingly interested in the length effect in word recognition in alphabetic languages. But little has been known about ideographic languages like traditional Chinese. The primary aim of this study is to investigate hemispheric laterality and the word length effect in Chinese script recognition. Different-length words consisting of two-, three- and five-characters were presented unilaterally in a lexical decision task. The results, from 23 Taiwanese subjects, supported the word-length effect showing significantly different recognition latencies for the multi-character words of different length, but no significant hemispheric lateralisation. There was a significant interaction between gender and visual field, with males tending to show a right visual field advantage.

Previous studies have demonstrated hemispheric lateralisation effects in recognizing words of different length (Ellis & Young, 1985), concrete and abstract words (e.g., Ellis & Shepherd, 1974) and a word/number difference (eg, Besner, Daniels & Slade, 1982). The principle finding of a right visual field (RVF) superiority has been repeatedly reported in physically long English words: increasing word length affects the left visual field (LVF) but not the RVF presentations, resulting in a RVF superiority.

The Chinese writing system, the so-called ideogram, is distinctive from the English writing system and is supposed to present more pictorial characteristics, involving an LVF superiority in recognition tasks. Chinese stimuli presented in the LVF are hypothesized to consume shorter time in lexical decision than those presented in RVF, because the right hemisphere, directly connected to LVF, is dominant in processing pictorial images.

In 1994, Fang conducted experiments with different-length Chinese words but failed to find a significant interaction between Visual Field and Word Length. Either a significant Word Length effect or a Visual Field difference was found in separate experiments. This failure to find an interaction between length and visual field is important given the robustness of the effect in English. Below we report a replication of Fang's experiment, but with an added manipulation of gender, to investigate word recognition in Chinese.

Experiment

The primary aim of this study is to investigate hemispheric laterality and length effects in Chinese script recognition. Different-length words consisting of two-, three- and five-character were presented unilaterally in a lexical decision task.

Subjects

In this experiment, we used subjects who were able to read Chinese in traditional fonts. Twenty-three Taiwanese students studying in the University of Edinburgh volunteered. Their average age was twenty-nine for twelve males and twenty-seven for eleven females. All of them were native Mandarin speakers and were skilled Chinese readers with normal or corrected-to-normal vision. Only one of them was ambidextrous, the rest were right-handed according to self-report. The criterion of handedness was which hand they use most frequently for writing, holding chopsticks and badminton rackets, and whether there were any of their family members who were ambidextrous or left-handed.

Design

The stimuli were 120 different-length vertically displayed Chinese words and non-words consisting of 2, 3 and 5 Chinese characters, which were chosen from the Corpus of Journal Chinese (1993). Each length category contained 20 non-words and 20 real-words. This was a within-subjects repeated measures design. Half of the words were presented in the LVF and the other half the RVF. Twenty-three volunteers were divided into two groups randomly. The stimuli were arranged in a Latin Square design, therefore the words used in the first group were identical to those in second group, except that the stimuli presented in the LVF for the first group were presented in the RVF for the second group.

Stimuli

Switching the positions of two characters within one word was the way we produced the non-words. For example, three-character words like 荷包蛋 changed to 荷蛋包. The fixation point was a 4 mm × 4 mm cross (Font: Bodoni MT Ultra Bold. Size: 24. Duration 1000 msec) presented at the center of the monitor. It was to draw participants' attention and fixate their eyes on the center. A masking pattern was produced by overlapping dozens of Chinese characters that did not appear in the formal experiment. In addition, there were fifteen practice trials preceding the experiment.

All of the Chinese materials were produced by PhotoShop, and presented by Psyscope Version 1.2b5 (1994) and a Macintosh computer. The size of each character was 13 mm × 13 mm and the inter-character space was 9 mm, thus the three different lengths of words were 13 mm × 35 mm, 13 mm × 57 mm and 13 mm × 100 mm respectively. All the stimuli were presented on the screen either 2 mm to the right hand side of the fixation point or 2 mm to the left hand side of the fixation point. The smallest visual angle was equivalent to 0.25 degree from the fixation point.

Procedure

Subjects were asked to complete the personal data questionnaire before doing the experiment. After being instructed to sit in front of the computer, they were to face the center of the monitor at a distance of 450 mm to 550 mm from their eyes to the monitor, and to press the right or left button with the right or left index finger to make lexical decisions. For all the subjects, pressing the right button with the right index finger was for real-words and pressing the left button with the left index finger was for non-words. The experimenter explained the instructions and watched subjects' responses during fifteen practice trials, then subjects would be left alone while the formal experiment was progressing. The Psyscope software recorded response latencies with millisecond precision.

The sequence of presentation was firstly a fixation point, presented centrally for 1000 msec, followed by a unilaterally presented vertical Chinese stimulus which was ended by the critical response or which ended automatically after 2000 msec, followed by a masking picture presented for 1000 msec.

Analysis and results

An analysis of variance of response latencies was carried out with Visual Field and Word Length as within-subject factors and Gender as a between-subject factor. A significant main effect was found for Word Length ($F(2,42)=270.832$, $p< .001$), but was not for Gender ($F(1,21)=.429$, $p> .05$) or Visual Field ($F(1,21)=.423$, $p> .05$). In the LVF, five-character words were recognized less efficiently than both two- and three-character words, however, the differences between two- and three-character words did not reach significance. On the other hand, in the RVF, response times to 2-character words were shorter than those to 3-character words which were in turn shorter than those to 5 character words. Thus, there was a strong main effect of word length, in the predicted direction, but not of Visual Field.

The two-way interaction between Gender and Visual Field was significant ($F(1,21)=6.014$, $p< .05$), but not the one between Gender and Word Length ($F(2,42)= .898$, $p> .05$) or between Visual Field and Word Length ($F(2,42)=.250$, $p> .05$). Figure 1 shows that Females tended to recognize Chinese scripts faster than Males when scripts were presented in the LVF. But the response time difference did not reach the significance level of .05. Gender differences were not significant either in the RVF or in the LVF. On the other hand, Visual Field was marginally significant in Males ($p= .086$) but not in Females ($p= .121$). That means, for Males, words presented in the RVF tended to be better recognized than those in the LVF. There was no significant three-way interaction between Gender, Visual Field and Length ($p> .05$).

In summary, a significant main effect was found for word length, with longer words taking predictably more time to process than shorter words. Although the response times in the LVF were slightly slower than those in the RVF, the main effect of Visual Field did not reach statistical significance, either by subjects or by items, nor was there any significant interaction

Table 1. The response latency of Lexical Decision for 2-, 3- and 5-character Chinese words in different visual fields. This table presents the figures analyzed by items.

RT(msec)	RVF	LVF	For Entire Population
2-character words	780.8219	767.8909	774.3564
3-character words	863.2826	875.1924	869.2375
5-character words	1145.5332	1182.9296	1164.2314
			Mean 935.9418

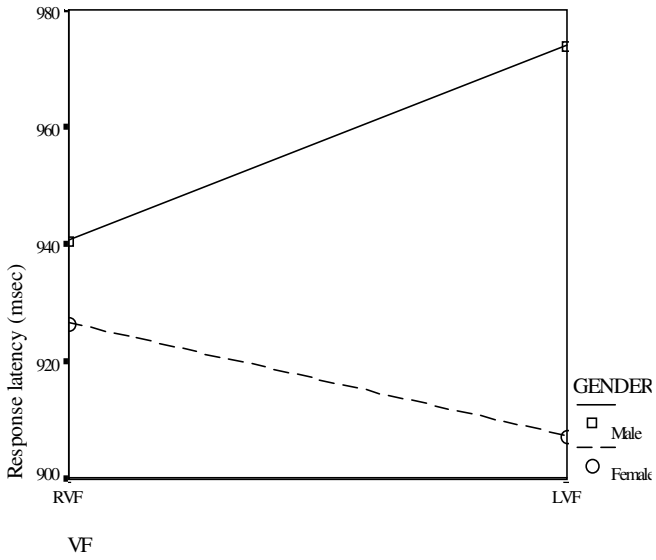

Figure 1 The interaction of Visual Field and Gender. The Visual Field difference was marginally significant in Males. That is, for Males, words presented in the RVF tended to be better recognized than those in the LVF.

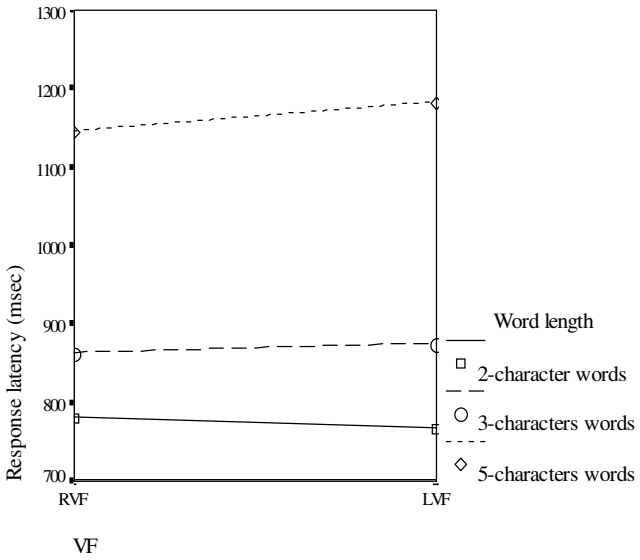

Figure 2 A significant main effect was found for Word Length, but was not for Visual Field or the interaction between Visual Field and Word Length.

between Word Length and Visual Field. In conclusion, hemispheric superiority for word length, as found in English, does not appear to exist in Chinese, from the results of this experiment.

Discussion

The methodology of this experiment was taken from Fang (1994). We extended the research of Fang by adding five-character words and introduced the gender differences. In the results, only the main effect of Word Length reached significance; neither the main effect of Visual Field nor the interaction between Visual Field and Word Length reached significance. There was, however, a significant interaction between Gender and Visual Field, the slowest reaction times coming from males responding to the LVF, supporting the idea that there are indeed visual field differences to be found in the processing of Chinese script, and comparable to those found in reading English orthography. Because of their interaction with gender, these visual field effects would seem to involve the lateralisation of phonological *versus* spatial processing. We may conclude that there is a qualitative difference between text processing in English and Chinese that prevents the emergence of a significant interaction between word length and hemifield in Chinese. Speculatively, the principal difference present in the current experiment is the vertical presentation of the words, compared with the exclusively horizontal presentation found in the relevant English experiments.

Two caveats are also necessary. Bole (1995) argued that the severity of the criteria in selecting handedness could affect the results of hemispheric superiority experiments. Mistaking left-handers for right-handers causes the data from right-handers to be less different from that of left-handers, and results in insignificant differences. Thus the current experimental procedure might be improved by using instruments such as the Edinburgh Handedness Inventory to investigate more detailed hand uses, together with a severe filter of subjects' family history in handedness.

Not all of studies of hemispheric lateralisation have reached the consistent conclusion that Chinese has significant LVF superiority with the increase of word length. But since Tzeng (1979) and following studies, it was accepted that Chinese words yield a RVF superiority whereas Chinese characters yield either a slight LVF superiority or inconsistent performance. However, many studies had failed to reduplicate these results. Thus arguments were raised from the consistency of hemispheric superiority in Chinese. Whether there is a consistent hemispheric lateralisation in recognizing Chinese words still remains doubtable.

Acknowledgments

I would like to thank my supervisor Dr. Richard Shillcock for his guidance and thank Dr. Sheng-Ping Fang for her generosity in providing the corpus and essential research papers.

Integrating Distributional, Prosodic and Phonological Information in a Connectionist Model of Language Acquisition

Morten H. Christiansen†‡ (morten@siu.edu)

Abstract

Children acquire the syntactic structure of their native language with remarkable speed and reliability. Recent work in developmental psycholinguistics suggests that children may bootstrap grammatical categories and basic syntactic structure by exploiting distributional, phonological, and prosodic cues. However, these cues are probabilistic, and are individually unreliable. In this paper, we present a series of simulations exploring the integration of multiple probabilistic cues in a connectionist model. The first simulation demonstrates that multiple-cue integration promotes significantly better, faster, and more uniform acquisition of syntax. In a second simulation, we show how this model can also accommodate recent data concerning the sensitivity of young children to prosody and grammatical function words. Our third simulation illuminates the potential contribution of prenatal language experience to the acquisition of syntax through multiple-cue integration. Finally, we demonstrate the robustness of the multiple-cue model in the face of potentially distracting cues, uncorrelated with grammatical structure.

Introduction

Before children can ride a bicycle or tie their shoes, they have learned a great deal about how words are combined to form complex sentences. This achievement is especially impressive because children acquire most of this syntactic knowledge with little or no direct instruction. Nevertheless, mastering natural language syntax may be among the most difficult learning tasks that children face. In adulthood, syntactic knowledge can be characterized by constraints governing the relationship between grammatical categories of words (such as noun and verb) in a sentence. But acquiring this knowledge presents the child with a "chicken-and-egg" problem: the syntactic constraints presuppose the grammatical categories in terms of which they are defined; and the validity of grammatical categories depends on how far they support syntactic constraints. A similar "bootstrapping" problem faces a student learning an academic subject such as physics: understanding momentum or force presupposes some understanding of the physical laws in which they figure, yet these laws presuppose these very concepts. But the bootstrapping problem solved by young children seems vastly more challenging, both because the constraints governing natural language are so intricate, and because young children do not have the intellectual capacity or explicit instruction available to the academic student. Determining how children accomplish the astonishing feat of language acquisition remains a key question in cognitive science.

By 12 months, infants are attuned to the phonological and prosodic regularities of their native language (Jusczyk, 1997; Kuhl, 1999). This perceptual attunement may provide an essential scaffolding for later learning by biasing children toward aspects of the input that are particularly informative for acquiring grammatical information. Specifically, we hypothesize that integrating multiple probabilistic cues (phonological, prosodic and distributional) by perceptually attuned general-purpose learning mechanisms may hold the key to how children solve the bootstrapping problem. Multiple cues can provide reliable evidence about linguistic structure that is unavailable from any single source of information.

In the remainder of this paper, we first review empirical evidence suggesting that infants may use a combination of distributional, phonological and prosodic cues to bootstrap into language. We then report a series of simulations, demonstrating the efficacy of multiple-cue integration within a connectionist framework. Simulation 1 shows how multiple-cue integration results in better, faster and more uniform learning. Simulation 2 establishes that the trained three-cue networks are able to mimic the effect of grammatical and prosodic manipulations in a sentence comprehension study with 2-year-olds (Shady & Gerken, 1999). Simulation 3 reveals how prenatal exposure to gross-level phonological and prosodic input facilitates postnatal learning within the multiple-cue integration framework. Finally, Simulation 4 demonstrates that adding additional distracting cues, irrelevant to the syntactic acquisition task, does not hinder learning.

Cues Available for Syntax Acquisition

Although some kind of *innate* knowledge may play a role in language acquisition, it cannot solve the bootstrapping problem. Even with built-in abstract knowledge about grammatical categories and syntactic rules (e.g., Pinker, 1984), the bootstrapping problem remains formidable: children must map the right sound strings onto the right grammatical categories while determining the specific syntactic relations between these categories in their native language. Moreover, the item-specific nature of early syntactic productions challenges the usefulness of hypothesized innate grammatical categories

(Tomasello, 2000).

Language-external information may substantially contribute to language acquisition. Correlations between environmental observations relating prior semantic categories (e.g., objects and actions) and grammatical categories (e.g., nouns and verbs) may furnish a "semantic bootstrapping" solution (Pinker, 1984). However, given that children acquire linguistic distinctions with no semantic basis (e.g., gender in French, Karmiloff-Smith, 1979), semantics cannot be the only source of information involved in solving the bootstrapping problem. Another extra-linguistic factor is cultural learning where children may imitate the pairing of linguistic forms and their conventional communicative functions (Tomasello, 2000). Nonetheless, to break down the linguistic forms into relevant units, it appears that cultural learning must be coupled with language-internal learning. Moreover, because the nature of language-external and innate knowledge is difficult to assess, it is unclear how this knowledge could be quantified: There are no computational models of how such knowledge might be applied to learning basic grammatical structure.

Though perhaps not the only source of information involved in bootstrapping the child into language, the potential contribution of *language-internal* information is more readily quantified. Our test of the multiple-cue hypothesis therefore focuses on the degree to which language-internal information (phonological, prosodic and distributional) may contribute to solving the bootstrapping problem.

Phonological information—including stress, vowel quality, and duration—may help distinguish grammatical function words (e.g., determiners, prepositions, and conjunctions) from content words (nouns, verbs, adjectives, and adverbs) in English (e.g., Cutler, 1993). Phonological information may also help distinguish between nouns and verbs. For example, nouns tend to be longer than verbs in English—a difference that even 3-year-olds are sensitive to (Cassidy & Kelly, 1991). These and other phonological cues, such as differences in stress placement in multi-syllabic words, have also been found to exist cross-linguistically (see Kelly, 1992, for a review).

Prosodic information provides cues for word and phrasal/clausal segmentation and may help uncover syntactic structure (e.g., Morgan, 1996). Acoustic analyses suggest that differences in pause length, vowel duration, and pitch indicate phrase boundaries in both English and Japanese child-directed speech (Fisher & Tokura, 1996). Infants seem highly sensitive to such language-specific prosodic patterns (for reviews, see e.g., Jusczyk, 1997; Morgan, 1996)—a sensitivity that may start in utero (Mehler et al., 1988). Prosodic information also improves sentence comprehension in two-year-olds (Shady & Gerken, 1999). Results from an artificial language learning experiment with adults show that prosodic marking of syntactic phrase boundaries facilitates learning (Morgan, Meier & Newport, 1987). Unfortunately, prosody is partly affected by a number of non-syntactic factors, such as breathing patterns (Fernald & McRoberts, 1996), resulting in an imperfect mapping between prosody and syntax. Nonetheless, infants' sensitivity to prosody provides a rich potential source of syntactic information (Morgan, 1996).

None of these cues in isolation suffice to solve the bootstrapping problem; rather, they must be integrated to overcome the partial reliability of individual cues. Previous connectionist simulations by Christiansen, Allen and Seidenberg (1998) have pointed to efficient and robust learning methods for multiple-cue integration in speech segmentation. Integration of phonological (lexical stress), prosodic (utterance boundary), and distributional (phonetic segment sequences) information resulted in reliable segmentation, outperforming the use of individual cues. The efficacy of multiple-cue integration has also been confirmed in artificial language learning experiments (e.g., McDonald & Plauche, 1995).

By one year, children's perceptual attunement is likely to allow them to utilize language-internal probabilistic cues (for reviews, see e.g., Jusczyk, 1997; Kuhl, 1999). For example, infants appear sensitive to the acoustic differences between function and content words (Shi, Werker & Morgan, 1999) and the relationship between function words and prosody in speech (Shafer, Shucard, Shucard & Gerken, 1998). Young infants can detect differences in syllable number among isolated words (Bijeljac, Bertoncini & Mehler, 1993)—a possible cue to noun/verb differences. Moreover, infants are accomplished distributional learners (e.g., Saffran, Aslin & Newport, 1996), and importantly, they are capable of multiple-cue integration (Mattys, Jusczyk, Luce & Morgan, 1999). When solving the bootstrapping problem children are also likely to benefit from specific properties of child-directed speech, such as the predominance of short sentences (Newport, Gleitman & Gleitman, 1977) and the cross-linguistically more robust prosody (Kuhl et al., 1997).

This review has indicated the range of language-internal cues available for language acquisition, that these cues affect learning and processing, and that mechanisms exist for multiple-cue integration. What is yet unknown is how far these cues can be combined to solve the bootstrapping problem (Fernald & McRoberts, 1996).

Simulation 1: Multiple-Cue Integration

Although the multiple-cue approach is gaining support in developmental psycholinguistics, its computational efficacy still remains to be established. The simulations reported in this paper are therefore intended as a first step toward a computational approach to multiple-cue integration, seeking to test the potential advantages of this approach to syntactic acquisition. Based on our previous experience with modeling multiple-cue integration in speech segmentation (Christiansen et al., 1998), we used a simple recurrent network (SRN; Elman, 1990) to model the integration of multiple cues. The networks were trained on corpora of artificial child-directed speech generated by a well-motivated grammar that includes three probabilistic cues to grammatical structure: word length,

lexical stress and pitch. Simulation 1 demonstrates how the integration of these three cues benefits the acquisition of syntactic structure by comparing performance across the eight possible cue combinations.

Method

Networks Ten SRNs were used in each cue condition, with an initial weight randomization in the interval [-0.1; 0.1]. Learning rate was set to 0.1, and momentum to 0. Each input to the networks contained a localist representation of a word, and a constellation of cue units depending on its assigned cue condition. Networks were required to predict the next word in a sentence along with the corresponding cues for that word. With a total of 44 words and a pause marking boundaries between utterances, the networks had 45 input units. Networks in the condition with all available cues had an additional five input units. The number of input and output units thus varied between 45-50 across conditions. Each network had 80 hidden units and 80 context units.

Materials We constructed a complex grammar based on independent analyses of child-directed corpora (Bernstein-Ratner, 1984; Korman, 1984), and a study of child-directed speech by mother-daughter pairs (Fisher & Tokura, 1996). As illustrated in Table 1, the grammar included three primary sentence types: declarative, imperative, and interrogative sentences. Each type consisted of a variety of common utterances reflecting the child's exposure. For example, declarative sentences most frequently appeared as transitive or intransitive verb constructions (*the boy chases the cat*, *the boy swims*), but also included predication using *be* (*the horse is pretty*) and second person pronominal constructions commonly found in child-directed corpora (*you are a boy*). Interrogative sentences were composed of wh-questions (*where are the boys?*, *where do the boys swim?*), and questions formed by using auxiliary verbs (*do the boys walk?*, *are the cats pretty?*). Imperatives were the simplest class of sentences, appearing as intransitive or transitive verb phrases (*kiss the bunny*, *sleep*). Subject-verb agreement was upheld in the grammar, along with appropriate determiners accompanying nouns (*the cars* vs. **a cars*).

Two basic cues were available to all networks. The fundamental distributional information inherent in the grammar could be exploited by all networks in this experiment. As a second basic cue, utterance-boundary pauses signalled grammatically distinct utterances with 92% reliability (Broen, 1972). This was encoded as a single unit that was activated at the end of all but 8% of the sentences. Other semi-reliable prosodic and phonological cues accompanied the phrase-structure grammar: word length, stress, and pitch. Network groups were constructed using different combinations of these three cues. Cassidy and Kelly (1991) demonstrated that syllable count is a cue available to English speakers to distinguish nouns and verbs. They found that the probability of a single syllable word to be a noun rather than a verb is 38%. This probability rises to 76% at two syllables, and 92% at three. We selected verb and noun tokens that exhibited this distinction, whereas the length of the remaining words were typical for their class (i.e., function words tended to be monosyllabic). Word length was represented in terms of three units using thermometer encoding—that is, one unit would be on for monosyllabic words, two for bisyllabic words, and three for trisyllabic words. Pitch change is a cue associated with syllables that precede pauses. Fisher and Tokura (1996) found that these pauses signalled grammatically distinct utterances with 96% accuracy in child-directed speech, allowing pitch to serve as a cue to grammatical structure. In the networks, this cue was a single unit that would be activated at the final word in an utterance. Finally, we used a single unit to encode lexical stress as a possible cue to distinguish stressed content words from the reduced, unstressed form of function words. This unit would be on for all content words.

Table 1: **The Stochastic Phrase Structure Grammar Used to Generate Training Corpora**

S → Imperative [0.1] | Interrogative [0.3] | Declarative [0.6]
Declarative → NP VP [0.7] | NP-ADJ [0.1] | That-NP [0.075] | You-P [0.125]
NP-ADJ → NP is/are adjective
That-NP → that/those is/are NP
You-P → you are NP
Imperative → VP
Interrogative → Wh-Question [0.65] | Aux-Question [0.35]
Wh-Question → where/who/what is/are NP [0.5] | where/who/what do/does NP VP [0.5]
Aux-Question → do/does NP VP [0.33] | do/does NP wanna VP [0.33] | is/are NP adjective [0.34]
NP → a/the N-sing/N-plur
VP → V-int | V-trans NP

Procedure Eight groups of networks, one for each combination of cues, were trained on corpora consisting of 10,000 sentences generated from the grammar. Each network within a group was trained on a different training corpus. Training consisted of 200,000 input/output presentations (words), or approximately 5 passes through the training corpus. Each group of networks had cues added to its training corpus depending on cue condition. Networks were expected to predict the next word in a sentence, along with the appropriate cue values. A corpus consisting of 1,000 novel sentences was generated for testing. Performance was measured by assessing the networks' ability to predict the next set of grammatical items given prior context—and, importantly, this measure did not include predictions of cue information.

To provide a statistical benchmark with which to compare network performance, we "trained" bigram and trigram models on the same corpora as the networks. These finite-state models, borrowed from computational linguistics, provide a simple prediction method based on strings of two (bigrams) or three (trigrams) consecutive

words. Comparisons with these simple models provide an indication of whether the networks are learning more than simple two- or three-word associations.

Results

All networks achieved better performance than the standard bigram/trigram models ($p's < .0001$), suggesting that the networks had acquired knowledge of syntactic structure beyond the information associated with simple pairs or triples of words. The nets provided with phonological/prosodic cues achieved significantly better performance than base networks ($p's < .02$). Using trigram performance as criterion, all multiple-cue networks surpassed this level of performance faster than the base networks ($p's < .002$). Moreover, the three-cue networks were significantly faster than the single-cue networks ($p's < .001$). Finally, using Brown-Forsyth tests for variability in the final level of performance, we found that the three-cue networks also exhibited significantly more uniform learning than the base networks ($F(1,18) = 5.14, p < .04$).

Simulation 2: Sentence Comprehension in Two-Year-Olds

Simulation 1 provides evidence for the general feasibility of the multiple-cue integration approach. However, to further strengthen the model's credibility closer contact with relevant human data is needed. In the current simulation, we demonstrate that the three-cue networks from Simulation 1 are able to accommodate recent data showing that two-year-olds can integrate grammatical markers (function words) and prosodic cues in sentence comprehension (Shady & Gerken, 1999: Expt. 1). In this study, children heard sentences, such as (1), in one of three prosodic conditions depending on pause location: early natural [e], late natural [l], and unnatural [u]. Each sentence moreover involved one of three grammatical markers: grammatical (the), ungrammatical (was), and nonsense (gub).

1. Find [e] the/was/gub [u] dog [l] for me.

The child's task was to identify the correct picture corresponding to the target noun (dog). Simulation 2 replicates this by using comparable stimuli, and assessing the noun activations.

Method

Networks Twelve networks from Simulation 1 were used in each prosodic condition. This number was chosen to match the number of infants in the Shady and Gerken (1999) experiment. An additional unit was added to the networks to encode the nonsense word (gub) in Shady and Gerken's experiment.

Materials We constructed a sample set of sentences from our grammar that could be modified to match the stimuli in Shady and Gerken. Twelve sentences for each prosody condition (pause location) were constructed. Pauses were represented by activating the utterance-boundary unit. Because these pauses probabilistically signal grammatically distinct utterances, the utterance-boundary unit provides a good approximation of what the children in the experiment would experience. Finally, the nonsense word was added to the stimuli for the within group condition (grammatical vs. ungrammatical vs. nonsense). Adjusting for vocabulary differences, the networks were tested on comparable sentences, such as (2):

2. Where does [e] the/is/gub [u] dog [l] eat?

Procedure Each group of networks was exposed to the set of sentences corresponding with its assigned pause location (early vs. late vs. unnatural). No learning took place, since the fully-trained networks were used. To approximate the picture selection task in the experiment, we measured the degree to which the networks would activate the groups of nouns following the/is/gub. The two conditions were expected to affect the activation of the nouns.

Results

Shady and Gerken (1999) reported a significant effect of prosody on the picture selection task. The same was true for our networks ($F(2,33) = 1,253.07, p < .0001$). The late natural condition elicited the highest noun activation, followed by the early natural condition, and with the unnatural condition yielding the least activation. The experiment also revealed an effect of grammaticality as did our networks ($F(2,70) = 69.85, p < .0001$), showing the most activation following the determiner, then for the nonsense word, and lastly for the ungrammatical word. This replication of the human data confers further support for Simulation 1 as a model of language acquisition by multiple-cue integration.

Simulation 3: The Role of Prenatal Exposure

Studies of 4-day-old infants suggest that the attunement to prosodic information may begin prior to birth (Mehler et al., 1988). We suggest that this prenatal exposure to language may provide a scaffolding for later syntactic acquisition by initially focusing learning on certain aspects of prosody and gross-level properties of phonology (such as word length) that later will play an important role in postnatal multiple-cue integration. In the current simulation, we test this hypothesis using the connectionist model from Simulations 1 and 2. If this scaffolding hypothesis is correct, we would expect that prenatal exposure corresponding to what infants receive in the womb would result in improved acquisition of syntactic structure.

Method

Networks Ten SRNs were used in both prenatal and non-prenatal groups, with the same initial conditions and training details as Simulation 1. Each network was supplied with the full range of cues used in Simulation 1.

Materials A set of "filtered" prenatal stimuli was generated using the same grammar as previously (Table 1), with the exception that input/output patterns now ignored individual words and only involved the units encoding word length, stress, pitch change and utterance boundaries. The postnatal stimuli were the same as in Simulation 1.

Procedure The networks in the prenatal group were first trained on 100,000 input/output filtered presentations drawn from a corpus of 10,000 new sentences. Following this prenatal exposure, the nets were then trained on the full input patterns exactly as in Simulation 1. The non-prenatal group only received training on the postnatal corpora. As previously, networks were required to predict the following word and corresponding cues. Performance was again measured by the prediction of following words, ignoring the cue units.

Results

Both network groups exhibited significantly higher performance than the bigram/trigram models ($F(1,18) = 25.32, p < .0001$ for prenatal, $F(1,18) = 12.03, p < .01$ for non-prenatal), again indicating that the networks are acquiring complex grammatical regularities that go beyond simple adjacency relations. We compared the performance of the two network groups across different degrees of training using a two-factor analysis of variance (ANOVA) with training condition (prenatal vs. non-prenatal) as the between-network factor and amount of training as within-network factor (five levels of training measured in 20,000 input/output presentation intervals). There was a main effect of training condition ($F(1,18) = 12.36, p < .01$), suggesting that prenatal exposure significantly improved learning. A main effect of degrees of training ($F(9,162) = 15.96, p < .001$) reveals that both network groups benefitted significantly from training. An interaction between training conditions and degrees of training indicates that the prenatal networks learned significantly better than postnatal networks ($F(1,18) = 9.90, p < 0.01$). The exposure to prenatal input—void of any information about individual words—promotes better performance on the prediction task; thus providing computational support for the prenatal scaffolding hypothesis.

Simulation 4: Multiple-Cue Integration with Useful and Distracting Cues

A possible objection to the previous simulations is that our networks succeed at multiple-cue integration because they are "hand-fed" cues that are at least partially relevant for syntax acquisition. Consequently, performance may potentially drop significantly if the networks themselves had to discover which cues were partially relevant and which are not. Simulation 4 therefore tests the robustness of our multiple-cue approach when faced with additional, uncorrelated distractor cues. Accordingly, we added three distractor cues to the previous three reliable cues. These new cues encoded the presence of word-initial vowels, word-final voicing, and relative (male/female) speaker pitch—all acoustically salient in speech, but which do not appear to cue syntactic structure.

Method

Networks Networks, groups and training details were the same as in Simulation 3, except for the addition of the three additional input units encoding the distractor cues.

Materials The three distractor cues were added to the stimuli used in Simulation 3. Two of the cues were phonetic and therefore available only in postnatal training. The word-initial vowel cue appears in all words across classes. The second distractor cue, word-final voicing, also does not provide useful distinguishing properties of word classes. Finally, as an additional prenatal and postnatal cue, overall pitch quality was added to the stimuli. This was intended to capture whether the speaker was female or male. In prenatal training, this probability was set to be extremely high (90%), and lower in postnatal training (60%). In the womb, the mother's voice naturally provides most of the input during the final trimester when the infant's auditory system has begun to function (Rubel, 1985). The probability used here intended to capture that some experience would likely derive from other speakers as well. In postnatal training this probability drops, representing exposure to male members of the linguistic community, but still favoring mother-child interactions.

Procedure Prenatal stimuli included the three previous semi-reliable cues, and only the additional prosodic, distractor cue encoding relative speaker pitch. In the postnatal stimuli, all three distractor cues were added. Training and testing details were the same as in Simulation 3.

Results

As in Simulations 1 and 3, both groups performed significantly better than the bigram/trigram models ($F(1,18) = 18.95, p < .0001$ for prenatal, and $F(1,18) = 14.27, p < .001$ for non-prenatal). We repeated the two-factor ANOVA computed for Simulation 2, revealing a main effect for training condition ($F(1,18) = 4.76, p < 0.05$) and degrees of training ($F(9,162) = 13.88, p < .0001$). This indicates that the presence of the distractor cues did not hinder the improved performance following prenatal language exposure. As in Simulation 3, the prenatal networks learned comparatively faster than the non-prenatal networks ($F(1,18) = 5.31, p < .05$).

To determine how the distractor cues may have affected performance, we compared the prenatal condition in Simulation 3 with that of the current simulation. There was no significant difference in performance across the two simulations ($F(1,18) = 0.13, p = 0.72$). A further comparison between these non-prenatal networks and the bare networks in Simulation 1 showed that the networks trained with cues of mixed reliability significantly outperformed networks trained without any cues ($F(1,18) = 14.27, p < .001$). This indicates that the

uncorrelated cues did not prevent the networks from integrating the partially reliable ones towards learning grammatical structure.

Conclusion

A growing bulk of evidence from developmental cognitive science has suggested that bootstrapping into language acquisition may be a process of integrating multiple sources of probabilistic information, each of which is individually unreliable, but jointly advantageous. However, what has so far been missing is a comprehensive demonstration of the computational feasibility of this approach. With the series of simulations reported here we have taken the first step toward establishing the computational advantages of multiple-cue integration. Simulation 1 demonstrated that providing SRNs with prosodic and phonological cues significantly improves their acquisition of syntactic structure—despite the fact that these cues are only partially reliable. The multiple-cue integration approach gains further support from Simulation 2, showing that the three-cue networks can mimic children's sensitivity to both prosodic and grammatical cues in sentence comprehension. The model also illustrates the potential value of prenatal exposure, since Simulation 3 revealed significant benefits for networks receiving such input. Finally, Simulation 4 provides evidence for the robustness of our neural network model, since highly unreliable cues did not interfere with the integration process. This implementation of our model still exhibited significant performance advantages over networks not receiving cues at all. Moreover, all the network models consistently performed better than the statistical benchmarks, the bigram and trigram models. This has important theoretical implications because it suggests that the SRNs acquired complex knowledge of grammatical structure and not merely simple two- or three-word co-occurrence statistics. Overall, the simulation results presented in this paper provide support not only for the multiple-cue integration approach in general, but also for a connectionist approach to the integration of distributional, prosodic and phonological information in language acquisition.

Abstract

Typicality effects are ordinarily tied to concepts and conceptualization. The underlying assumption in much of categorization research is that effects such as typicality are reflective of stored conceptual structure. This paper questions this assumption by simulating typicality effects by the use of a co-occurrence model of language, Latent Semantic Analysis (LSA). Despite being a statistical tool based on simple word co-occurrence, LSA successfully simulates subject data relating to typicality effects and the effects of context on categories. Moreover, it does so without any explicit coding of categories or semantic features. The model is then used to successfully predict participants' judgements of typicality in context. In the light of the findings reported here, we question the traditional interpretation of typicality data: are these data reflective of underlying structure in people's concepts, or are they reflective of the distributional properties of the linguistic environments in which they find themselves.

Introduction

The world contains a myriad of objects and events that an intelligent observer could seemingly infinitely partition and generalise from. So how it is that humans can adopt a particular partitioning in the mass of data that confronts them? How do they pick out regularities in the stuff of experience and index them using words? What are these regularities? And how do humans recognise, communicate, learn and reason with them? These questions are central to cognitive science, and traditionally, their close linkage has tempted researchers to seek a unified answer to them: categorization – the act of grouping things in the world – has been commonly linked to the representation of concepts[1], with many researchers assuming that a theory of one provides for the other (Armstrong, Gleitman & Gleitman, 1983; Keil, 1987; Lakoff, 1987).

In much of this work, it is assumed that linguistic behavior (such as naming features associated with a concept, c.f. Rosch, 1973) is determined by, and reflective of, underlying concepts that are grounded in perceptual experience of objects and artifacts themselves. Here, we wish to consider the idea that language itself is part of the environment that determines conceptual behavior. A growing body of research indicates that *distributional information* may play a powerful role in many aspects of human cognition. In particular, it has been proposed that people can exploit statistical regularities in language to accomplish a range of conceptual and perceptual learning tasks. Saffran, Aslin & Newport (1996; see also Saffran, Newport, & Aslin; 1996) have demonstrated that infants and adults are sensitive to simple conditional probability statistics, suggesting one way in which the ability to segment the speech stream into words may be realized. Redington, Chater & Finch (1998) suggest that distributional information may contribute to the acquisition of syntactic knowledge by children. MacDonald & Ramscar (this volume) have shown how information derived from a 100 million word corpus can be used to manipulate subjects' contextual experience with marginally familiar and nonce words, demonstrating that similarity judgements involving these words are affected by the distributional properties of the contexts in which they were read.

The objective of this paper is to examine the extent to which co-occurrence techniques can model human categorization data: What is the relationship between typicality judgements and distributional information? Indeed, are the responses people provide in typicality experiments more reflective of the distributional properties of the linguistic environments in which they find themselves than they are of the underlying structure of people's concepts?

Typicality Effects

The first empirical evidence of typicality effects was provided by Rosch (1973), who found participants judged some category members as more (proto)typical than others. Rosch (1973) gave subjects a category name such as *fruit* with a list of members such as apple,

[1] In the experiments reported, we follow the common assumption (Medin & Smith, 1984; Komatsu, 1992) that categories are classes, concepts are their mental representations and that an instance is a specific example of a category member.

fig, olive, plum, pineapple, strawberry, etc. and asked subjects to rate on a 7-point scale how good an example each member was of its category. The results showed a clear trend of category gradedness – apples are consistently judged a typical *fruit*, while olives are atypical. Further evidence underlines the pervasiveness of typicality (or "goodness of example") and its ability to predict a variety of results. Typicality was found to predict reaction times in sentence verification tasks (Rosch, 1973; McCloskey & Glucksberg, 1979) and order of item output when subjects are asked to name members of a category (Barsalou & Sewell, 1985).

Roth & Shoben (1983) showed that the context a concept appears in affects the typicality of its instances. A typical *bird* in the context-free sense may be a *robin*, but if it appears in the context "The bird walked across the barnyard", then *chicken* would instead be typical. Subject reaction times to sentence verification tasks are faster for the contextually appropriate item (*chicken*) than the normally typical, but contextually inappropriate item (*robin*). Roth and Shoben found that measures of typicality determined in isolation no longer play a predictive role once context has been introduced.

Typicality, Substitutability and LSA

According to Rosch (1978): "The meaning of words is intimately tied to their use in sentences. Prototypicality ratings for members of superordinate categories predict the extent to which the member term is substitutable for the superordinate word in sentences."

This notion of contextual substitutability has a parallel in distributional approaches to word meanings (e.g. Landauer & Dumais, 1997; Burgess & Lund, 1997). In a distributional model of word meaning such as Latent Semantic Analysis (LSA), the corpus analysis calculates a contextual distribution for each lexeme encountered by counting the frequency with which it co-occurs[2] with every other word in the corpus. The contextual distribution of a word can then be summarized by a vector – or point in high-dimensional space – that shows the frequency with which it is associated with the other lexemes in the corpora. In this way, two words that tend to occur in similar linguistic contexts – i.e. are *distributionally* similar – will be positioned closer together in semantic space than two words which do not share as much distributional information. By using the proximity of points in semantic space as a measure of their contextual substitutability, LSA offers a tidy metric of distributional similarity.

Rosch (1973; 1978) held that such substitutability arises as a result of similarities between the underlying structures of the concepts representing the words (although describing these underlying structures has proven elusive, see Komatsu, 1992; Ramscar & Hahn, in submission). However, distributional theories suggest that information about substitutability and word similarity can instead be gleaned from the structure of the *linguistic environment*. Such information is readily – and objectively - obtainable for the purposes of model building and hypothesis testing.

[2] How words are used together within a particular context, such as a paragraph or moving-window.

Experiment 1 – Canonical Typicality

The purpose of this experiment is to examine whether data from typicality studies (Rosch, 1973; Armstrong, Gleitman & Gleitman, 1983; Malt & Smith, 1984) can be modeled using a distributional measure. Specifically, it was predicted that subject typicality scores from previous studies would correlate with a distributional measure (LSA; Landauer & Dumais, 1997) when comparing similarity scores for category members against their superordinate category name.

Materials

Each set of typicality data was divided up according to the taxonomy used in the original study: Set A was taken from Rosch (1973), B from Armstrong, Gleitman & Gleitman (1983), and C from Malt & Smith (1984).

Within these three data sets, 18 sets of typicality ratings existed, across 12 separate categories due to overlap between categories used in Sets A, B and C.

Procedure

For each category in each data set, all items were compared in LSA to the superordinate category name and the similarity scores noted. All scores were calculated in LSA using a corpus whose texts are thought to be representative of reading materials experienced by students up to first year in college[3].

The LSA scores were then scaled from the given [-1, +1] range to fit the standard 7-point typicality scale used in the subject studies, where a score of 1 represents the most typical rating. Malt & Smith used the 7-point scale in reverse order (where 7 represented most typical) so these scores were inverted. LSA score scaling was done by aligning the highest of the LSA scores for each category with the most typical rank on the 7-point scale[4]; i.e. the highest LSA score for a category would be matched to 1, and the other scores falling proportionately towards 7.

[3] Using General Reading up to 1st Year College semantic space, with term-to-term comparison and maximum factors.

[4] The exact formula used is as follows: Where X is the LSA score one wishes to scale and M is the maximum LSA score for this category set:
Scaled LSA score = $M - (M - 1) / (M * X)$.

Results

Spearman's rank correlation (*rho*) was used to compare scaled LSA and subject scores. The global rank correlation between the subject ratings and LSA scores across Sets A, B and C (193 items) was *rho*=0.515 (2-tailed $p<0.001$). Many of the categories that failed to produce greatly significant correlations correlated significantly with the removal of one member, due to it having an extremely high or low LSA score (usually because of its low frequency of occurrence in the corpus). See Table 1 for full LSA results. Also, Set A / Set B correlations for their 4 shared categories of *sport*, *fruit*, *vehicle* and *vegetable* were *rho*=1.0 ($p<0.01$), *rho*=0.943 ($p<0.05$), *rho*=0.886 ($p<0.05$) and *rho*=0.886 ($p<0.05$) respectively.

Table 1: Rank correlation coefficients *rho* (with levels of significance *p*) between LSA and subject scores

Set	Category	Initial category	Adjusted category
A	sport	1.000 ($p<0.01$)	
	fruit	0.886 ($p<0.05$)	
	vehicle	0.829 ($p<0.10$)	1.000 ($p<0.05$)
	crime	0.814 ($p<0.10$)	0.975 ($p<$ (0.10)
	bird	0.714 ($p<0.10$)	0.900 ($p<0.10$)
	science	0.414 (-)	0.675 ($p<0.10$)
	vegetable	0.371 (-)	
B	sport	0.811 ($p<0.01$)	
	vehicle	0.788 ($p<0.01$)	
	vegetable	0.580 ($p<0.10$)	0.745 ($p<0.05$)
	fruit	0.539 ($p<0.10$)	0.748 ($p<0.05$)
	female	0.346 (-)	0.558 ($p<0.10$)
C	trees	0.705 ($p<0.01$)	
	clothing	0.521 ($p<0.05$)	0.676 ($p<0.05$)
	furniture	0.466 ($p<0.05$)	0.609 ($p<0.01$)
	bird	0.375 (-)	0.640 ($p<0.05$)
	fruit	0.157 (-)	
	flowers	-0.499 (-)	

Values (-) represent insignificant correlation of p>0.10

It must be noted that the same rank correlation coefficient results in differing levels of significance within Table 1. This is due to different sizes in categories' data sets (from 5 to 20), where the same score could be significant for one size set and not another; e.g. perfect rank correlation of 1.000 is significant to $p<0.01$ with $N=10$, but only to $p<0.05$ when $N=5$. This high sensitivity to the degrees of freedom from small-sized data sets is why one outlying item was capable of skewing the rank correlation. With small data sets such as these, the power of the tests being used is restricted and they are overly sensitive to individual data points. Larger category data sets are to be found in Sets B and C, where although the rank correlation coefficients may be lower, they are more significant. Thus, it seems reasonable to consider as marginally significant those results where $p<0.10$, given the constraints of the data.

Discussion

In this experiment, LSA similarity scores correlated significantly with subject typicality ratings. Without any hand-coding of category membership or salient features, LSA's semantic space successfully modeled gradients of typicality within categories. Significant global correlation existed between LSA-to-subject typicality ratings at *rho*=0.515 ($p<0.001$). Items that subjects judged typical correlated with those that LSA scored highly in similarity with the category name. The same correlation is true of items that subjects judged to be highly atypical members of their category – these received low similarity scores in LSA. The more closely the ranking of LSA scores mirrored that of the subjects', the higher the correlation, and the closer the level of significance dropped to zero.

Regarding the categories themselves, there were cases where LSA modeled a category's typicality gradient successfully in one data set but not in another. An example of this is the category *fruit*, which was modeled with rank correlation of *rho*=0.886 ($p<0.05$) in Set A and 0.748 ($p<0.05$) in Set B (adjusted), but failed to correlate significantly at all in Set C.

Only one of the 5 category types in Set B came from what Armstrong, Gleitman & Gleitman (1983) term as "well-defined" categories – the category *female*. Despite Armstrong, Gleitman and Gleitman's designation of this category as well-defined, it seems reasonable to regard typicality in *female* as one would any other category examined in this experiment – a measure of contextual substitutability. In this case, the contextual substitutability shown by LSA similarity scores failed to convincingly model the typicality scores for *female*, only reaching correlation of 0.558 ($p<0.10$) when the category was adjusted. We propose the reason for this is that typicality ratings for a category such as *female* are subject to social conditioning in a way other categories such as *fruit* or *sport* are not. For example, the item that LSA scored highest against *female* was *housewife*, which was next followed by *chairwoman*. Although this simply reflects the general contextual substitutability of the words across all of LSA's corpora, it also reflects a ranking that may not be found within a social group. It would be inconsistent for a group of subjects to rate *housewife* as the most typical *female* (a stereotyped sexist attitude), while rating *chairwoman* (a stereotyped politically correct attitude) closely behind. Thus LSA may have failed to convincingly model this category's typicality gradient because it reflects an average of social attitudes across

its corpora, and not just those of one particular group – 1980's Philadelphia undergraduates.

One of the most interesting findings is that in 3 out of 4 cases of shared categories between Set A and Set B, LSA provided as good a fit to Set A typicality ratings as Set B did. When the item *skis* was removed from Set A's *vehicle* category, LSA's correlation bettered that of Set B (with the sole exception of the category *vegetable*). This serves to make an important point and put the data in Table 1 into perspective: it suggests that the difference between subject groups in Rosch's (1973) and Armstrong, Gleitman & Gleitman's (1983) experiments is comparable to the difference between LSA and human subjects. In other words, a co-occurrence model like LSA is as successful at matching the typicality gradients of a subject group as another subject group would be.

Experiment 2 – Contextual Typicality

The first experiment indicates that a co-occurrence model such as LSA can be used to model typicality judgements in canonical (context-free) categories. However, categorization is also subject to linguistic context, whose capacity to skew typicality has been demonstrated by Roth & Shoben (1983).

Having examined canonical typicality in Experiment 1, the purpose of Experiment 2 was to test if LSA could be used to predict subject responses for typicality in context. The hypothesis was that LSA could predict human judgements of exemplar appropriateness (typicality) for given context sentences. LSA similarity scores for each context sentence[5] and respective category members were used to form significantly different clusters of appropriate (high scores / high similarity) and inappropriate (low scores / low similarity) items. It was predicted that subject ratings of typicality in context for these items would fall into the same clusters, and that these clusters would also be significantly different.

Materials

Materials consisted of 7 context sets, each of which consisted of a context sentence and 10 possible members of the category. 3 of the context sentences were taken from Roth & Shoben (1983), the other 4 created for this experiment. Category members were chosen in two ways, to form the appropriate and inappropriate clusters for the context.

First, appropriate items were found by randomly selecting 4-5 high-level category members (e.g. *cow* not *calf* for category *animal*) that appeared in the LSA list of 1500 near neighbors of the context sentence[6]. This list corresponds to the 1500 points in LSA's high-dimensional space that are closest to the context sentence, and would receive the highest similarity scores.

Second, inappropriate items were found by compiling a large list of category members and selecting the 5-6 of those that had the lowest (preferably negative) LSA similarity score against the context sentence.

These materials were split into two sections. Each section consisted of 7 context sets, now with 5 items, selected so that there were at least 2 of both appropriate and inappropriate items in the set and so that each category member appeared only once per section. Subjects received one section apiece, with presentation of section 1 or 2 alternated between subjects. All 35 items within each section were presented in random order, resampled for each subject.

Participants

19 native speakers of English took part in this experiment. All were volunteers who participated by completing an electronic questionnaire.

Procedure

LSA Procedure The scores were calculated in LSA by comparing the context sentence to each item in the list, using the same corpus as for Experiment 1[7].

The LSA scores were then scaled from the given [-1, +1] range to fit the standard 7-point typicality scale used in the subject studies. Due to the presence of very low negative LSA scores, this was done by aligning the extremes of the LSA scores for each category with the opposite extremes of the 7-point scale; i.e. the highest LSA score for a category would be matched to 1, the lowest score to 7, and the intermediate scores falling proportionately in between[8].

Human Procedure Participants read instructions that explained typicality and the 7-point scale as per Rosch (1973) and Armstrong, Gleitman & Gleitman (1983). They were then given this example of a context sentence (not used in experiment) "The girl played the GUITAR while the others sang around the campfire",

[5] The LSA score for a sentence is computed by taking a weighted average of the vectors for each word.

[6] The sentence was processed as a pseudodoc using maximum factors in the same semantic space as used in Experiment 1, from which all words in the corpus with a frequency of less than or equal to 5 had been removed.

[7] Using document-to-term comparison and maximum factors.

[8] The exact formula used is as follows: Where X is the LSA score one wishes to scale, M is the maximum LSA score for this category set and L is the midpoint of the LSA score range for this category set:
Scaled LSA score = $4 - [(L - X) * 3] / (L * M)$.
(4 = midpoint of 7-pt scale; 3 = scale end [7] – midpoint [4]).

and told to consider the appropriateness of the capitalized word in the context given.

Participants were asked not to spend more than 10 seconds deciding on what score to give, and were told that it would not be possible to go back and change an answer (the questionnaire was set up to prevent participants from doing this).

Results

Subjects agreed with LSA's predictions of typicality for 62 of the total 70 items – 10/10 items in 3 context sets, 9/10 items in 3 further context sets, and 5/10 in the remaining context set. Significant difference in clusters, not rank correlation, is the important factor here, because even subject data with low correlation to the LSA score may fall into the two specified clusters (and thus provide support for the main prediction).

Table 2: Wilcoxon's *W* and significance of difference between clusters for each context sentence.

Context Sentence	LSA	Subjects
Stacy volunteered to milk the *animal* whenever she visited the farm *	10 ($p<0.01$)	10 ($p<0.01$)
Fran pleaded with her father to let her ride the *animal* *	15 ($p<0.01$)	15 ($p<0.01$)
The *bird* swooped down on the helpless mouse and carried it off	10 ($p<0.01$)	10 ($p<0.01$)
Jane liked to listen to the *bird* singing in the garden	15 ($p<0.01$)	18 ($p<0.1$) *10 ($p<0.05$) adjusted*
Jimmy loved everything sweet and liked to eat a *fruit* with his lunch every day	15 ($p<0.01$)	18 ($p<0.1$) *10 ($p<0.05$) adjusted*
Sophie was a natural athlete and she enjoyed spending every day at *sport* training	15 ($p<0.01$)	19.5 ($p<0.1$) *10.5($p<0.05$) adjusted*
During the mid morning break the two secretaries gossiped as they drank the *beverage* *	15 ($p<0.01$)	25 ($p<0.7$)**

* Sentences taken from Roth & Shoben (1983)
** Not significant but included for completeness

For all 7 context sets, Mann-Whitney (Wilcoxon Summed Ranks, 2-tailed) tests showed the LSA scores fell into two significantly different clusters. When testing subject scores for difference between the predicted clusters, results varied from three context sets showing significant differences at $p<0.01$ (those at 10/10 agreement), to one set failing to achieve any significant difference at $p=0.69$ (5/10 agreement). Data for clustering in both LSA and subject scores are given in Table 2. Three of the context sets that only produced clusters which were significantly different to $p<0.10$ were those where subjects agreed with LSA-predicted clusters for 9/10 items. With the removal of this lone contentious item, each of these three adjusted subject sets achieved significance of $p<0.025$ (see Table 2).

Discussion

The results support the basic hypothesis that, in the majority of cases, distributional information (in this case modeled in LSA) can predict whether members of a category will be appropriate or inappropriate in a given context. In other words, it can predict human judgements of typicality in context as well as in canonical categories (as demonstrated in Experiment 1). For example, LSA predicted in the context set for *animal* ("Fran pleaded with her father...") that the item *elephant* would be placed in the inappropriate cluster, even though it is entirely possible to ride on an elephant.[9]

In 3 of the 7 context sets, subject typicality scores agreed with LSA predicted clusters for 10/10 items and separated the clusters to a difference significance of $p<0.01$. These sets involved natural kinds as the category for which typicality was taken (*animal*, *bird*). In a further 3 context sets, subjects agreed with LSA's clustering for 9/10 items and separated the clusters to a significant difference of $p<0.05$ when these 9 items were considered. For these sets, two categories were of natural kinds (*bird*, *fruit*) and one was an abstract artifact kind (*sport*). Finally, the context set for which only 5/10 items were agreed to be in the predicted clusters was also for an artifact kind (*beverage*). This suggests that distributional information (or at least, LSA) may perform better in predicting the contextual typicality of natural kinds than artifact kinds. This is perhaps as a result of the vectors for artifact kinds containing a greater degree of contextual variation and thus scoring more unpredictably against the context sentence. Such a theory is compatible with psychological data showing that artifact kinds are processed differently because they may be found in a variety of functional and relational roles, and/or are often polysemous (e.g. Wisniewski & Gentner, 1991).

General Discussion

The success of a distributional measure (LSA) in these modeling experiments suggests interesting possibilities for a theory of categorization based in context, that incorporates information from the structure of language as well as from the structure of the world. Distributional models of language use a representation that is learned from the language alone, assuming that the way words co-occur with one another gives rise to

[9] Although we anticipated a problem with participants' judgements here, the prediction was consistent with the data, where *elephant* received a typicality score of 4.1 and resided in the inappropriate cluster. Is this respect, LSA predictions were sometimes unexpectedly appropriate.

clues about their semantic meaning. Gleitman (1990) has discussed a similar approach with regards to first language acquisition, where this type of representation can be easily learned from an individual's response to their linguistic environment, thus lending a psychologically plausible base to such a theory.

In this respect, the results of these simulations raise interesting questions with regard to people's mental representations of the meanings of words: Do people use distributional information to construct their representation of word meanings? Or are distributional properties of words (which models such as LSA extract) merely an epiphenomenonon; a reflection of the fact that underlying concepts share certain semantic features? By the latter account, the distributional properties associated with words would arise *because* the concepts underlying the words possess certain features, and it is sensitivity to similarities between these concepts that subjects actually manifest. However, MacDonald & Ramscar (in submission) have shown that manipulating the distributional properties of the contexts in which nonce words are read can significantly influence similarity judgements between existing words and nonces. This indicates that not *all* distributional responses can be explained in terms of existing conceptual structure – nonce words won't have an existing conceptual structure. Equally, it seems highly unlikely that the structure of the linguistic environment is entirely unreflective of the structure that people extract from their interactions with the world.

What the results presented here (and other distributional research) seem to indicate is that any proper characterization of conceptual thought will have to consider more than just the information that comes from physical experience and the physical environment. One must also consider experience of language, and the structure of the linguistic environments in which speakers find themselves.

Young Children's Construction of Operational Definitions in Magnetism: the role of cognitive readiness and scaffolding the learning environment

Abstract

In this paper, we examine the importance of scaffolding the environment and the role of cognitive readiness in young childrens' construction of operational definitions in magnetism. We discuss various resource constraints and the conceptual background of preschoolers. Then we present an experimental study of 165 children aged 4-6 who took part in an extended structured intervention in which they were guided to construct two operational definitions of a magnet. The two definitions differed with regard to the cognitive demands imposed upon the children attempting to construct them. The construction of the second operational definition required cognitive abilities that the construction of the first did not. Our results demonstrate that children older than 5 years are mostly able to construct both definitions while younger children are able to construct only the first one. Based on this result, we discuss the issue of cognitive readiness and its role in learning. Additionally, by teaching one experimental group of older children the second definition directly and observing their limited success to construct it, we argue for the necessary role of scaffolding the conceptual structure of the curriculum materials to achieve learning.

Introduction

Real understanding of a concept is only demonstrated when children can construct operational definitions (McDermott, 1996). The reason may be that guiding children to formulate such definitions fosters the formation of explicit declarative knowledge, which benefits understanding of the concepts (Peters, et. al., 1999).

A child can be expected to understand those concepts for which the epistemologically prerequisite concepts are manageable and the necessary cognitive resources that will allow concept construction have been acquired. The set of these concepts cannot be determined *a priori* but only through empirical research.

A successful model of teaching should be designed with an eye to the limitations that constrain children's perception and interpretation of the world. It should also seek to take advantage of these limitations by scaffolding the learning environment in ways that enable children to explore their difficulties and to explicitly resolve them.

One of the concepts that have proven recalcitrant to successful teaching is that of magnets. Research (Barrow, 1987; Gagliari, 1981; Selman et. al., 1982) shows that preschoolers notice magnetic attraction but cannot spontaneously offer a successful definition of a magnet. It also shows that they find magnetic repulsion more difficult. Since repulsion is important in differentiating between magnets and non-magnetized ferrous materials, it is important that an understanding of magnets be based on the interactions between two magnets (Gagliari, 1981).

In this paper, we aim to examine the extent to which preschoolers (4-6 years of age) can successfully construct two operational definitions of a magnet. In the first part of the paper, we present the theoretical background regarding preschoolers' representation of the world and the constraints that shape it. We will discuss their intuitive theories of magnetism and will elaborate on the term "cognitive readiness", by which we mean a set of cognitive skills and resources at a given age.Then, we will present a school-based didactic intervention aiming to test whether preschoolers could successfully be taught two different operational definitions of a magnet. The first definition treated magnetism as a substantial property of some objects. The second definition requires that children understand magnetism as a relation between two objects. This, in turn requires, first, that children can combine information from two independent sources, and second, that they can coordinate causal schemes. In this sense, the second definition is cognitively more demanding than the first one. With this approach, we aim to explore the way in which children's cognitive readiness, or lack thereof, manifests itself in the construction of operational definitions of a magnet. Prior to and after the intervention we carried out individual interviews designed to evaluate the children's prior experience with magnets and their ability to apply each of the two definitions.

Theoretical Background

The cognitive basis of intuitive notions of magnetism

One of the basic traits of the preconceptual experiential background, is the tendency of children to believe that properties belong to objects and exist independently of interactions with other bodies. Thus they find it very difficult to comprehend physical

concepts that are relational and to represent processes among interacting bodies, such as, electrical or magnetic interactions, gravity or thermal transfer (Carey, 1986; Chi, 1993).

This trait may find its explanation in the fact that preschoolers encode and remember only categorical information (Demetriou *et. al.*, 1993; Fisher, 1980), and furthermore, that they fail to encode comparative or contrastive information. Thus, they systematically misrepresent data that contain comparative information (Thelen and Smith, 1994).

The concepts that are based upon our basic interaction with the world have a meaning constituent that is not conceptual but experiential in nature and upon which semantic content is subsequently progressively built. The experiential non-propositional meaning constituent is an image schema (Johnson, 1987). This intuitive, or primitive, meaning is so fundamental that it constitutes the "hard core" of some of our concepts. diSessa (1993) calls such meaning carriers "phenomenological primitives" and they are the main tools that render experience meaningful in the first instance. By virtue of the fact that they are grounded in experience, image schemata are very persistent. This explains the tremendous difficulties we encounter in our effort to revise an image shema, should it prove to be inconsistent with the corresponding scientific concepts. Examples of such schemata are the various image schemata of "force", and pertaining to the topic of this paper, the image of attraction.

In so far as magnetism is concerned, the image schema, or phenomenological primitive, of an attractive force gives rise to the "pulling model" (Erickson, 1994). According to this model the magnet is viewed as an object that has the capability to pull other objects, or, sticks to other objects (Barrow, 1987; Gagliari, 1981; Selman et. al., 1982). This conception of magnetism characterizes the intuitive conceptions of children up to the age of 10.

Children use a wide variety of causal explanations to account for phenomena, and seem to observe both domain-general and domain-specific causal principles. Among the domain general causal principles is the thesis that the causes must resemble their effect - "homeopathy" (Spinger and Keil 1991). With regard to magnetism, this means that it is difficult for young children to grasp a causal mechanism that can lead to disparate and often antithetical effects, as in the case of a magnet that can attract and repel objects. Demetriou et. al. (1993a) argue that children between the ages of 3 and 5 employ proto-causal schemes that allow them to differentiate causal from random sequences on the basis of the structure of events in space and time. Around the age of 5, children can coordinate the proto-causal schemes and search for causes by testing some hypothesis that can be formulated on the basis of the surface structure of the event.

Our discussion thus far reveals the cognitive basis of some of the difficulties that children have with respect to magnets. To recapitulate: (a) children view magnetism as a substantial property of some objects; (b) this property is conceived as the force magnets have in order to pull toward them, or "stick to", other objects; and (c) children find it difficult to understand the fact that a magnet can both attract and repel other objects.

Learning is conditioned upon the epistemological structure of the domain and the cognitive profile of the learner, including the resources that the learning system bears upon the task. Thus, it is important to identify these resources and examine their impact on learning.

Resource limitations and their role in learning

It is now well documented (Kemler 1983; Shepp 1978; Smith and Kemler, 1977) that in classification and discrimination tasks, younger children (up to around 4.5 years of age) tend to perform in a way which suggests that they perceive dimensional combinations as integral, and consequently base their decisions with respect to the classificatory or discriminatory tasks on the perception of the overall similarity of the presented stimuli. Older children classify or discriminate among objects by attending to, and analyzing, the dimensions of the stimuli. This allows them to perceive the embedded structure in the stimuli array. This ability is the decisive factor determining age differences with respect to performance. Further evidence (Gentner and Toupin, 1986; Vosniadou, 1987) suggests that the same maturational trend is attested in tasks of analogy, metaphor, and knowledge transfer.

Another resource limitation is the lack of capacity of children younger than 5 years to combine and integrate information from two independent sources (Halford and McDonald, 1977). They do not have what Piaget calls the capacity to perform logical multiplication. This capacity can influence children's construction of concepts whose definitions require the integration of information.

Resource limitations, far from being a hindrance to learning, render learning possible by scaffolding the environment and the information it feeds to the learning system (Elman, 1991; Raftopoulos, 1997). The key to success lies in effectively limiting the initial access of the cognizer to the full body of information, and in the gradual introduction of the system to the domain's full complexity. This "undersampling" of a complex domain gives the system the opportunity to learn first the domain's features and regularities, and eventually build on them the more complex features which will allow it to generalize.

This conforms with Clark and Thorton's (1997) account of learning, in which problems can be divided into two categories: those whose solution requires finding of the surface structure of the data, that is, first order regularities (type-1), and those whose solution requires finding the deep structure of the data, that is, the more abstract regularities, (type-2 problems). Problems

of type-1 can relatively easily be solved by means of an inductive search of the relevant problem space that can extract the basic statistical distributions in the data. Statistical procedure cannot be applied directly to type-2 problems. Thus, problems of type-2 could be solved if transformed to type-1 problems. This can be achieved by recoding and reorganizing the data so that they can render clear the underlying hidden structure. The first operational definition is a typical case of a type-1 problem. It requires that the children limit themselves to examining only information regarding the phenomenon of attraction between bodies. When the first definition is understood, the children "know" that those bodies that can attract others are to be categorized as magnets, all other factors becoming irrelevant to the problem. The property of "attraction" becomes the recoding schema on the basis of which they will attack the second definition, which is a type-2 problem. Once other factors have been eliminated, those children that have the appropriate cognitive readiness include information regarding mutual repulsion and eventually also understand the second operational definition. This is a clear case of undersampling the domain and scaffolding the environment.

In this part of the paper we have discussed certain characteristic developmental trends of preschool aged children, namely, the emergence of the ability to perform logical multiplication, the emergence of the ability to combine proto-causal schemes, and the emergence of the ability to discover embedded structure in an array and go beyond surface similarities. There is also evidence that all these skills appear around the age of 5. Thus, around the age of 5 preschoolers acquire skills that enhance their comprehension of the surrounding world. We will say that these children acquire a "cognitive readiness".

In the next section, we will present an experimental study that was designed in the light of the preceding theoretical framework and aimed to examine the way preschoolers can be quided to comprehend magnetism, by constructing operational definitions of a magnet.

The Experimental Study

The research questions of our study are the following:

(a) can preschoolers learn successfully to construct operational definitions of magnetism?
(b) can preschoolers construct a relational operational definition based on mutual attractions and repulsions, overcoming persistent epistemological obstacles?
(c) is effective scaffolding of the learning environment a necessary condition for preschoolers to construct the second, more complex, operational definition?

Children Participants

The sample included 165 children ranging in age from 3 years and 11 months to 5 years and 7 months (sample mean 4 years and 10 months and standard deviation 6 months). The children attended three kindergartens in a small city and were distributed in six different classrooms. All teachers underwent training in content knowledge, and curriculum implementation procedures.

Description of the teaching intervention

In our intervention, we explicitly encourage children to use evidence (particularly their own observations) to always support their viewpoints. The curriculum materials are very detailed in offering guidance to the teachers as to how to create an environment where children are encouraged to express themselves and every opinion is valued. Some aspects of the curriculum, such as guiding children to classify objects according to material, are not trivial and the activity sequence required many trials before it could be refined to a version that was deemed effective. The unit includes 6 sequential lessons as follows:

1. Exploring magnets
2. Metals and non-metals
3. Are all metals attracted by a magnet?
4. How can I tell if something is a magnet?
5. Magnets with other magnets
6. Is there another way to tell if something is a magnet?

Our interest was in investigating children's ability to construct and apply consistently operational definitions uniquely distinguishing a magnet from other objects. The curriculum guided children to formulate the following operational definitions:

I. Find two objects that do not attract each other. Does your object attract both of them? If yes, then it is a magnet. If not, then try with other objects. (Lesson 4)

II. Find two objects that when approached in some orientation they attract each other AND when approached in another orientation they repel each other. Both of these objects are magnets. (Lesson 6)

The words attraction, orientation and repulsion were usually avoided by the children. Instead they would typically use the words pull, another way, and push, respectively.

Data Collection

The data was collected through individual interviews prior to the intervention, at the end of lesson 4 (Operational Definition I) and in the two weeks following lesson 6 (Operational Definition II).

Task 1: Pretest Interviews

In our initial (pre-test) evaluation, each child was given a bowl with ten objects including 3 magnets and was asked to group them on the basis of interactions between objects. Children were encouraged to settle on one best classification and this was recorded, both photographically and in note form, at the end of the interview. Each classification was then coded based on the criterion that the child seemed to employ.

Task 2: Operational Definition I

In this task, children were presented with a group of 10 objects each of which was hidden in a matchbox wrapped in white paper and sealed with cellotape. This group of hidden objects included only one magnet. Children were explicitly told this and were then asked to give directions to the interviewer so that s/he could identify the magnet. The interviewer acted out the directions so that the child could see the result. All interviews were audiotaped. Children's responses were then coded as a success or a failure based on whether they could provide directions so that the interviewer could apply Operational Definition I consistently.

A set of directions was graded as successful only if it specified all of the following three items:

a) Finding two objects at random that attracted each other,
b) Testing each of the objects repeatedly with a third object;
c) Rejecting one of the two objects that was found not to interact with a third object interacting with the other of the initial two.

Operational Definition II

In this second task, children were presented with a set of 10 identically looking objects wrapped in the same manner as in the first task. They were explicitly told that the objects included two magnets this time and they were asked to give directions to find both magnets in one go. The interviewer again acted out the directions so that the child could see the result. Some children spontaneously resorted to applying operational definition I. When this happened the interviewer clarified once that they were to give one set of directions so that both magnets could be found simultaneously. A response was graded as successful only if it specified all of the following three items:

a) Finding two objects at random that attracted each other,
b) Testing different orientations of the two objects to see of they also repelled
c) Rejecting one object at a time until two objects were found that both attracted and repelled.

Any response that did not include anyone of these items was deemed unsuccessful.

Results

Pre-test interviews

Table 1 presents the results from children's responses in the initial interviews. Many noticed the magnets but ignored them in their groupings. 47 children did not recognize the magnets in their bowls. Most of the groupings were on the basis of colour, shape, heaviness or more than one of these criteria were used simultaneously. The responses of 32 children could not be categorized unambiguously and the criterion is listed as "unidentified".

Table 1: Criteria used by children (N=165) to classify objects in their initial pre-test interviews

Criterion	Number of children
Magnetic attraction	11
Shape	26
Color	32
Heaviness	19
Texture	9
Material	7
Mixed	29
Unidentified	32

118 children appeared to recognize the magnets in their bowls. This number gives an indication of how many of these children remembered having seen a magnet prior to the start of our intervention. Only 11 children noticed that there was a magnet among their objects *and* used it in any way to influence their grouping. This number provides an upper bound on the number of children who may have been able to give an acceptable form of Operational Definition I prior to the intervention. Both, these 11 children and the 32 children who used unidentified criteria were distributed roughly evenly in the 6 classrooms.

Operational Definition Tasks

The total number of children participants is N=165. The number of children who received the whole treatment (lessons 1-6) is N=136. 90.4% (N=123) of these children performed successfully on the Operational Definition I task. Only 47.8% (N=65) of these performed successfully on the Operational Definition II task. Another class of children (N=29) were only examined for Operational Definition II. The success rate for this class was 41.4%.

In order to test the hypothesis on cognitive readiness, we decided to separate the children into three different age groups. Based on our hypothesis we would expect children older than five to perform significantly better on Operational Definition II than children aged below 5. Table 2 presents the children's performance in the two operational definition tasks as a function of age (N=136). The children are divided into three groups according to age (below 4 and 6 months, above 5 and in between). The percentage of children who perform successfully on Operational Definition I is very high. This seems to suggest that after appropriate intervention virtually all children in this age range are able to construct Operational Definition I. Operational Definition II has a substantially lower success rate for every age group. Operational Definition II also demonstrates a strong dependence on age. Only 14.3% below age 4 and 6 months perform successfully. In contrast, 85.4% of children above age 5 are able to consistently construct Operational Definition II.

Table 2: Children's performance on Operational Definitions I and II for different age groups

Group Age Range	N (N_t=136)	Mean Age (yr:mos)	Stand. Devn (mos)	Success rate Opernal Defn I	Success rate Opernal Defn II
> 5	41	5:4	2	95.1%	85.4%
4.5 - 5	46	4:8	2	97.8%	50.0%
< 4.5	49	4:3	2	79.6%	14.3%

We performed a χ^2 test for Operational Definition I: $\chi^2(2) = 10.6$, $p<005$ (Cramer's coefficient $\phi=0.28$, $p<.01$, N=136). This result indicates that children's performance on Operational Definition I statistically depends on age. The test with Operational Definition II gave the following result: $\chi^2(2)=45.3$, $p<.000$ (Cramer's coefficient $\phi=0.58$, $p<.005$, N=136). The Cramer coefficient indicates that performance on Operational Definition I is only weakly associated with age. In contrast, performance on Operational Definition II and age show a moderate to strong association. The difference between these two Cramer coefficients is statistically significant (t=3.44. p<.001) (Howell, 1997).

Relative Demands of Operational Definitions I and II.

Table 3 shows the number of children that succeeded or failed in either of the two operational definition tasks. Only 9% (N=12) of the children failed both tasks. Forty-seven percent (N=64) of the children succeeded on both tasks. These values testify to the effectiveness of the teaching intervention. Forty-three percent (N=59) of the children succeeded in Operational Definition I and failed in II. In contrast, only 1 child succeeded in Operational Definition II and failed in I. These findings support the sequencing of our curriculum by indicating that Operational Definition II (Lesson 6) is more demanding than Operational Definition I (Lesson 4).

Table 3: Children's performance on Operational Definitions

	Operational Definition I	
Operational Definition II	Failure	Success
Failure	12	59
Success	1	64

To confirm this finding we carried out McNemar's test for the significance of change on the sample of children that were taught all 6 lessons (N=136): $\chi^2(1)=54.2$, p=.000. The result clearly confirms that Operational Definition II is significantly more difficult than Operational Definition I.

Tables 2 and 3 do not include the performance of children in class 5 because this class received the modified intervention (lessons 1-3, 5, 6) and was only tested for Operational Definition II. Class 5 and the group of children listed in Table 2 with age higher than 5 years have very similar average ages. The t-test between these two groups shows that the difference in mean age is not statistically significant. In other words, class 5 is matched to the group of older children in Table 2 in age ($t(38)=-0.6$, $p>.5$). Only 41.3% of the children in class 5 performed successfully in Operational Definition II. In comparison with 85.4% success rate for the older children in Table 2, this is appreciably lower. The children in class 5 performed closer to the 4.5–5 year olds rather than the >5 year olds. The χ^2 test for Operational Definition II ($\chi^2(1)=13.8$, $p<.005$) indicates that there is a statistically significant difference in the performance of class 5 and the older group of children who received the complete intervention. Not teaching lesson 4 and Operational Definition I seems to have influenced these children's performance on Operational Definition II significantly. This would indicate that to some extent Operational Definition I (and lesson 4) functions as a conceptual pre-requisite to successful performance on the Operational Definition II task.

Discussion

It is evident that even though the children across all ages could not initially categorize magnets, the appropriate didactic intervention led them to construct the first operational definition. Our study shows that 79.6% of the first age group, 97.8% of the second age group, and 95.1% of the third group succeeded in constructing the first operational definition.

The nature of the first definition explains the success rate across all ages. Some objects attract others, whereas some other objects do not. Attraction was the only factor to be taken into account. The definition could be constructed by using information from one source only and did not clash with children's conception of magnetism as a substantial property and with their view of causality as an homeopathy. Additionally, it was consistent with the image schema of attracting force and the pulling model.

Only 14.3% of the first group could construct Operational Definition II. In contrast, fifty percent of the second group and 85.4% of the third group succeed in the task. Thus, only children older than 5 years of age succeed. Almost all younger children fail.

In the second definition, some objects sometimes attract and sometimes repel other objects. In this case, there are two factors to be taken into account and the information must be combined for successful categorization. Thus, children who cannot perform logical multiplication are unable to understand it. Magnetism is seen, now, as the result of an interaction between bodies and not necessarily as a property that an object may have by itself. This is a second reason that makes it more difficult for the younger children to succeed. The phenomenon of repulsion further complicates matters. Homeopathy seems to be violated, since the same object can attract and repel other objects. The causal patterns that can explain the phenomenon become more complex.

Children over 5 years of age, having mostly acquired the skill of logical multiplication and being able to coordinate causal schemes, can benefit from instruction and are ready to construct the second definition. We do not claim that the children who succeed, understand the relational nature of magnetism. The fact still remains that a necessary step toward accomplishing this has been undertaken that will allow them to overcome the epistemological obstacle of conceiving all physical properties as substantial properties of matter.

We have elaborated on the crucial issue of scaffolding the learning environment, and argued that successful learning requires that the learner does not process the full complexity of the problem from the beginning. The learning system has the opportunity to learn first the domain's basic features and regularities. These provide the learning system with a code that will allow it to recode the information pertaining to the complex problem.

Children who are cognitively ready (older than 5 years of age) and have been trained with appropriately scaffolded material are expected to exhibit a markedly different performance pattern. To test this, we bypassed lesson four and the first operational definition with a group of 29 students, proceeding directly to the second operational definition. The study shows that only 41,4% succeeded in constructing the second definition, in comparison with 85.4% of the preschoolers of the same age (the third group). Our study, thus, confirms the decisive role of diminishing the cognitive load that the learner initially faces.

Testing a computational model of categorisation and category combination: Identifying disease categories and new disease combinations

Fintan Costello (fintan@compapp.dcu.ie)
School of Computer Applications, Dublin City University,
Glasnevin, Dublin 9, Ireland.

Abstract

The diagnostic evidence model gives a computational account of how people classify items in single categories and in category combinations (complex categories formed by combining two or more single categories). This model sets out to explain generativity in category combination (the fact that people can classify items in new category combinations even if they have never seen any examples of those combinations). The model also aims to explain context effects such as overextension in category combination. In an experiment people learned to identify imaginary diseases from artificially-constructed patient descriptions, and then classified new patient descriptions into combinations of those disease categories. The model accurately predicted people's classification scores for patient descriptions in these disease combinations, requiring no free parameters to fit the experimental data. The experiment showed that both generativity and overextension can occur in combinations of artificially-constructed disease categories, and confirmed the model's predictions about when overextension and generativity will occur.

Introduction

The ability to combine mental representations is a basic part of human cognition. For example, to understand a combined phrase such as *pet fish* we must somehow combine our representations of the constituent categories *pet* and *fish*. Category combination is generative: we can understand a new combined phrase such as *pet lobster*, even though we may never have seen an example of a *pet lobster* before. Generativity is important because it allows us to think new thoughts, understand new expressions, and respond to new situations. However, generativity poses a problem for theories of classification in which an item's membership in a category is proportional to its similarity to previously seen exemplars of that category (e.g. the Context theory; Medin & Schaffer, 1978). Since no previously-seen exemplar is available for combined categories such as *pet lobster*, membership in such a category cannot be computed by exemplar similarity (Rips, 1995). While such theories give a good account for classification in single categories, they do not extend well to category combination.

Context effects such as overextension occur reliably in category combination. These effects also pose a problem for current theories of classification. Overextension occurs when people classify an item as a poor member of a constituent category of a combination, but as a good member of the combination as a whole; for example, when people rate goldfish as poor members of the single categories *pet* and *fish*, but as highly typical members of the conjunction *pet fish* (Hampton, 1988). Overextension shows that an item's category membership can change depending on the context in which classification occurs: being poor if the category occurs singly, but good if it occurs as part of a combination. For theories in which classification is based on fixed rules for category membership (e.g. Nosofsky, Palmeri, & McKinley, 1994), these changes in membership are difficult to explain. While such theories apply well to classification in single categories, the do not extend to category combination.

This paper describes a computational model which explains classification in both single and combined categories. This model, called the diagnostic evidence model, also explains generativity and overextension in category combination. This paper also describes an experiment investigating classification, category combination, generativity and overextension in artificial laboratory-learned categories. In this experiment people learned to identify imaginary diseases from artificially-constructed patient descriptions, and then classified new patient descriptions into combinations of those disease categories. Both generativity and overextension occurred reliably in these combinations of artificial categories. The model accurately predicted people's classification scores for patient descriptions in these disease combinations, requiring no free parameters to fit the data. The patterns of overextension and generativity in the experiment closely matched those predicted by the model.

The Diagnostic Evidence Model

The diagnostic evidence model is an extension of a model originally developed to explain how people interpret novel noun-noun phrases (Costello & Keane, 1997, 2000, 2001). The model aims to explain classification in both single categories (see Costello, 2000) and category combinations. The model assumes that people represent categories by storing sets of category members in memory. From these sets, diagnostic attributes for categories are computed: these attributes serve to identify new category members. An item's classification in a single or combined category is a function of the diagnosticity of its attributes for that

category or for the constituent categories of that combination. An item has a high classification score in a category if it has diagnostic attributes of that category. An item has a high score in a combination if it has some attributes diagnostic for one constituent of the combination, and others diagnostic for the other.

Attribute Diagnosticity

Diagnostic attributes are attributes which occur frequently in members of a category, but rarely in that category's contrast set (the set of non-members of that category). These attributes serve to identify members of a category: a new item having an attribute which is diagnostic for a category is likely to be a member of that category. Equation 1 defines the diagnosticity of an attribute x for a category C. Let K be C's contrast set. Let j_X be 1 if an item j has attribute x, and 0 otherwise. $D(x|C|K)$, the diagnosticity of x for C relative to K, is equal to the number of members in C which have attribute x, divided by the total size of C plus the number of items in K which have x:

$$D(x \mid C \mid K) = \frac{\sum_{j \in C} j_x}{|C| + \sum_{j \in K} j_x} \quad (1)$$

If the attribute x occurs in all items in C, but no items in C's contrast set, then x is fully diagnostic for C ($D(x|C|K) = 1$). Such an attribute is a perfect guide to membership of C: a new item having that attribute is most likely a member of C. An attribute which does not occur in all members of C, or which occurs in some members of C's contrast set, will be less diagnostic for the category. Such an attribute will be a poorer guide to membership of C: a new item with that attribute is less certain to be a category member.

Diagnosticity changes in combination

The contrast set is important in computation of attribute diagnosticity: the fewer occurrences of an attribute in the contrast set for a category or combination, higher its diagnosticity will be. The contrast set for a single category consists of all items which are not members of that category. The contrast set for a combined category, however, consists of all items that are not members of any constituent of the combination. This change in contrast set means some attributes that are not diagnostic for a category occurring singly can be diagnostic for that category in a combination. This change in diagnosticity is the basis for overextension in category combination.

Table 1 shows 10 stored members of categories such as *pet* and *fish*, described on 4 dimensions. Computation of attribute diagnosticity can be illustrated using this set of stored category members. Consider the diagnosticity of the attribute <found:house> for the category *fish*. <found:house> occurs in 2 of the 4 members of *fish* in Table 1, and occurs 4 times in the

Table 1. Example items: 10 stored category members.

Item	Categories		Item Attributes			
			FOUND	KEPT	COLOR	PARTS
1		lobster	sea	------	pink	claws
2		lobster	aquarium	tank	pink	claws
3	fish	goldfish	house	tank	gold	scales
4	fish	guppy	house	tank	silver	skin
5	fish	salmon	sea	------	silver	scales
6	fish	shark	sea	------	silver	skin
7	pet	spaniel	house	basket	brown	tail
8	pet	pitbull	house	kennel	black	tail
9	pet	bulldog	house	basket	brown	-----
10	pet	terrapin	house	tank	green	skin

contrast set K_{fish} (the set of items which are not members of the category *fish*). The diagnosticity of <found:house> for *fish* is

$$D(found:house \mid fish \mid K_{fish}) = \frac{2}{4+4} = 0.25 \quad (2)$$

This attribute has a low diagnosticity for the single category *fish*: <found:house> does not identify members of category *fish* well. In the context of the combination *pet fish*, however, the attribute has a higher degree of diagnosticity for *fish*. $K_{petfish}$, the contrast set for the combination *pet fish*, consists of items that are members neither of *pet* nor of *fish* (items 1 and 2 only). <found:house> does not occur in any items in $K_{petfish}$. The diagnosticity of <found:house> for *fish* relative to the contrast set $K_{petfish}$ is thus

$$D(found:house \mid fish \mid K_{petfish}) = \frac{2}{4+0} = 0.5 \quad (3)$$

Attribute <found:house> is thus more diagnostic for *pet fish* than for *fish* alone. Given this, the diagnostic evidence model would predict overextension for the combination *pet fish:* an item such as *goldfish*, which possessed the attribute <found:house>, could be classified as an untypical *fish*, but as a typical *pet fish*.

A logic for evidence

Diagnostic attributes give evidence for an item's classification in a category. Items usually contain a number of different attributes, however, which may be more or less diagnostic for the category in question, or diagnostic for other categories. The diagnostic evidence model uses a continuous-valued logic to combine the diagnosticity of multiple attributes. This logic assumes continuous variables with values between 0 and 1, and uses the logical operations

$$NOT\ A = 1 - A \quad (4)$$

$$A\ AND\ B = AB \quad (5)$$

$$A\ OR\ B = 1-(1-A)(1-B) \quad (6)$$

These equations can be justified by considering the operations *AND*, *OR*, and *NOT* for samples of independent variables. Suppose A is true in 75% of samples, and B

is true in 50% of samples. Then the probability of *NOT A* being true is *0.25 (1-0.75)*. The probability of *A AND B* being true is *0.375 (0.75 x 0.5)*: *A* is true in 75% of samples, *B* is true in 50% of those. Finally, the probability of *A OR B* being true is *0.875 (1-(1-0.75) x (1-0.5))*: *A* is false in 25% of samples, *B* is false in 50% of those, and thus *A OR B* is true in 87.5% of samples.

Combining attribute diagnosticities

To compute an item's overall evidence for membership in a category, the diagnosticity of the item's attribute are combined using the equation for *OR* (Equation 6). An item *i* with a set of attributes x_1, x_2, x_3 will be a member of category *C* if x_1 *OR* x_2 *OR* x_3 is diagnostic for C. This is formalised in Equation 7. Let *A* be the set of attributes of item *i* and let *D(x|C|K)* be the diagnosticity of attribute *x* for *C*. Then *E(i|C|K)*, the overall evidence for classifying item *i* as a member of *C*, is

$$E(i \mid C \mid K) = 1 - \prod_{x \in A} (1 - D(x \mid C \mid K)) \qquad (7)$$

If an attribute *x* strictly defines a category *C* (occurs in all members of *C* and never occurs outside *C*), then *x* is perfectly diagnostic of *C (D(x|C|K) = 1)*. If any item *i* possesses attribute *x* , then by Equation 7 *E(i|C|K)* will be 1, and the item *i* will definitely be a member of category *C*. In categories which have no single defining attribute but rather a range of attributes of medium diagnosticity, Equation 7 combines evidence from different attributes in computing evidence for category membership: the more diagnostic attributes the item has, the higher its degree of membership will be. This fits with the observed family resemblance structure of natural categories (Rosch, 1978). The relationship between diagnosticity and membership is supported by Rosch & Mervis' (1975) finding that people's judgements of an item's typicality in a category rises with the number of the item's diagnostic attributes.

Diagnostic evidence in combinations

In the diagnostic evidence model, an item will be a member of a combined category if it gives evidence for membership in each constituent category in that combination: if it has some attributes diagnostic for one constituent of the category, and other attributes diagnostic for the other. In computing an item's membership in a combined category, the model uses the equation for *AND* to combine the item's evidence for membership in each constituent. An item *i* will be classified as member of a combined category $C_1 \ldots C_N$ if it gives evidence for membership in C_1 *AND* evidence for membership in C_2 *AND* evidence for membership in C_3 and so on. Formally, *E(i|C1...CN|K1...N),* the evidence for classifying *i* as a member of $C_1 \ldots C_N$, is

$$E(i \mid C_1 \ldots C_N \mid K_{1\ldots N}) = \prod_{n=1\ldots N} E(i \mid C_n \mid K_{1\ldots N}) \qquad (8)$$

Table 2. Classification of the item *goldfish* in single categories *pet* and *fish* and combination *pet fish.*

Evidence for membership in		Attribute Diagnosticity			
		FOUND house	KEPT tank	COLOR golden	PART scales
pet singly :	**0.7**	0.7	0.1	0.0	0.0
fish singly:	**0.8**	0.2	0.3	0.2	0.5
***pet fish*:**					
constituent *pet*	**1**	1.0	0.2	0.0	0.0
constituent *fish*	**0.9**	0.5	0.4	0.2	0.5
Pet fish overall:	**0.9**				

where the contrast set $K_{1\ldots N}$ is the set of items not in any category $C_1 \ldots C_N$. In this equation an item *i* gives evidence for membership in each constituent of a combination if it has attributes diagnostic for each. Note that, in computing the evidence for membership in each constituent category (r.h.s. in Equation 8), the contrast set for the combination as a whole is used. In computing membership in those categories occurring singly, their single contrast sets would be used.

Table 2 illustrates the diagnostic evidence model by showing the computed membership for the item *goldfish*, which has attributes <found:house>, <kept:tank> <color:golden> and <part:scales>, in the single categories *pet* and *fish* and in the combination *pet fish*. The diagnosticity of the item's attributes for single categories and for constituents of the combination are listed in columns under those attributes. The item's membership scores in the single categories and the constituents of the combination are computed from those diagnosticities (shown in bold, to the left of those diagnosticities). At the bottom of Table 2 is the item's overall membership score in the combination (obtained by multiplying its constituent membership scores).

Explaining overextension and generativity

In the diagnostic evidence model, overextension arises if some attributes have low diagnosticity for a single category but high diagnosticity for that category in a combination. Table 2 illustrates this overextension. The item in Table 2 has a higher overall membership score in the combination *pet fish* than in the categories *pet* or *fish* presented singly, because the item's attributes are more diagnostic for the combination than for the single categories. For example, <found:house> has lower diagnosticity for the single category *fish*, but higher diagnosticity in context of the combination *pet fish* (it occurred often in the contrast set for the single category *fish*, but not in the contrast set for *pet fish*). The model thus predicts overextension for that item.

The diagnostic evidence model gives a generative account of category combination, in which an item can be classified in a new combination even if no previous examples of that combination have been seen. An item

Table 3. Training materials for learning diseases.

Training Item	Item features D1	D2	D3	Member of Category or Combination
1	A	X	C	*A*
2	A	Y	Y	*A*
3	A	A	X	*A*
4	Y	A	Y	*A*
5	X	A	B	*A&B*
6	A	B	X	*A&B*
7	Z	B	B	*B*
8	X	B	B	*B*
9	Y	X	B	*B*
10	Z	Y	B	*B*
11	C	A	Y	*C*
12	C	X	B	*C*
13	C	Y	C	*C*
14	C	A	C	*C*
15	C	X	C	*C*
16	X	Y	C	*C*

is classified in such a combination if it has diagnostic attributes for each constituent category in the combination: some attributes diagnostic for one constituent, other attributes diagnostic for the other. For example, in Table 1, there are no stored members of the combination *pet lobster*. However, an item could be classified as a good member of the combination *pet lobster* if it possessed the attributes <has-part:claws> (diagnostic for *lobster* in Table 1) and <found:house> (diagnostic for *pet*). The model thus predicts generativity for that combination. The next section describes an experiment testing the diagnostic evidence model's predictions about classification, overextension, and generativity in category combination. This experiment uses artificial categories in the domain of disease diagnosis.

Disease Diagnosis: An Experiment

Most experiments investigating category combination examine how natural-language categories are combined. The current experiment examines category combination with artificial, laboratory-generated categories representing imaginary diseases. In this experiment, every subject was given a set of 16 patient descriptions (16 training items), each with 3 symptoms and each having a given disease or disease combination. The abstract distribution of symptoms in training items was identical for all subjects, and is shown in Table 3. The training materials used ill-defined categories: no symptom perfectly indicated any disease. In the training phase of the experiment, subjects used these training items to learn to identify diseases. In the transfer phase subjects were given new patient descriptions (transfer items) and asked, for each disease and each possible disease combination, to indicate whether the new item was a member of that disease category or disease combination.

Method

Subjects. 19 Dublin City University undergraduates.
Materials. Each subject received a set of 16 patient-description cards (training items) with the abstract structure shown in Table 3. In these, abstract attribute A (on any dimension) is most diagnostic for category *A*, attribute B for category *B*, and C for category *C*. Each subject received a different set of patient descriptions, generated via a unique mapping from abstract attributes to concrete symptoms. For example, for one subject, attribute <A> on dimension D1 became symptom *eyes:puffy*; <A> on D2 became *skin:flaking*, and <A> on D3 became *mucles:taut*. For other subjects the attributes were mapped to different symptoms.

Procedure. In the training phrase subjects spent 15 minutes learning to identify diseases by studying their 16 patient-description cards. Subjects were then shown, in random order, patient descriptions with the same symptoms as those they had learned, but sometimes with incorrect diagnoses. Subjects indicated whether diagnoses were correct and incorrect. If a subject got a diagnosis wrong, they were shown the correct answer. The transfer phase of the experiment examined subjects classification of 5 new patient descriptions (the transfer items). Table 4 gives abstract representations for these items. Each subject's transfer items were formed by applying their attribute-to-symptom mapping to this representation. Each item was presented 6 times, each time with a different single or combined category. Subjects rated the given item as a member or non-member of the given category or combination, using a –10 to +10 rating scale, with a positive rating indicating membership and a negative rating non-membership.

Results

Analysis of subject's performance in the training phase showed that most had no problem in classifying items. One subject got most of the training-phase test classifications wrong and was excluded from analysis.
The 2nd-last column in Table 4 ('classification probability: observed') shows the observed probability (proportion) of subjects rating each transfer item as a member of the given combination. (For space reasons the corresponding data for single categories are not shown.) For example, the observed probability of transfer item <ABY> being classified in combination *A&B* was 0.5: 50% of subjects rated that item as a member of that combination.
The data in Table 4 shows that subjects responded consistently to items. For example, there were some items which had high observed classification probabilities for particular combinations, indicating that many subjects agreed that those items did belong in

Table 4. Observed and predicted classification of the 5 transfer items in 3 different category combinations.

Item			Combination	Classification probability	
D1	D2	D3		Observed	Predicted
A	B	Y	A&B	0.50	0.47
A	B	Y	A&C	0.11	0.13
A	B	Y	B&C	0.11	0.07
C	Y	B	A&B	0.06	0.19
C	Y	B	A&C	0.28	0.21
C	Y	B	B&C	0.72	0.77
Y	A	C	A&B	0.22	0.14
Y	A	C	A&C	0.50	0.50
Y	A	C	B&C	0.17	0.17
X	B	C	A&B	0.28	0.23
X	B	C	A&C	0.17	0.27
X	B	C	B&C	0.39	0.42
X	X	B	A&B	0.28	0.29
X	X	B	A&C	0.11	0.15
X	X	B	B&C	0.39	0.45

those combinations. For example, 72% (0.72 observed classification probability) of participants identified item <CYB> as a member of combination *B&C*: most subjects agreed in classifying that item as a member of that combination. Conversely, a number of items had very low observed classification probabilities for particular combinations, indicating that a large proportion of subjects agreed that those items did not belong in those combinations. For example, only 6% (0.06 observed classification probability) of participants classified item <CYB> as a member of combination *A&B*. The remaining 94% of participants indicated that the item did not belong in that combination. Because each subject's patient descriptions used a unique mapping from abstract attributes to symptoms, this consistency depended only on the distribution of those symptoms in the learned categories.

Model fit. To apply the diagnostic evidence model to the experimental materials, the equations described earlier were used to compute the classification score for each of the transfer items in Table 4 in every possible single and combined disease category. The diagnosticity of each item's attributes for each category was computed from the distribution of those attributes in the training items shown in Table 3. The last column in Table 4 ('classification probability: predicted') shows computed classification scores for each item in each combined category. These computed scores were compared with the observed probability with which people classified the items as members of each combination. There was a strong correlation between the predicted and observed classification scores for the combined categories (r=.95, p <.01, *%var*=.9). Comparing predicted and observed classification scores for items across all single and all combined categories also showed a significant correlation (r=.85, p <.01, *%var*=.73). No free parameters were used to fit the model's classification scores to the experimental data.

Table 5. The 6 item-combination-constituent triplets for which overextension occurred or was predicted.

Item	Combination	Constituent	Overextension	
			Observed	Predicted
A B Y	*A&C*	*C*	Yes (0.50)	Yes
C Y B	*A&C*	*A*	Yes (0.56)	Yes
C Y B	*B&C*	*B*	Yes (0.67)	Yes
Y A C	*A&C*	*C*	Yes (0.56)	**No**
X X B	*A&B*	*A*	**No** (0.41)	Yes
X X B	*B&C*	*C*	Yes (0.61)	Yes

Generativity. The generativity of category combination was examined by comparing the classification of transfer items in the combinations *A&B*, *A&C*, and *B&C*. In the training phase, subjects saw examples of the combination *A&B* but not of the other combinations. If combination is not generative, participants will only be able to identify items as members of the previously-seen combination *A&B*, but not as members of the other two combinations. Table 3 shows that 72% of participants classified the item <CYB> as a member of the previously-unseen combination *B&C*. More participants classified the item in that new combination than classified the item <ABX> in the previously-seen combination *A&B*. There was no significant difference between the number of items classified in the previously-seen combination *A&B* and in the other, new combinations. This supports a generative view of category combination.

Overextension. The occurrence of overextension in the experimental data was analysed at the individual subject level. Overextension was taken to have occurred every time an individual subject gave a particular transfer item a higher score as a member of a combined category than they gave that item as a member of one of the constituent categories of that combination. For example, if a given subject gave the transfer item <ABY> a high classification score as a member of *A&C*, but the same subject gave <ABY> a lower classification score as a member of *C*, that would be taken as a case of overextension (an overextension response). In the experiment there were 5 different transfer items, each of which was classified in 3 different category combinations (*A&B*, *A&C*, *B&C*), where each combination had two different constituent categories. There were thus 30 possible cases in which overextension could arise. Out of those 30 cases, there were 5 in which 50% or more subjects produced overextension responses. Table 5 shows all item-combination-constituent triplets for which overextension

either occurred in the experiment or was predicted by the model. The 5 cases with at least 50% overextension responses in the experiment are indicated in Table 5 by a "Yes" in the 2nd-last column (with the proportion of overextension responses for each case). For these cases, at least 50% of subjects rated the given item as a better member of the given combination than of the given constituent category presented singly. In a significant number of cases subjects rated the given item as a member of the combination, but as a non-member of the constituent category. For example, 44% of subjects rated the item <CYB> as a member of the combination *B&C*, but the same subjects rated that item as a non-member of the constituent category *B*. These cases show that overextension occurs reliably even for artificial categories. (Order of presentation had no reliable influence on overextension in these cases.)

To analyse the model's predictions about overextension, the model's computed classification scores for all transfer items in all category combinations were compared with the scores for those items in the constituents presented singly. If an item had a higher classification score in a combination than in one of its constituent categories presented singly, the model predicted overextension for that item. Again, there were 30 cases in which overextension could happen: out of those 30 cases, the model predicted overextension in only 5 cases. These are indicated by a "Yes" in the last column in Table 5. Of the 5 cases in which overextension occurred in the experiment, 4 were cases in which overextension was predicted by the model. Of the remaining 25 cases in which overextension was not observed, 24 were cases in which the model predicted overextension would *not* occur. The model accurately predicted the occurrence and non-occurrence of overextension in these materials.

Discussion and Conclusions

The results obtained in the above experiment are important for a number of reasons. They show that both overextension and generativity occur even for combinations of artificial laboratory-learned categories. Previous research has investigated these factors in natural-language category combinations alone. They show that the patterns of overextension and generativity seen in the experiment have a close quantitative match with those predicted by the diagnostic evidence model. Other models give a looser qualitative account of overextension and generativity. Finally, these results show that the diagnostic evidence model accurately predicts people's classification of items in both single categories and category combinations, needing no free parameters to fit the data. Other models typically apply either to single categories or to category combination, but not to both. These models typically require a number of free parameters to fit the relevant data.

The diagnostic evidence model, in accounting accurately for the results of the above experiment, represents an advance on other current theories of classification. However, there are results which the model cannot currently explain. For example, studies show that people can learn correlations between pairs of attributes and use those correlations in classification (Medin, Altom, Edelson, & Freko, 1982). The diagnostic evidence model, because it has no mechanism for learning correlations between attributes, cannot account for these results. In future work the model will be extended to learn attribute correlations by forming new "composite" attributes, and to use those attributes in classification. This may allow the model account for these findings.

Exploring Neuronal Plasticity: Language Development in Pediatric Hemispherectomies

Stella de Bode (sdebode@ucla.edu)

Susan Curtiss (scurtiss@ucla.edu)
UCLA, Department of Linguistics; 405 Hilgard Ave
Los Angeles, CA 90095

Abstract

We investigated the categories of neural plasticity and the genesis of the neural representation for language in population of 43 pediatric hemispherectomies. We have chosen to correlate language outcomes with the stages of neuronal plasticity rather than age at insult because of the unavoidable confound between the latter and etiology (Curtiss and de Bode, submitted). We argue that by examining the neural substrate for language and language outcomes post-hemispherectomy, it is possible a) to investigate the progression of neural representation from pluripotential and distributed to localized and specialized and b) to accurately predict language outcomes.

Introduction and Rationale

It is still unclear whether neural systems underlying adult organization for language crucially differ from their respective counterparts in the young brain. Though the assumption of complete and rapid recovery of children after brain lesions has been abandoned by the majority of researchers, there is no question that the rate and extent of reorganization in children differ from adults recovering from similar insults. The two most obvious hypotheses explaining this phenomenon make two different sets of assumptions. First, it is possible that language representation in a young brain is not identical to its adult counterpart. Indeed, more diffuse brain organization of the immature brain is suggested both by recent brain imaging studies and language acquisition research in clinical and normal populations (Dapretto, Woods, & Bookheimer, 2000; Mills, Coffey-Corina, & Neville, 1993; Papanicolaou, DiScenna, Gillespie, & Aram, 1990). Under this hypothesis faster recovery rates in children may be explained by the fact that functional localization and cortical commitment have not yet reached their peak, i.e. their adult pattern. An alternative explanation does not need to assume brain organization that is different from adults. Empirical support for this hypothesis is provided by investigations of childhood acquired aphasia. This research indicates the presence of adult-like neural representation for language and similar consequencies of brain damage in children and adults (Paquier & Van Dongen, 1998). Thus it is possible that more efficient reorganization is achieved due to neural plasticity of a young brain, in other words, with the help of the same mechanisms that are already in place guiding and supporting brain maturation in the first decade of life.

The two accounts need not be mutually exclusive. It is possible that what seems like wider functional distribution is, in fact, the reflection of both exuberant neuronal connectivity and increased neuronal excitation characteristic of an immature brain. This suggestion is supported by the findings of some recent brain imaging studies. Dapretto et al. (2000) demonstrated that both phonological and semantic conditions activated similar though not completely identical areas in adults and children. Furthermore, cortical areas activated only by specific linguistic tasks in adults showed reliable activation during all tasks in children. The authors interpret these findings in terms of increased functional specialization with development and redundancy in the neural system subserving language early in development. Taking these conclusions one step further, we suggest that the dichotomy of 'pluropotential and distributed' versus 'specialized and localized' exists only on the functional level. On the neurobiological level, language representation in children is similar to adults, but this similarity is masked by diffuse connectivity and exuberant synaptic proliferation that characterize the young brain.

For the purpose of this paper we assume that an innate endowment and cortical representation for language are present from birth. We also assume that quantitative differences of an immature cortex lead to some qualitative differences (such as pluripotential

cortex and distributed functional organization in infants) but represent a developmental continuum within the framework of similar language representation in children and adults. What do we attribute to the processes underlying quantitative differences between the young and mature brains? Similar to animal research, morphometric and brain imaging studies (EEG, glucode metabolism, blood flow volumes, etc.) in humans imply the presence of the period of massive overproduction of synapses, dendritic arbors and exuberant connectivity. This period, known as the Critical Maturation Period, leads to the next stage of development - the process of elimination when neuronal/synaptic numbers, density, connectivity are adjusted to their respective adult values. Though there is no complete data regarding the exact timetables of these events for the entire brain, it is known, for example, that these overproduction/adjustment processes in the frontal lobes continue into adolescence (Huttenlocher, 1993). The outline of our hypothesis is shown in Table. 1:

Table 1. Rationale for our hypothesis

	Young brain	Adult brain
Neurobiological level	Similar language representation	
	Morphological/Quantitative changes underlying brain maturation (synaptogenesis, dendritic proliferation, neuronal volume adjustment)	
Functional level	Pluripotential & distributed	Specialized & localized

Methods

Subjects consisted of 43 patients who underwent hemispherectomy for intractable seizures at the UCLA Medical Center. Etiology was catalogued according to the following breakdown: developmental pathology - 28 subjects (hemimegalencephaly - HM, cortical dysplasia/multilobar involvement - ML, and prenatal infarct); acquired pathology - 15 subjects (Rasmussen's encephalitis - RE and postnatal infarct). Postoperative spoken language outcome was rated based on spontaneous speech samples from 0 = no language to 6 = fluent mature grammar. Language scores were defined on the basis of stages in normal language development. The complete information regarding the breakdown of our population is shown in Table 3.

Discussion

Based on the animal studies we suggest that the Critical Maturation Period in humans is limited by the following thresholds: the lower threshold that is characterized by the completion of neuro/morthogenesis and establishment of experience independent connectivity; and the upper threshold of the completion of the period of neuronal/synaptic adjustment. Next, following Greenough et al. (1999) we assume that the following components underlie functional and neurological maturation of language: (1) developmental processes that are insensitive to experience, i.e. the genetic envelope of predetermined plasticity; (2) an experience-expectant period of neuronal plasticity also known as the Critical Maturation Period; and (3) an experience-dependent period of neuronal plasticity which underlies the ability to encode new experiences throughout the lifespan (Table 2). We thus hypothesized that superimposing effects of specific etiologies on these developmental stages would allow for more accurate prediction of language outcomes following hemispherectomy, since in our model functional reorganization reflects underlying neurobiological reorganization.

Our results confirmed our hypothesis in that postoperative language outcomes correlated with etiology. This would be expected since as shown in Table 2 different etiologies result in different potential for recovery (due to timing and extent). Developmental plasticity, i.e. reinnervation and neuronal sparing, seem to be more efficient in etiologies with later onset. In addition, when pathology disrupts genetically determined processes (as in hemimegalencephaly and cortical dysplasia) functional development seems to be particularly compromised. Thus the best language scores were found in Rasmussen's encephalitis and the poorest in hemimegalencephaly. Moreover, etiology

(developmental or acquired) consistently emerged as a significant variable distinguishing linguistic outcomes in all statistical analyses. In all cases it was possible to predict post-surgery language outcomes by considering the effect of specific etiologies within the framework of the categories of neural plasticity. It should be noted that we have deliberately chosen to relate functional outcomes and the broad categories/stages of neuronal plasticity instead of providing direct correlations with age at insult. It is our belief that in such correlations the confound between etiology and age at insult is unavoidable (Curtiss, de Bode and Mathern, submitted).

The rate and quality of neuronal reorganization reflected in language outcome also confirmed the left hemisphere's predisposition to support language, since children with an isolated right hemisphere had significantly more problems acquiring/restoring their language. Importantly, however, though age at surgery for two of our RE children was as old as 12, neither of them has remained mute after left hemispherectomy, suggesting that language specialization had not yet reached its peak, and reorganization was still possible. Our preliminary research also indicates that even in the most severely compromised cases, language development follows the normal course of language acquisition albeit on a prolonged scale. These findings lead us to suggest that innate language universals are resilient to brain damage, although language representation in the brain does not seem to be anatomically-bound to the left hemisphere only.

Table 2. The impact of specific etiologies on the categories of neural plasticity

Stages/Etiology	Genetic Envelope (innate constraints specifying cortex differentiation including ensembles that would support language-related properties)	Experience-Expectant Period (=Critical Maturation Period, input-dependent period of maximum plasticity)	Experience-Dependent Period (plasticity underlying the ability to incorporate new experiences throughout the lifespan)
Normals	normal	birth – 12 years, reduced vulnerability to injury	normal, life-long
Hemimegalencephaly	affected	increased vulnerability	Limited in most cases, thus lowered FSIQ
Cortical Dysplasia	affected-to-normal	variable	
Infarct prenatal	affected-to-normal	variable	
Infarct postnatal	normal	reduced vulnerability to injury similar to normals	
Rasmussen's Encephalitis	normal	reduced vulnerability to injury similar to normals	

Acknowledgements

We are grateful to all the children and their parents who have graciously agreed to participate in this study.

Abstract

Reasoning with conditionals involving causal content is known to be affected by retrieval of alternative and disabling conditions. Recent evidence indicates that besides the number of stored conditions, the relative strength of association of the alternative conditions with the consequent term is another important factor that affects the retrieval process. In this study we examined the effect of the strength of association for the disabling conditions. We identified causal conditionals for which there exists only one highly associated disabler. With these conditionals we constructed conditional inference problems in which the minor premise was expanded with the negation of a strongly or weakly associated disabler. Results indicate that strength of association of the disabling conditions is affecting reasoning performance: Acceptance of Modus Tollens increased when there was no strongly associated disabler available.

Introduction

Conditional reasoning has attracted a lot of interest from cognitive scientists studying human reasoning. Conditional reasoning consists in making inferences on the basis of ‘if p then q’ sentences. In a conditional inference task people are usually asked to assess four kinds of arguments: Modus Ponens (MP, ‘if p then q, p therefore q’), Modus Tollens (MT, ‘if p then q, not q therefore not p’), Denial of the Antecedent (DA, ‘if p then q, not p therefore not q’), and Affirmation of the Consequent (AC, ‘if p then q, q therefore p’).

Under the material implication interpretation of standard logic, MP and MT are considered valid inferences while DA and AC are regarded as fallacies. Much of the work on conditional reasoning has tried to identify the factors that influence performance on these four problems (for a review, see Evans, Newstead, & Byrne, 1993).

A growing body of evidence is showing that peoples knowledge about the relation between the p (antecedent) and q (consequent) part of the conditional has a considerable effect on the underlying reasoning process (e.g., Byrne, Espino, & Santamaria, 1999; Markovits, 1984; Newstead, Ellis, Evans, & Dennis, 1997; Rumain, Connell, & Braine, 1983; Thompson, 1994).

In the case of reasoning with conditionals involving causal content (e.g., ‘If cause p, than effect q’) seminal work has been done by Cummins and her colleagues (1995; Cummins et al., 1991). Following Byrne (1989), Cummins examined the effect of the alternative and disabling conditions of a causal conditional. An alternative condition is a possible cause that can produce the effect mentioned in the conditional while a disabling condition prevents the effect from occurring despite the presence of the cause. Consider the following conditional:

If the brake is depressed, then the car slows down

Possible alternative conditions for this conditional are:

running out of gas, having a flat tire, shifting the gear down…

The occurrence of these conditions will result in the car slowing down. The alternatives make it clear that it is not necessary to depress the brake in order to slow the car down. Other causes are also possible.

Possible disabling conditions are:

a broken brake, accelerating at the same time, skid due to road conditions…

If such disablers are present, depressing the brake will not result in the slowing down of the car. The disablers make it clear that it is not sufficient to depress the brake

in order to slow down the car. There are additional conditions that have to be fulfilled.

When people (fallaciously) accept DA and AC inferences, they fail to see that there are other causes that may lead to the occurrence of the effect beside the original stated one. Cummins (1995) and Cummins et al. (1991) found that peoples acceptance of DA and AC inferences decreased for conditionals with a high number of possible alternative conditions. This showed that a crucial factor in making the fallacious inferences is the number of alternative causes people can think of. In addition, she found that the number of disabling conditions affected the acceptance of the valid MP and MT inferences: If there were many conditions that could disable the relation between antecedent and consequent, people tended also to reject the valid inferences.

Recently, Quinn and Markovits (1998) have identified another factor that may influence reasoning with causal conditionals. They showed that not only the number of alternative conditions is important, but also what they call the 'strength of association' of the alternative conditions. Quinn and Markovits developed a framework (see also Markovits, Fleury, Quinn, & Venet, 1998) where reasoning performance is being linked to the structure of semantic memory. In this framework it is assumed that, when confronted with a causal 'if p then q' conditional, reasoners will access a causal structure in semantic memory that corresponds to 'ways of making q happen' (i.e., alternative conditions). Within the structure, there will be causes that are more strongly associated with q than others. The more strongly associated a specific cause is, the higher the probability that it will be retrieved by the semantic search process.

Quinn and Markovits (1998) measured strength of association by frequency of generation: In a pretest, participants were asked to write down as many potential causes for a certain causal consequent (effect, e.g., 'a dog scratches constantly'). This allowed the construction of conditionals with a strongly (e.g., 'If a dog has fleas, then it will scratch constantly') and weakly (e.g., 'If a dog has skin disease, then it will scratch constantly') associated cause. With the weak conditional, reasoners will be able to activate the strongly associated cause, while they will have to activate some other, less closely associated term for the strong conditional. Thus, it will be more difficult to retrieve an alternative condition in case of the strong conditional, which would lead to a greater acceptance of DA and AC inferences. The results of the study were consistent with the predicted response pattern.

The identification of the strength of association effect raises the question whether this effect is also present for the disabling conditions. Indeed, although knowledge of disabling conditions is also stored in semantic memory, Quinn and Markovits (1998) restricted their case to an analysis of the alternative conditions. Cummins (1995) already showed that both the number of alternatives and disablers is affecting reasoning performance. In addition, Elio (1998) has shown that the process of disabler retrieval is not only important in conditional reasoning but also in the field of belief revision and non-monotonic reasoning: Belief in a conditional after contradiction was lower when people could find many disablers. Thus, both for reasoning psychologists and the psychological and AI community studying belief revision, examining the effect of associative strength of disablers can identify a new factor affecting the crucial disabler retrieval. Therefore, we examined in this study whether Quinn and Markovits' strength of association effect also generalized to the disabling conditions.

The framework developed by Quinn and Markovits (1998) was adopted and extended to the disabling conditions. It was assumed that when presented a causal conditional, people will not only access a causal structure with alternative conditions but also one that corresponds to 'ways that prevent q to occur' (see Vadeboncoeur & Markovits, 1999). When such disabling conditions are retrieved, p will no longer be perceived as a sufficient condition for q what renders the MP and MT conclusions uncertain.

In a generation task we identified strongly and weakly associated disablers for a number of conditionals. We constructed experimental items by expanding the original antecedents of the conditionals with the negation of the strongly or weakly associated disabler. Suppose that for a certain conditional we find that S is a strongly associated disabler, while W is a weak one. This allows the construction of the expanded conditionals: 'If P and not S, then Q' (strongly expanded) and 'If P and not W, then Q' (weakly expanded). These expanded conditionals have an equal number of possible disablers (i.e., the original number minus one). However, reasoners presented with 'If P and not W, then Q' will still be able to activate the strongly associated disabler S, while with 'If P and not S, then Q' they will have to activate a less closely associated one. Thus, it will be harder to access and retrieve disablers for the strong conditionals. This access-to-disablers manipulation rests solely on the strength of association of the disablers and not on the number of accessible disablers.

Retrieving disablers from semantic memory will decrease the acceptance of MP and MT inferences. Therefore, we predict that acceptance ratings for MP and MT inferences will be higher for the strongly expanded conditionals than for the weakly ones. In the present experiment we did not manipulate the access to alternative conditions. Since, Cummins (1995) findings indicate that retrieving disablers has no effect on DA and AC it follows that no difference should be observed

on DA and AC acceptance between the strong and weak conditionals.

Experiment

Pretest

The material for the present experiment was selected from previous pilot work (see De Neys, Schaeken, & d'Ydewalle, 2000), where 20 participants wrote down as many disabling conditions as possible for a set of 20 causal conditionals (with 1.5 min generation time for each conditional).

For every conditional we established the relative frequency of appearance of the disablers that participants wrote down. We needed conditionals with a set of disablers in which there was one specific disabler that was very frequently generated. The expanded conditionals manipulation also forced us to take an additional criterion into account. We could not allow disablers that express a quantification of the original antecedent (e.g., 'brake not depressed hard enough'). Expanding the original with this kind of disablers would result in inconsistencies for some problems (e.g., DA, 'The brake was not depressed and the brake was depressed hard enough'). We selected 3 conditionals that met these criteria. From each set of disablers one infrequently generated disabler was selected. This weakly associated disabler had to meet the non-quantification criterion. Furthermore, if the strongly expanded conditional contained an explicit negation (e.g., 'If the apples are ripe and they are not picked'), we opted to express the selected weakly associated disabler in an explicit negated way too. The negation criterion should guarantee that the strongly and weakly expanded conditionals have comparable lexical complexity. Finally, the selected disablers had to sound as natural (according to our intuitions) as possible (e.g., 'not too little wind' was not accepted). Table 1 presents the material that was selected for the experiment.

We note that one might utter reservations about the use of frequency of generation as a measure of strength of association. Quinn and Markovits (1998) did not address this issue. However, our pilot study showed that frequency of generation was related to other possible strength of association measures such as plausibility and generation order: More frequently generated disablers were judged more plausible and tended to be generated prior to less frequently generated ones.

Method

Participants and Material

89 first-year university students participated in the experiment. Participants received a 4-page booklet. Page one included the instructions for the task. On the top of each of the next three pages appeared the selected conditionals. Each conditional was embedded in the four inference types (MP, DA, MT, AC). So, each of the three pages included one conditional with four inference problems. For each conditional there was a specific presentation order of the four inferences (AC, MT, DA, MP or MP, MT, DA, AC or MP, DA, MT, AC). The three pages were bound into booklets in randomized order. Below each inference problem appeared a seven point rating scale. This resulted in the following item format:

Rule: If water is heated to 100°C, then it boils

Fact: The water is heated to 100°C and the water is pure
Conclusion: The water boils

```
                                  I
-1--------2--------3---------4--------5--------6--------7-
very sure  somewhat sure  I somewhat sure  very sure
```

That I CANNOT draw this conclusion — That I CAN draw this conclusion

Figure 1. An example of the item format

Figure 1 presents an example of the MP problem. On the same page participants would also find the MT, DA and AC problem. The access to disablers manipulation

Table 1.
Relative frequency of generation of the most frequently mentioned disablers for the three selected conditionals. The disablers are given in order of frequency (%). Selected strongly and weakly associated disablers are highlighted.

If the apples are ripe, then they fall from the tree	If John grasps the glass with his bare hands, then his fingerprints are on it	If water is heated to 100° C, then it boils
Picked (65%)	*Hands not greasy (50%)*	*No pure water (75%)*
Too little wind (25%)	Grasped glass with palms only (35%)	*No normal pressure (30%)*
Not enough weight (20%)	Prints wiped off (30%)	Bad temperature measure (30%)
Not ripe enough (20 %)	*Glass was wet (25%)*	
Apples caught in branches (10 %)		

consisted in the presentation of two different minor premises (the information under the heading 'Fact'); the above example would belong to the strongly associated group were the original information was expanded with the negation of the strongest associated disabler. Similarly, in the weakly associated group, the negation of the selected weakly associated disabler was added to the 'Fact:'-information. In both expanded groups appeared the original conditionals on top of the item pages. Thus, participants were not presented explicit expanded conditionals but rather conditional inference problems with expanded minor premises. All the items in a single booklet belonged to the same group. Table 2 gives an overview of the different material in the two groups (for an MP problem)

Table 2.
Different contents in the experimental groups. Both groups only differ by the kind of information that is presented in the minor premise.

Expanded strongly associated:
(a) Water is heated to 100°C and the water is pure (b) The apples are ripe and they are not picked (c) John grasps the glass with his bare hands and his hands are greasy
Expanded weakly associated:
(a) Water is heated to 100°C and the pressure is normal (b) The apples are ripe and they are not caught in the branches (c) John grasps the glass with his bare hands and the glass is dry

Procedure
The booklets were randomly given out to students who agreed to participate in the experiment. No time limits were imposed. The instructions explained the specific item format of the task. Participants were told that the task was to decide whether or not they could accept the different conclusions. The instruction page showed an example problem (always standard MP) together with a copy of the rating scale. Care was taken to make sure that participants understood the precise nature of the rating scale. As in Cummins (1995), participants were NOT specifically instructed to accept the premises as always true. With Cummins we assume that this encourages people to reason as they would in everyday circumstances.

Results

Participants rated each of the four inference types three times. For every inference type the mean of these three ratings was calculated. This resulted in a 4 (inference type, within-subjects) x2 (group, between-subjects) design. All hypotheses were tested with planned comparison tests and rejection probability of .05.
Table 3 shows the overall mean acceptance ratings for the four inference types in the expanded weakly and strongly associated group. Planned contrasts indicated that the acceptance ratings in both groups differed significantly [$F(1, 87) = 4.55$, $MSe = 3.85$, $p < .04$]. As expected, both expanded groups did not differ in terms of the acceptance ratings for DA and AC inferences. For MT inferences we did obtain significantly higher ratings in the strongly associated group [$F(1, 87) = 4.99$, $MSe = 2.67$, $p < .03$]. Although, the effect on MP problems was in the expected direction (higher ratings in the strongly than in the weakly associated group), it did not reach significance.

Table 3.
Mean acceptance rating for the four inference types in the strongly associated and weakly associated groups.

Inference type	Group	
	Expanded weakly associated (n=45)	Expanded strongly associated (n=44)
MP	5.7	5.92
DA	4.78	5.11
MT	4.37*	5.14*
AC	4.98	5.44

* planned contrast $p<.05$

Discussion

The study showed that the strength of association of a disabling condition is affecting the conditional reasoning process. As predicted, peoples acceptance of MT inferences increased when there was no strongly associated disabler available, while the associative strength of the disablers had no effect on DA and AC inferences. This supports the hypothesis that in addition to the number of disabling conditions (Cummins, 1995), retrieving disablers from semantic memory is affected by their strength of association.

We suspect that the non-significance of the expected effect on MP may be due to a ceiling effect on the MP acceptance ratings. In the pretest, relatively few disablers were generated (less than the overall mean) for the three conditionals that were adopted for the experiment. Cummins (1995) already obtained high MP acceptance ratings for these conditionals. The 'expansion' manipulation in the present experiment

then further decreased the available number of disablers. This may have resulted in a ceiling effect. It could be the case that MP acceptance was already at the top in the weakly associated group. Mean acceptance for MP in the weakly associated group (Mean = 5.7, see Table 3) indeed tended to the 'sure that I can draw this conclusion' rating, located at the upper end of the scale. As in Cummins (1995), acceptance ratings on the (more difficult) MT inference were lower, what allowed the associative strength effect to show up.

It is interesting to note that for all of the four inference types acceptance ratings were lower when there was a strongly associated disabler available. Although the effect on AC and DA was not significant, one could suggest that the availability of a strongly associated disabler results in an overall decrease in certainty for every inference type (and not just for MT or MP). This might tie in with recent evidence (e.g. Manktelow & Fairley, 2000) showing that acceptance of DA can be affected by disabling conditions. This issue, together with the hypothesized ceiling effect on MP, will need to be addressed in further research.

In this study we adopted Quinn and Markovits' (1998) notion of a semantic search process and extended it to the disabling conditions. We should note that Quinn and Markovits (see also Markovits et al., 1998) incorporated the postulated semantic search process in the mental models theory (Johnson-Laird and Byrne, 1991). Here we refrained from making specific claims about the nature of the basic inferential principles (i.e., mental models or mental inference rules). The general semantic search process can be incorporated in other reasoning theories like mental logic (Braine & O'Brien, 1998; Rips, 1994) or the probabilistic approach (Oaksford & Chater, 1998). Comparing these different implementations is not within the scope of the present study or the Quinn and Markovits experiment.

We mentioned the relevance of the present study for the work of Elio (1997, 1998) and other researchers in the domain of belief revision and non-monotonic reasoning. Elio established that the number of stored disabling conditions affected peoples belief revisions and stated that conditional reasoning and belief revision are guided by the same memory search process. Our results show that successful retrieval is not only affected by the number of stored disabling conditions but also by their strength of association.

The present study can also be related to the work of Chan and Chua (1994). They examined the effect of 'relative salience' of disabling conditions. This factor can be interpreted as strength of association. Chan and Chua presented participants inference problems with two conditionals (e.g., 'If p then q, If r then q, p, thus q?'). The second conditional mentioned a possible disabling condition while the categorical premise was not expanded (see Byrne, 1989). Acceptance of MP and MT decreased with the strength of association of the mentioned disabler. However, a crucial difference with our study is that the present manipulation specifically affected the retrieval of disablers from semantic memory. In Chan and Chua's experiment, reasoning was affected by the strength of association of the mentioned disabler per se. The expansion of the categorical premise in the present experiment eliminated a strongly or weakly associated disabler and thereby affected the strength of association in the residual disabler set.

In sum, our study indicated that the conditional inferences people make are influenced by the strength of association of the disabling conditions. This complements Quinn and Markovits' (1998) contention that the strength of association of elements in semantic memory is an important factor in predicting conditional reasoning performance.

Abstract

This paper will offer a framework and a methodology for determining whether subjects have conscious or unconscious knowledge. The implicit-explicit distinction will be related to consciousness using the framework of Dienes & Perner (1999; 2001a,b,c) and the higher-order thought theory of Rosenthal (1986, 2000). Whether a mental state is conscious or not depends on whether certain inferences are unconscious or not, in a way we will specify; this is the interaction between implicit and explicit knowledge we will consider. The arguments will be illustrated with the artificial grammar learning paradigm from the implicit learning literature.

Introduction

In this paper we will argue that there is an intimate and generally unappreciated interaction between implicit and explicit knowledge that occurs all the time. Consideration of this interaction is important in determining whether a subject possesses conscious or unconscious states of knowledge. To make the argument, in the first section below we will overview the framework of Dienes and Perner (1999, 2001a,b,c) for understanding the implicit-explicit distinction in terms of the properties of representations. We will take an everyday use of the implicit-explicit distinction and apply it in a particular way to what it is to represent something. Given a representational theory of knowledge, this produces a hierarchy of ways in which knowledge can be implicit or explicit. We will then use the higher-order thought theory of Rosenthal (1986, 2000) to show full explicitness is almost the requirement for mental states of knowing to be conscious. There is one further stipulation above and beyond full-explicitness needed for consciousness and it is this that shows the importance of an interaction between implicit and explicit knowledge in producing conscious or unconscious states. We will discuss this relationship and illustrate how subjects' knowledge of an artificial grammar could be shown to be conscious or unconscious (in fact we will argue that the evidence shows that subjects can acquire fully unconscious knowledge).

Implicitly vs Explicitly Representing

Dienes and Perner's (1999, 2001a,b,c) framework could be structured as semi-independent modules: a notion of representation, a notion of the implicit-explicit distinction, the hierarchy of implicitness, and a theory of consciousness. To a degree, one can reject one of the modules and still accept the others to build an understanding of implicit knowledge and consciousness. We begin first with the notion of representation: In order to be clear how one might explicitly or implicitly represent something we need to be clear about what it is to represent something. In this we follow the functional theories of representation. For example, according to Millikan (1984, 1993), there must be a producer of the representation that has as its function that it brings about a mapping from the representation to a state of affairs. For example, in a bee dance, the bee can produce a dance such that the angle of the dance maps onto the location of the nectar. Further there will be consumers of the representation that perform various functions as they react to it. But they can only perform their functions under normal conditions if the representation does indeed map onto a certain state of affairs: This state of affairs is the content of the representation. This is what we mean by a representation. On this account, representations do not need to have further properties (e.g. compositional semantics) to be representations. The weights of a connectionist network are representations: They must map onto statistical regularities in the world in a certain way for the consumers of these weights to perform their functions, so the weights represent statistical regularities. What is it for a representation to represent something implicitly or explicitly, and what makes some representations conscious (those that have the contents that are the contents of our consciousness) while other representations are unconscious?

A bee dance represents the location of nectar. We say it represents location explicitly, because variations in the representational medium (angle of dance) map onto variations in location. However, it does not explicitly represent that it is about nectar: There is nothing in the medium that varies with whether it is nectar that it is about or something else. We say it represents the fact that it is about nectar only implicitly. Just so, in everyday terms when one answers the question "what is this?" to a succession of animals, and responds with the statement "cat" (or "dog" etc), the statement explicitly represents the property of being a cat, because variations in the representational medium (words) map precisely into variations in this content. The statement implies that it is this that is a cat, but it does not say so explicitly: There is not a part of the medium that varies directly with this rather than that being a cat.

Now consider what it is to have knowledge. In general knowledge consists of a proposition ("this word has the meaning butter") towards which you have an attitude of knowing. One can know without making all of these components of knowledge explicit. One can represent the proposition explicitly but not the fact that it is knowledge. It can in fact be knowledge (because it is taken as true and acted upon) without there being a representation that goes into one state for it being knowledge and another state if it is not knowledge. Minimally one could just make explicit the property without making explicit the individual that has this property (compare the bee dance). In subliminal perception we argue that it is indeed just a property of a presented word that is represented explicitly e.g. having the meaning "butter". There is no representation with the content "I see that the word in front of me has the meaning butter" so this cannot be the content of any experience of the subject; but the representation of merely "butter" can allow the subject to e.g. say "butter" as the first dairy product that comes to mind. At the next stage, the full proposition is made explicit ("The word in front of me has the meaning butter"). This stage involves the binding of features to individuals. At the next stage the factuality or otherwise of the proposition is made explicit ("it is a fact that the word in front of me has the meaning butter"). This is precisely the developmental milestone that occurs in a child's representational capacity at about 18 months (Perner, 1991), and is needed for appreciating hypotheticals, changing temporal states of affairs (and hence is necessary for explicit memory), and counter-factual reasoning. At the final stage the propositional attitude by which one holds the proposition is made explicit ("I see that the word in front of me has the meaning butter"). This is full self and attitude explicitness. We argue that this is necessary for knowledge to be conscious knowledge. This link from full explicitness to consciousness is made via the higher order thought theory of consciousness (Rosenthal, 1986, 2000; Carruthers, 1992, 2000).

The Higher-Order Thought Theory

Rosenthal (1986, 2000) develops an account of when a mental state is a conscious mental state. He argues that when one is in a conscious mental state one is conscious of that mental state. It would be inconceivable to claim that one is in a conscious state of, for example, seeing the word butter, while at the same time denying being conscious of seeing the word butter. So the question is, how does one become conscious of mental states? The relevant way, Rosenthal argues, is to think about them. We become conscious of our seeing the word butter when we think that we are seeing the word butter. That is, when we are consciously seeing the word butter, we have a thought like "I see that the word is butter". Because this thought (this mental state) is about another mental state (seeing), it is called a higher order thought. Note that this higher order thought is just our requirement for knowledge to be fully explicit: There is a natural relationship between explicitness and consciousness.

A Method For Determining Unconscious States

These considerations show that knowledge states being conscious or not is essentially a metacognitive issue (Dienes & Perner, 2001b). Roughly, simply knowing something and hence being able to respond discriminatively does not make the knowing a conscious mental state; for the latter, one must know that one knows. Metacognition has both a monitoring and a control aspect, and both of these aspects can be used to form methodologies for determining the conscious status of knowledge via an analysis of the relationship of different types of control and monitoring to the hierarchy of implicitness (Dienes & Perner, 2001b). Here we will focus exclusively on monitoring; the criterion for a state being conscious or unconscious is essentially that of the subjective threshold in the subliminal perception literature (Cheesman & Merikle, 1984).

Consider a subject in an artificial grammar learning experiment (Reber, 1967, 1989). The subject is exposed to strings of letters generated by a finite state grammar and asked to memorize them. After some minutes exposure, the subject is told actually there was a set of complex rules that determined the order of letters within the strings, and could they now classify a new set of strings as obeying the rules or not. Reber found that subjects could do so above chance but they found it difficult to say what the rules were. How could we

determine whether their knowledge is actually unconscious?

When subjects classify a test string they bring to bear their knowledge of the grammar to produce a new piece of knowledge: Whether this string is grammatical or not. We must distinguish these different knowledge contents: knowledge of the grammar, and knowledge of a particular string being grammatical (the grammaticality judgement).

When subjects make grammaticality judgements to the same strings several times they respond with different degrees of consistency to different strings (Reber, 1989; Dienes, Kurz, Bernhaupt, & Perner, 1997). For some strings the subject responds highly consistently, for others the subject may give a "grammatical" or "non-grammatical" response with 50% probability. Our interpretation of this fact is that subjects are in different knowledge states about the different test strings. Regardless of whether they have induced the same grammar as the experimenter or not (in fact, their grammar is correlated with the experimenter's grammar), the subjects themselves are treating themselves as being in different knowledge states about different strings. But have they conceptualized themselves as being in those different knowledge states? That is, have they formed attitude-explicit representations - higher-order thoughts - about those states? (Note that it was important to establish that there were different knowledge states before this question could be asked.)

When confidence ratings are taken after each classification decision, subjects can classify at above chance rates even when they claim they are literally guessing (for a review see Dienes & Berry, 1997). Further, under some conditions, there will be no within-subject relationship between confidence and accuracy: Subject do not know about the different knowledge states they are in fact in (Dienes & Berry, 1997; see Dienes & Perner, 2001c for this finding with a context-free grammar). Their knowledge is attitude-implicit, and hence unconscious.

The Crucial Interaction Between Conscious and Unconscious Knowledge

Consider now two objections one may have to assessing unconscious knowledge with confidence ratings. First, Allwood, Granhag, Johansson (in press) found the normal evidence for attitude-implicit knowledge in an artificial grammar learning experiment when the typical amount of learning and testing was used. In a second experiment that involved greater exposure to strings at learning and test subjects' confidence and accuracy was well-calibrated and so the knowledge seemed entirely atittude-explicit, despite the authors' feeling that the fundamental nature of subjects' knowledge had not changed. Allwood et al suggest that confidence ratings can come to be based on implicit knowledge as much as explicit knowledge, and this possibility undermines the usefulness of a dissociation between confidence and accuracy as a measure of implicit knowledge. Second, there is the standard objection to subjective measures of consciousness: Are they not dependent on the vicissitudes of subjects' idiosyncratic theories of consciousness, knowledge, etc (e.g. Shanks & St John, 1994)? This second objection is taken up in Dienes & Perner (2001a) and especially Twyman and Dienes (2001); we will develop a different, complementary response in this paper. To address these objections we need to return to a subtlety of the higher-order thought theory that we glossed over.

Rosenthal argues that to make a mental state conscious, the higher order thought must assert that one is in the state and it must not arise from any inferences of which we are conscious. That final stipulation is crucial. If I am driving along and swerve, and wonder why I swerved, I might think "I must have swerved because I saw that truck". That thought is a higher order thought about one being in a mental state of seeing. But it does not make the original seeing conscious; it does not make it conscious precisely because it arose from an inference of which one was conscious.

A mental state is conscious if we are non-inferentially conscious of it; the mental state would be unconscious if we were conscious of the mental state only by virtue of inferences of which we are conscious. This is just why blindsight patients' seeing is still unconscious even though they may consciously infer they must be seeing "because the experimenter tells me I am consistently correct." They have a higher-order thought that they are seeing, but our intuitions are that the seeing remains unconscious; and it remains unconscious precisely because the higher-order thought (the attitude explicit representation) arose from an inference of which the patient is conscious.

How do these considerations apply to determining whether a subject in an experiment has acquired conscious or unconscious knowledge? One has to be careful when the mental state is knowing, because knowing need not refer to an occurrent mental state at all. Knowing is often used in a dispositional sense: if you are asked if you know your times tables, that does not mean to say you are actively thinking about them now; the question is just whether you could do so accurately if asked. We will see how this can lead to a paradox.

Imagine a person is asked a general knowledge question and they believe they know the answer. The person is asked "Why do you conclude that you know

that?" When a person consciously knows something they might be able to provide conscious inferences by means of which they conclude that they know. They might justify their knowledge as knowledge because e.g. " I can describe the reasoning by which I drew the conclusion"; "I remember the event in which a trusted authority told me the knowledge"; or, more generally, "I can consciously link the knowing to some conscious perception."

These conscious inferences do not make the knowledge unconscious. (Further, they are not essential for the knowledge being conscious either: I might not know why I know something, I just insist that I know it.) This seems to go against the conclusion that mental states are only conscious if one knows about them by inferences of which one is unconscious.

The problem arises because knowing is not an occurrent mental state. An occurrent mental state associated with knowing is "thinking with conviction" or "thinking with a certain degree of conviction". Even if a person is aware of the inferences by which they know something, they just directly know that "I am thinking with conviction" if the thinking is a conscious state. In answer to the question "How do you know you are thinking with conviction?" one does not need to list the inferences that justify the knowledge as knowledge; they are not inferences leading to the conclusion that one is thinking with conviction. One just directly knows that one is thinking with conviction if the thinking-with-conviction is a conscious mental state. It is a conscious state because the inferences, if any, by which one ascertained that one was in the state were unconscious.

In answer to the question "Why do you conclude that you know that?" a person might provide conscious inferences by means of which they conclude they know something by observing their behaviour: "I respond consistently, quickly or effectively". For example, a person may select the correct capital of a country, let's presume, due to being in an unconscious state of thinking-with-conviction. This state makes the person respond consistently and quickly; the state of thinking-without-conviction (let's presume) makes the person respond inconsistently and slowly. The person does not know he is in a state of thinking with conviction at first; but he consciously infers from the speed with which the answer came to him that he must have been in an occurrent state of knowing. Because he is conscious of this inference, the state is unconscious. If the same inference had been drawn for the same reason but unconsciously, his thinking-with-conviction would be a conscious mental state. In this sense, explicit knowledge of ones mental state depends on that explicit knowledge being produced only implicitly; for example, only with inferences that are themselves implicitly represented. This is the crucial interaction between implicit and explicit knowledge we wish to dwell on.

Applying these notions to artificial grammar learning, consider a subject who sees a test string, applies knowledge-of-the-grammar, classifies the test string as grammatical or not (knowledge-of-the-test-string), and then gives a confidence rating.

Subjects' different degrees of consistency to different test strings show that subjects, when classifying different strings, are in states of thinking with different degrees of conviction. If subjects confidence ratings are unrelated to their consistency then their higher order thoughts (confidence ratings) are not sensitive to their actual mental states of thinking with more or less conviction ("knowledge states", for short). We have taken this to be evidence of the knowledge states being unconscious. In fact, however, in some cases they will be in a state of thinking-with-a-lot-of-conviction and give a high confidence rating; in these cases, they do have a higher-order thought (attitude-explicit knowledge) to the effect that they are in a state that they are in; so if the confidence rating came to them in a way that appeared unmediated, the state would be a conscious state. If confidence ratings appear unmediated to the subject, the lack of relationship between confidence and consistency implies some knowledge is unconscious, even though it allows some knowledge to be conscious. This is one refinement we must add to our previous interpretation of a lack of relationship between confidence and accuracy.

Now consider Allwood et al's results. Demonstrating a relationship between confidence and accuracy is not sufficient for demonstrating that the knowledge is conscious; one also needs to determine what the subject believes the confidence ratings are based on. Strictly speaking, if subjects base the ratings on inferences (e.g. perceived reaction times, perceived fluency) of which they are conscious, the knowledge states are still unconscious. Although we are in progress with an experiment that includes asking subjects to report on the bases of their confidence ratings, we regard this more as a means for us as psychologists to generate ideas, rather than as a test of the conscious status of their knowledge; the latter needs to be methodologically simpler. A lack of relationship between confidence and accuracy does imply that at least some of the knowledge states are unconscious, and so this remains a valuable criterion.

If subjects' ratings are based on explicit inferences, including the products of implicit knowledge (e.g. fluency), the knowledge states are unconscious; if confidence ratings come to be based on implicit

knowledge in a way that appears unmediated to the subject, and hence confidence is calibrated with accuracy, then the states of knowledge are conscious. The knowledge states referred to here are knowledge about the grammatical status of test strings. Even if these knowledge states were all conscious, it would leave open the possibility that knowledge of the grammar was unconscious.

Thus, Allwood et al's intuitions that subjects in their experiment two still had, in some sense, implicit knowledge could be due to (a) despite the subjects' well calibrated confidence ratings, this calibration was based on conscious inferences regarding the mental state the subjects must have been in (states of knowing the grammatical status of strings), and so those mental states were still in fact unconscious; or (b) the mental states of knowing the grammatical status of the strings were in fact conscious (the confidence ratings were not based on conscious inferences), but the mental states of knowing the grammatical rules were not conscious; subjects did not have non-inferential higher order thoughts about being in those latter states.

If subjects' become conscious of their mental states responsible for grammaticality judgements, methods of using confidence ratings for grammatcaility judgements can no longer be used to show knowledge of grammatcal rules is unconscious. Dienes and Perner (2001b) discuss how to measure implicit knowledge under these conditions.

Rosenthal (2000) discusses how higher order thoughts need not be produced by a 100% reliable means; however they are produced, so long as they appear unmediated, they produce conscious awareness of being in a certain mental state. The first order mental state about which one has a second order thought need not even exist for the subject to consciously experience being in a certain state. Subjects' higher-order thoughts partly constitute their theories about their mental states; such theories are not therefore a nuisance that get in our way as experimenters; they are part of the very thing to be investigated and explained.

Conclusion

We have argued for a second-order representational account of consciousness. Consciousness can never be produced just by, for example, a sustained pattern of activation in a connectionist network per se (e.g. O'Brien & Opie, 1999); the properties of the representation must in certain respects be like those of people to count as mental states and the system must be able to refer to those states in further representations (Perner & Dienes, 1999; see Dienes & Perner, 2001c for discussion). Such considerations lead directly to metacognitive measures of the consciousness of mental states. Conscious states cannot be measured just by discriminative responding, but only by evidence that the subject is conscious of the mental state.

To summarize the argument of this paper, we have taken two points made by Rosenthal regarding his higher order thought theory; namely that (a) higher order thoughts are occurrent states rather than dispositional states (like knowing might be); and (b) the higher order thoughts must not result from inferences of which the person is conscious. These two points turn out to have important implications for the measurement of implicit or explicit knowledge in (for example) the implicit learning literature. The contribution of this paper is to show in detail the relevance of Rosenthal's theory to psychologists interested in determining the conscious or unconscious status of mental states in (for example) implicit learning studies.

We are conscious of mental states when our explicit knowledge of them is based purely on implicit knowledge, when the knowledge of being in the state does not arise out of any inference of which we are conscious. Note there is a symmetry here with volition; we have voluntary control over an act only when the intention produces the act by mechanisms of which we are unconscious (Dienes & Perner, 2001b).

The importance of considering the conscious status of the inferences leading to a judgement has also been highlighted by Koriat (e.g. 1998). We hope we have elucidated further implications of the interaction between implicit and explicit inferences and implicit and explicit knowledge states.

Acknowledgments

Thanks to David Rosenthal for valuable discussion before this paper was written.

What Can Homophone Effects Tell Us About the Nature of Orthographic Representation in Visual Word Recognition?

Abstract

In a lexical decision task (LDT), Pexman, Lupker, and Jared (2001) reported longer response times for homophones (e.g., MAID-MADE) than for non-homophones (e.g., MESS) and attributed these effects to orthographic competition created by feedback activation from phonology. The focus of the present research was the grain-size of the orthographic units activated by feedback from phonology. We created 9 categories of homophones based on the sublexical, orthographic overlap between members of homophone pairs. We also manipulated the type of foils presented in LDT (consonant strings, pseudowords, pseudohomophones) to create conditions involving less vs. more extensive processing. Homophone effect sizes varied by category; effects were largest when spellings of both onsets and bodies differed within the homophone pairs (e.g., KERNEL-COLONEL) and when members of the homophone pairs differed by vowel graphemes (e.g., BRAKE-BREAK). These results suggest that several specific grain-sizes of orthographic representation are activated by feedback phonology.

Introduction

In a number of recent articles in the word recognition literature, the notion of feedback activation has been invoked to explain particular findings (e.g., Hino & Lupker, 1996; Pecher, in press; Pexman & Lupker, 1999; Pexman, Lupker, & Jared, 2001; Stone, Vanhoy, & Van Orden, 1997; Taft & van Graan, 1998; Ziegler, Montant, & Jacobs, 1997). In a fully interactive model of word recognition (e.g., the PDP model of Plaut, McClelland, Seidenberg, & Patterson, 1996) activation between sets of units can be bi-directional. For instance, in a lexical decision task, when a target word is presented, there is initial activation of an orthographic representation for the target, and then very quickly there is also activation of semantic and phonological representations for that word. Those semantic and phonological representations then re-activate, via feedback connections, the orthographic representation. This bi-directional flow of activation can help the system settle on a representation for the target word. The purpose of the present research was to address an unresolved issue regarding feedback activation: What is the nature (grain-size) of the orthographic units that are activated by feedback from phonology?

Feedback activation is assumed to operate between all sets of units in the word recognition system. The focus of the present research, however, was feedback activation from phonology to orthography. Taft and van Graan (1998; see also Taft, 1991) argued for bi-directional activation between orthography and phonology by what they termed "orthography-phonology-orthography rebound". The model of word recognition they described was similar to models proposed by Grainger and Ferrand (1994), Plaut et al. (1996), and Van Orden and Goldinger (1994). A version of this model is illustrated in Figure 1. This is a connectionist model with sets of processing units representing orthographic, phonological, and semantic information. Importantly, the orthographic and phonological components of the model (but not the semantic component) are "composed of a hierarchy of units ranging from graphemes (e.g., C, A, and T) and phonemes (e.g., /k/, /æ/, and /t/) up to whole words. Activation passes up this hierarchy as well as between O and P units at the same level." (p. 206).

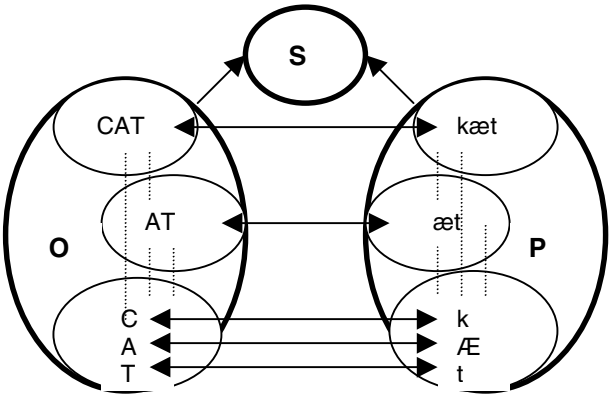

Figure 1: As depicted in Taft & van Graan (1998), a model of word recognition with sets of units representing orthography (O), phonology (P), and semantics (S).

Taft and van Graan (1998) argued that, when processing printed words, there is automatic activation of the phonological component of the model. Certainly, there has been controversy about the role that phonology plays in

visual word recognition (e.g., Davelaar, Coltheart, Besner & Jonasson, 1978; Jared & Seidenberg, 1991; Pugh, Rexer, & Katz, 1994, etc.). While Taft and van Graan found evidence that phonology did not mediate access to word meaning, they concluded that there was evidence for activation of phonology. That evidence came from studies involving homophone stimuli (e.g., MAID-MADE) (e.g., Jared & Seidenberg, 1991; Van Orden, 1987, etc.).

In several studies, researchers have investigated whether homophones create confusion when presented without context, in a lexical decision task (LDT) (e.g., M. Coltheart, Davelaar, Johnasson, & Besner, 1977; Rubenstein, Lewis, and Rubenstein, 1971). Recently, Pexman et al., (2001) reported longer decision latencies for homophones than for nonhomophonic control words in LDT, particularly for low frequency homophones with higher frequency homophone mates. Those homophone effects were larger with pseudohomophone foils than with pseudoword foils. Pexman et al. concluded that homophone effects in LDT were robust, and argued for automatic activation of phonology in visual word recognition.

Pexman et al. (2001) offered an account of homophone effects in LDT that was similar in many ways to the notion of orthography-phonology-orthography rebound (Taft & van Graan, 1998). Pexman et al.'s account was based on the concept of feedback phonology. The notion that feedback activation from phonology to orthography might influence the process of word recognition was first explored by Stone, Vanhoy, and Van Orden (1997).

Stone et al. (1997) argued that the process of word recognition is best explained by a model that includes both feedforward and feedback connections (resonance) between orthographic and phonological units. As support for this claim, they reported feedback consistency effects in LDT. Feedback inconsistent words are words for which the body can be spelled in more that one way (e.g., /-ADE/ in FADE can be spelled /-AID/ or /-AYED/ as in PAID or SWAYED), whereas feedback consistent words are words for which the body can only be spelled one way (e.g., /-IMP/ in LIMP). Stone et al. observed slower lexical decision latencies for feedback inconsistent words than for feedback consistent words. Accordingly, they suggested that, when a feedback inconsistent word is processed in an LDT, the phonological representation can activate, via feedback connections, orthographic representations for several word bodies. These orthographic representations will compete with each other, and this competition will slow the recognition process. In a replication study, Zeigler, Montant, and Jacobs (1997) also reported feedback consistency effects, thus supporting the notion that feedback activation can influence word recognition performance.

Although much current research supports the feedback account, it should also be noted that Peereman, Content, and Bonin (1998) reported a failure to replicate feedback consistency effects with French stimuli in LDT. Peereman et al. suggested that whereas homophone effects in various tasks "can be interpreted as showing that lexical phonological codes reverberate to orthographic word forms, they do not imply interactions between orthographic codes and phonological codes at the sublexical level" and argued for a "restricted interactivity account in which interactions are limited to lexical processing levels" (p. 170).

Pexman et al.'s (2001) feedback account of homophone effects in LDT also involved interactivity at the lexical level, although did not deny the possibility of sublexical interaction. Pexman et al. suggested that, when the phonological representation of a member of the homophone pair is activated, it feeds back to the orthographic representations for both spellings of the word. Thus, while some of the feedback is directed towards the representation for the correct orthographic unit, some of it is also captured by activity in the orthographic representation of the incorrect homophone mate, thus creating competition and resulting in longer decision latencies for homophones. This account involves the assumption that LDT responses are made primarily on the basis of activation in the orthographic units (see Pexman & Lupker, 1999, and Pexman et al., 2001, for more detailed explanations of this assumption).

The Present Research

If it is the case that phonology feeds back to, and creates competition in, the orthographic units, then it becomes important to characterize and attempt to understand the exact nature of this orthographic competition. In previous research there have been several different suggestions about the nature of orthographic representations. As mentioned above, one suggestion is that feedback activation from phonology influences activation of whole word orthographic representations (Peereman et al., 1998; Pexman et al., 2001). There have also been suggestions about the sublexical orthographic representations that might be activated by feedback from phonology. These sublexical representations have been described as grapheme based (Zeigler et al., 1997) or syllabically based, with feedback to onset and rhyme units (Stone et al., 1997), however, both Ziegler et al. and Stone et al. acknowledged that other levels of orthographic representation could be activated via feedback. There is, in fact, a suggestion that several different grain-sizes of units are activated in the process of word recognition, such that feedback activation would influence both lexical and sublexical levels of orthographic representation (Taft & van Graan, 1998). The purpose of the present research was to investigate the grain-size of orthographic units activated by feedback from phonology. To do this, we investigated whether homophone effects are modulated by the type of orthographic overlap that exists between homophone mates. In previous investigations of homophone effects in LDT (e.g., Pexman et al., 2001; Pexman & Lupker, 1999; Rubenstein et al., 1971) homophone pairs have only been categorized by frequency. Yet homophone pairs vary widely in orthographic overlap; some homophone pairs differ only by a single internal grapheme (e.g., BERTH-BIRTH), while others differ by onset and also by word body (e.g., ATE-EIGHT). Our question for the present research was whether these sublexical differences in orthographic overlap lead to

differences in the size of observed homophone effects. To this end, we created nine separate categories of homophones. Our aim was to divide homophones according to types of sublexical, orthographic overlap within homophone pairs (see Table 1), but our divisions between categories were also unavoidably influenced by the type of homophones that tend to occur in English. We restricted our analysis to low frequency homophones that have higher frequency mates since these were the homophones that produced the largest effects in Pexman et al. (2001).

In the following experiments we presented low frequency homophones from each homophone pair in the above homophone categories, along with sets of low frequency non-homophonic control words matched to the low frequency homophones. Our tasks were 3 LDTs, across which we manipulated the type of foils presented, to create task conditions that required less vs. more extensive processing. In Experiment 1A foils were consonant strings (e.g., PRNVR), in Experiment 1B foils were pseudowords (e.g., PRANE), and in Experiment 1C foils were pseudohomophones (e.g., BRANE). Pexman et al. (2001), and Pexman and Lupker (1999) have reported that when foils are more word like (e.g., pseudohomophones), homophone effects are larger. The explanation is that pseudohomophone foils create a difficult LDT, in which participants tend to process all of the stimuli more extensively. With more extensive processing, there is more opportunity for feedback activation to influence activation at the orthographic level and, hence, more competition and larger homophone effects. By using progressively more difficult LDTs, we hoped to capture homophone effects at several different "moments" of processing, allowing for more thorough contrasts between the homophone categories.

Method

Participants

The participants in these experiments were undergraduate students at the University of Calgary. There were 35 participants in Experiment 1A, 37 participants in Experiment 1B, and 41 participants in Experiment 1C.

Stimuli

Words The words used in this experiment were 95 homophones (mean frequency = 16.92 per million; Kucera & Francis, 1967) and 95 control words (mean frequency = 15.43) matched for frequency, onset, length and neighbourhood size (Coltheart, Davelaar, Jonasson, & Besner, 1977).

Foils Foil stimuli were required in all three parts of the experiment. There were 95 foils of each of the three types: consonant strings (Experiment 1A), pseudowords (Experiment 1B), and pseudohomophones (Experiment 1C).

Procedure

On each trial, a letter string was presented in the center of a 17-inch Sony Trinitron monitor controlled by a Macintosh G3 and presented using PsyScope (Cohen, MacWhinney, Flatt & Provost, 1993). Lexical decision responses were made by pressing either the left button (labelled NO) or the right button (labelled YES) on a PsyScope response box.

Experiment 1A – Results and Discussion

For this and each of the following experiments, mean decision latencies, mean error percentages, and homophone effect sizes for each category are presented in Table 1. In all analyses, data were analyzed with subjects ($F1$ or $t1$) and, separately, items ($F2$ or $t2$) treated as random factors.

To test the view that whole-word units are the important orthographic units for feedback activation, we conducted a 9 (homophone category type) X 2 (homophony) ANOVA to see if the effects of homophony varied by category. The overall homophone effect was significant in the latency analysis ($F1(1, 34) = 6.73$, $p < .05$, $MSE = 3514.11$; $F2(1, 86) = 4.26$, $p < .05$, $MSE = 916.53$), and in the error analysis ($F1(1, 34) = 18.87$, $p < .001$, $MSE = 128.50$; $F2(1, 86) = 18.86$, $p < .001$, $MSE = 36.66$). Thus, we confirmed the existence of homophone effects in LDT, replicating the results of Pexman et al. (2001), but here with a larger set of items and with consonant string foils. There was a main effect of category in the latency analysis ($F1(8, 27) = 3.81$, $p < .01$, $MSE = 3422.01$; $F2(8, 86) = 2.37$, $p < .05$, $MSE = 1514.47$) and in the error analysis ($F1(8, 27) = 5.08$, $p < .01$, $MSE = 54.31$; $F2(8, 86) = 1.90$, $p = .07$, $MSE = 46.84$). The interaction of category and homophony was not significant in the latency analysis ($F1(8, 27) = 1.71$, $p = .13$, $MSE = 4446.21$; $F2(8, 86) = 1.47$, $p = .18$, $MSE = 916.53$) but was significant in the error analysis by subjects ($F1(8, 27) = 5.19$, $p < .01$, $MSE = 38.05$; $F2(8, 86) = 1.71$, $p = .11$, $MSE = 36.66$). These effects indicate that the size of the homophone effects differed somewhat across the nine categories of homophones. Since this LDT involved consonant string foils, decisions could be made on the basis of relatively shallow processing.

As illustrated in Table 1, none of the homophone effects were significant in both latency and error analyses. Significant latency effects were observed for the Body Only and Onset and Body categories, and significant error effects were observed for the Single Vowel Only, Silent E or Word Internal Dipthong, /-s/ Morpheme, and Silent Onset and Body categories. In the case of the Single Vowel Only and Silent Onset and Body categories, error rates were relatively high for the homophones (15.0 % and 10.0 %, respectively). These error rates are surprisingly high for a LDT involving consonant string foils, and suggest that some of our participants may not have known some of these homophones (e.g., BERTH, WHOLLY, etc.). In the latency analyses for these categories, which include only correct responses, there were no differences between latencies for homophones and latencies for control words. Thus, the error effects in these categories may not really be indicative of orthographic competition. Hence, in the following experiments we draw conclusions only about homophone effects that are significant in both latency and error analyses.

Table 1: Homophone Effect Sizes

Homophone category	Example	Experiment 1A (consonant string foils) RT	Error	RT effect	Error effect	Experiment 1B (pseudoword foils) RT	Error	RT effect	Error effect	Experiment 1C (pseudohomophone foils) RT	Error	RT effect	Error effect

Experiment 1B – Results and Discussion

In the 9 (homophone category type) X 2 (homophony) ANOVA, the overall homophone effect was significant in the latency analysis ($\underline{F}1(1, 36) = 43.01$, $\underline{p} < .001$, $\underline{MSE} = 3118.18$; $\underline{F}2(1, 86) = 21.57$, $\underline{p} < .001$, $\underline{MSE} = 2966.35$), and in the error analysis ($\underline{F}1(1, 36) = 75.17$, $\underline{p} < .001$, $\underline{MSE} = 139.16$; $\underline{F}2(1, 86) = 18.09$, $\underline{p} < .001$, $\underline{MSE} = 150.30$). The main effect of category was significant in the latency analysis ($\underline{F}1(8, 29) = 5.55$, $\underline{p} < .001$, $\underline{MSE} = 3147.14$; $\underline{F}2(8, 86) = 2.52$, $\underline{p} < .05$, $\underline{MSE} = 6521.49$) and in the error analysis ($\underline{F}1(8, 29) = 8.39$, $\underline{p} < .001$, $\underline{MSE} = 77.04$; $\underline{F}2(8, 86) = 2.19$, $\underline{p} < .05$, $\underline{MSE} = 178.82$). Importantly, the interaction of category and homophony was significant in the latency analysis ($\underline{F}1(8, 29) = 5.74$, $\underline{p} < .001$, $\underline{MSE} = 3007.84$; $\underline{F}2(8, 86) = 2.34$, $\underline{p} < .05$, $\underline{MSE} = 2966.35$) and was significant by subjects in the error analysis ($\underline{F}1(8, 29) = 11.69$, $\underline{p} < .001$, $\underline{MSE} = 74.91$; $\underline{F}2(8, 86) = 1.80$, $\underline{p} = .09$, $\underline{MSE} = 150.30$). These effects indicate that the size of the homophone effects differed across the nine categories of homophones. This result confirms that homophone effects vary by category and reveals that the source of homophone effects is not only competition from whole-word orthographic units. Thus, it is not the case that homophone effects arise whenever one phonological representation maps onto two orthographic representations. The magnitude of homophone effects seems to depend to some extent on competition between orthographic units that represent the sublexical structure of the homophones.

As illustrated in Table 1, homophone effects were observed in this experiment for 5 of the 9 types of homophones. The largest homophone effects seemed to arise in the categories of homophones that differ from their high frequency mates in onset structure (as long as the onset is articulated, since there was no effect in latencies for the Silent Onset and Body category), body structure, or by a single vowel grapheme (although not for the EA or EE Grapheme category).

Notably, the /-ed/ Morpheme homophones actually produced an effect in the reverse direction, while the /-s/ Morpheme homophones produced a null effect in the latency analysis. A tentative conclusion is that homophone effects do not arise for homophones that differ in morphological structure from their homophone mates (e.g., GUESSED-GUEST). Before interpreting this result any

further, we examined effect sizes for all categories again in Experiment 1C.

Experiment 1C – Results and Discussion

As in Experiment 1B, the overall homophone effect was again significant in the latency analysis ($F1(1, 40) = 77.58$, $p < .001$, $MSE = 9481.57$; $F2(1, 86) = 35.62$, $p < .001$, $MSE = 7658.91$), and in the error analysis ($F1(1, 40) = 170.92$, $p < .001$, $MSE = 138.34$; $F2(1, 86) = 27.68$, $p < .001$, $MSE = 212.49$). There was a main effect of Category in the latency analysis ($F1(8, 33) = 7.93$, $p < .001$, $MSE = 7307.81$; $F2(8, 86) = 2.24$, $p < .05$, $MSE = 13926.27$) and in the error analysis ($F1(8, 33) = 24.87$, $p < .001$, $MSE = 87.94$; $F2(8, 86) = 2.59$, $p < .05$, $MSE = 235.16$). There was also an interaction of Category and Homophony that was significant by subjects in the latency analysis ($F1(8, 33) = 2.74$, $p < .01$, $MSE = 7082.59$; $F2 < 1$) and in the error analysis ($F1(8, 33) = 13.20$, $p < .001$, $MSE = 87.14$; $F2\ (8, 86) = 1.54$, $p = .16$, $MSE = 212.49$). These effects indicate that the size of the homophone effects differed across the nine categories of homophones.

As in Experiment 1B, the greatest homophone effects in Experiment 1C were observed in the categories where homophone pairs differed by a vowel grapheme or by onset-body units. These effects affirm the notion that graphemes and onset-body units are important sources of competition for homophones. The implication is that these units receive feedback activation from phonology.

The /-ed/ Morpheme category demonstrated facilitation for homophones in Experiment 1B, yet, in Experiment 1C with pseudohomophone foils, we found that this facilitation disappeared and a null homophone effect was observed instead. This finding, along with the relatively small homophone effects observed for the /-s/ Morpheme category across foil conditions, suggests that homophone effects are not generally observed for pairs of homophones that have different morphological structure. There are two possible interpretations of these null homophone effects. One interpretation is that the orthographic representations for the two members of the homophone pairs are so similar that no competition arises. The second interpretation is that the orthographic representations for the two members of the homophone pairs are so different that no confusion or competition arises. We would tend to support the latter interpretation. If one ignored morphological structure, the homophones in the /-ed/ Morpheme category could be classified as Body Only homophones. Yet the Body Only homophones produced quite robust homophone effects compared to those produced by the /-ed/ Morpheme homophones. Therefore, the morphological structure of the /-ed/ homophones is an important factor in explaining the null (and sometimes facilitory) effects for that category. Homophones like GUESSED, that have different morphological characteristics than their homophone mates (GUEST), are apparently not confused with their homophone mates at the orthographic level. The extra morpheme /-ed/ seems to create an orthographic representation that is easily distinguished from the orthographic representation for the homophone mate.

As in Experiment 1B, the homophone effect for the Silent Onset and Body category in Experiment 1C was not significant in the latency analysis (although it was significant by subjects in the error analysis). Again, there are two possible interpretations for a null (or relatively small) homophone effect. One possible interpretation is that the representations for the words in these homophone pairs are so similar that minimal competition arises. That is, 'silent' letters may not have much bearing on the nature of orthographic representations for words like WHOLLY or KNOT. Hence KNOT may be encoded very much like NOT, with little competition arising. The second interpretation is that the representations for the words in these pairs are so different that minimal competition arises. That is, because the onsets and many of the bodies are orthographically different within the homophone pairs, KNOT may be easily distinguished from NOT, resulting in minimal competition. We tend to favour the first interpretation. The reason for this is that the homophone effect for the Onset and Body category is much larger than the homophone effect for the Silent Onset and Body category. The fact that the effect size is markedly smaller for the Silent Onset and Body category suggests that the silent onsets are not competing in the same way that the articulated onsets are, causing smaller (non-significant) homophone effects.

General Discussion

The purpose of the present research was to conduct a precise examination of the orthographic factors that modulate homophone effects, in order to determine the grain size of units activated by feedback activation from phonology.

The homophone effects observed in the experiments reported here provide support for the notion that phonology is activated in the process of visual word recognition and feeds back to units in orthography. We also observed differences in the extent to which different types of homophones produced homophone effects. Analysis of effect sizes for our homophone categories revealed that homophone effect sizes varied by sublexical orthographic overlap of homophone mates. Homophone effects were greatest when the members of homophone pairs differ by a single vowel grapheme, or by the word body, or by the word body and articulated onset, within one morpheme boundary. In terms of identifying precisely what the levels of sublexical representation are, the trends in our data suggest that the levels likely correspond to graphemes, and onsets and bodies. We acknowledge, however, that the ambiguities inherent in the orthography of English homophones (e.g., some of our homophones differed slightly on orthographic properties other than those defined by the category labels, many of our categories were "grapheme" categories since these are the most common type of English homophone pairs) prevent us from making stronger conclusions. Nonetheless, the cross-category differences in our homophone effects make it apparent that the feedback

process does not reflect a mapping of phonology onto only whole word constituents at the orthographic level. This is not to say that lexical units are not also involved in the feedback process. According to the model depicted in Figure 1, activation at sublexical levels within the orthographic units feeds up to the lexical level. Presumably, activation at the lexical level must reach a certain point before a response is made. For homophones, responses seem to be delayed by competition at sublexical levels within the orthographic units. These delays are most obvious when an LDT is difficult (e.g., with pseudohomophone foils), because a higher threshold of activation is set and hence competition must be more fully resolved before a response is made.

These data provide support for a fully interactive model of word recognition, in which sublexical information is part of the orthographic and phonological components (e.g., Plaut et al., 1996; Taft & van Graan, 1998; Van Orden & Goldinger, 1994). The homophone effects reported in this paper suggest that there is bi-directional activation between the orthographic and phonological components of such a model, and that this activation is captured in several different grain-sizes of representation.

Abstract

Various characteristics can be encoded to define the source of particular information. How these characteristics interact to describe and define a source has so far been ignored. Our work focuses on the representation of source information in memory using the General Recognition Theory. The results are discussed in relation to current modelling efforts.

Introduction

How is a source defined? How do we represent context information about an event? How do we use this information in source monitoring? Source monitoring refers to the proper attribution of an item to its source (Lindsay and Johnson, 1991; Johnson, Hashtroudi, and Lindsay, 1993). Sources may be defined by a variety of characteristics, including but not limited to size, font, location, cognitive processes at encoding, affect, and so on. For written material, font, location, size, and possibly the syntax and structure used in a part of text may identify a part of text as a source. Memory for source is vulnerable, and source misattributions (SM) are common. Such errors may arise due to (1) failure of cognitive processes underlying the judgment, (2) adoption of a lax criterion which does not involve deliberate and conscious consideration of each judgment, and (3) similarity of the sources to such an extent that they are indistinguishable from one another. In other words, source monitoring involves normal memory processes and decisional processes, and a separation of the two can yield a better understanding of how sources are actually defined and how decisional processes can fail and cause SM errors.

Recently, a number of multinomial models of source monitoring have been proposed (Bayen, Murnane, and Erdfelder, 1996; Batchelder and Reifer, 1990; see Batchelder and Reifer, 1999 for a review). These statistical models assume a processing tree with a single root. Each branch of the tree represents one possible path in the stage of the process, and each fork in the branch represents a possible division of probabilities for a specific outcome. The branches end in response categories, from which all the fork parameters are estimated. This type of modelling allows an analysis of every possible contribution to each factor and thus enables one to model a cognitive process into discrete stages, collect categorical data, and then estimate the contributions made at each stage.

The advantages of such a model are easily visible. Interpretations are made effortless by the simple tree structure. Assumptions of independence between various fork parameters allow one to divide and separate various components of a process and to demonstrate independence between these components. However, such representation of source information is not modelled by this technique, and as such, these modelling efforts are limited in capturing the global features of source monitoring.

There are at least two major limitations to multinomial modelling. The first involves the degrees of freedom in the estimation procedure. Given that there are often more parameters than categories, some parameters must be assumed equal. This may sometimes be beneficial, since a model is reduced to its minimal, simplest components. Unfortunately, even with this parameter reduction, one may still have more parameters than categories, and the estimation procedure will thus result in a number of possible models rather than a single possible solution. From this pool of resulting models, using goodness of fit tests, one must determine which model actually represents the expected design or the data.

A consequence of this is that as findings in the field increase, such a model is more difficult to grow because of the increase in the free parameters. A multinomial model will therefore be limited to more general processes and will not be able to model details of a process, such as how source information is represented in memory. A lack of understanding about the details of a process can, in turn, result in a misunderstanding of the process as a whole as well

as the relation of that process in the grand scheme of cognition.

The second limitation, already hinted at, is the requirement of assuming statistical independence between various fork parameters. What this means is that a process stage, modelled on a fork further down a tree, is thought to be independent of a process stage modelled further up the tree; no two processes can have dependence in such a model. As we will see below, this assumption presents a crucial limitation of multinomial models in capturing the representation of source information in memory.

How to test statistical independence

In a multidimensional setting of a source characteristics where various factors influence source memory and source judgments, how is one to assess independence while accounting for the influence of all memory and decision factors? Historically, for unidimensional stimuli, signal detection theory (SDT; Banks, 1970; see Swets, 1996) has been the method of choice for separating decisional and perceptual factors in perception and recognition. However, SDT does not allow for a test of independence and is also limited to the analysis of only unidimensional stimuli. Ideally, we would want a statistical technique similar to SDT that could also account for interactions of various dimensions on a recognition task while providing a test of independence and separation of decisional and perceptual factors. General Recognition Theory (GRT; Ashby and Townsend, 1986; Ashby, 1988), and the analytical method permitted by it (Multidimensional Signal Detection Analysis, or MSDA, Kadlec & Townsend, 1992a; Kadlec & Townsend, 1992b), meet our requirements.

GRT and MSDA

The GRT was developed by Ashby and Townsend (1986) in response to various issues that had been raised in perception research. These issues concerned the notion of independence and separability of the perception of stimulus dimensions as well as decisional factors. The GRT is a formal method of assessing independence and separability in terms of both stimulus dimensions and decisional processes. MSDA was then developed by Kadlec and Townsend (1992a) in order to facilitate the implementation of GRT in perception studies. This analytic method maps the traditional SDT parameters of sensitivity (d') and response bias onto a multidimensional scheme and permits us to analyse both interaction and independence between various stimulus dimensions.

Multidimensional signal detection analysis MSDA was originally developed to analyse the effects of manipulation on the perception of a stimulus, when the manipulations are varied on a number of dimensions (Kadlec, 1995). An example study would be one that looks at the dependence of the perception of eyebrow curvature on the perception of lip curvature. First, we would need a feature-complete factorial design, and we would create this by manipulating each of the two dimensions on two levels. We would thus manipulate each of the two dimensions on two levels. Thus the eyebrows will be varied on two levels (low and high curvature) and the same manipulation would be used for lip curvature. Table 1 demonstrates this matrix for all variations of stimulus A.

Table 1: Example of a feature-complete factorial design.

	Eyebrow Curve	
Lip Curve	Low $_{(a)}$	High $_{(b)}$
Low $_{(i)}$	A_{ai}	A_{bi}
High $_{(j)}$	A_{aj}	A_{bj}

The participant will see stimuli, which vary on two levels of two dimensions. It should be noted that the stimuli at each level vary only slightly from the stimuli at the other level. This is mainly due to the fact that the final analysis will be based on the amount of errors committed during the task, and simplifying the task and making the difference between the stimuli obvious may result in a near absence of errors.

In a typical experiment utilizing this design, participants are given a practice session in which they view the set of stimuli, one at a time, varied on the given dimensions, and make judgments about their location at the different levels of the dimensions. In other words, a participant who views stimulus Abj must try to categorize this stimulus on both dimensions. The correct response for this stimulus is high eyebrow curvature and high lip curvature. There are three types of errors that could be made in the categorization of each stimulus. These errors can be tabulated, resulting in proportions of each type of error, which then represents the volume under the distribution in one of 4 possible response regions. These response regions can be represented by normal distributions in multiple dimensions.

How could we, from these data and types of distributions, answer questions regarding independence of dimensions and decisional boundaries? In order to answer such questions, a slightly different view of the graphs must be utilized. Consider a plane passing horizontally through all the normal distributions in this multidimensional space at a given density level. Examining such a plane from above would yield a topography of the distributions, as can be seen in Figure 1.

The shape of these distributions corresponds to three types of independence (Ashby & Townsend, 1986). The first type is perceptual independence (PI), which is a statistical form of independence. PI is stated when for a stimulus Abj:

$$fbj(x,y) = gbj(x)*gbj(y)$$

In this equation g(x) refers to marginal densities, which are obtained by integrating (measuring the area under the curve) the two-dimensional density distribution across one dimension. Marginal densities can be thought of as the picture of a density distribution as would be taken from having a camera parallel to a dimensional axis.

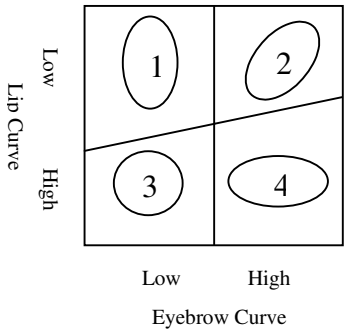

Figure 1: Topography of the distributions

PI is a strictly statistical form of independence and can be likened to coin toss probabilities, where the probability of obtaining two heads (assuming a fair coin; p(1H) = 0.5) is equal to the product of the probability of obtaining one head by the same probability:

$$p(2H) = p(1H) * p(1H) = 0.25$$

Thus PI asserts that the perception of one dimension within a stimulus is not dependent on the perception of the other dimension. From the topographical diagram, PI is represented by circular distributions and distributions which are elliptical but parallel to the axis of one dimension. From the diagram it may be observed that within stimuli 1, 3 and 4 the two dimensions are perceptually independent and the two-dimensional density distributions are equal to the product of the marginal densities of the stimulus on the individual dimensions.

Another form of independence, called perceptual separability (PS), is taken to exist when within one level of one dimension, the levels of the other dimension do not affect perception. In this case,

$$gi1(x) = gi2(x) \text{ and } gj1(x) = gj2(x)$$

where 1 and 2 refer to stimuli 1 and 2, i and j represent the two levels of eyebrow curvature, and g(x) refers to their marginal density distributions. If the two marginal distributions at the levels of one dimension (say high eyebrow curvature) are equal, then levels of the other dimension (lip curvature) do not influence the perception of the eyebrow curvature.

A third form of independence is decisional separability (DS). Recall that within the single dimension signal detection framework, a decisional boundary was set between the two distributions. Here too, within the multidimensional framework, some decisional boundary must be set. This decisional boundary is set by the participant and defines the area within which a stimulus will be identified by its specific characteristics. In our example, a decisional boundary must be set in order to differentiate between faces that vary differentially on eyebrow curvature and lip curvature. In other words, the decisional boundaries divide the multidimensional space into regions that define specific stimuli. Within this context, DS is observed when the decision about one dimension is not influenced by the decision made on the other dimensions. In our topography, DS holds when the decisional boundaries are parallel to the dimensional axis.

Methodology

From the above description of MSDA and its required experimental paradigm, it is more apparent how we would go about testing the independence of various source characteristics in a final source judgment. What we need is to create a feature-complete factorial design of at least two stimulus characteristics that can define a source, and then conduct our analysis on these dimensions.

Our study uses the characteristics of written text to assess this independence. The dimensions of written text tested are limited to size (large vs. small) and location (top vs. bottom). Within a multinomial framework, these two dimensions would have to be assumed independent of one another. In other words, independent of decisional biases, memory for an item being on top should have no effect on the memory of it being large. Such a model would represent a very basic and simple framework in which all sources are believed to be equal; if source characteristics do not interact and are independent, then any combination of the characteristics is remembered equally well.

Below we will present data to show that in this case, the assumption of independence is invalid, thus lying outside the structure of a multinomial model of source memory. Because the question of how various characteristics interact to define a source is central to the concept of source memory, we propose that multinomial models are limited in that they cannot capture this fundamental aspect of source memory.

Experiment 1

Participants

Eighteen undergraduate students enrolled in an introductory psychology course at the University of Victoria participated in the study for bonus marks. Responses from 3 participants were excluded because of incompleteness due to shortness of time. Responses from an additional participant were excluded due to apparatus failure. Overall, data from 14 participants were analysed. All data were kept confidential and no one was penalized for non-participation.

Material

A word-list was composed using 256 five-letter words randomly selected from the Francis-Kucera Frequency Norms. Of the 256 words, 160 were used at study and the remaining words were used as controls (novel words). Study items were factorially manipulated on size (large or small), font (Times or San Sarif), and location (top or bottom). An IBM-compatible computer with an Intel 486 processor was used for the experiment. All presentations were made on a 17" computer monitor and responses made on the computer keyboard.

Procedure

Participants were informed that they would view a list of words on the computer screen, varying in location, size, and font. They were instructed to try and remember all aspects of the words, as their memory for the words as well as these attributes would later be assessed. Following the instructions, the study list of 40 words was presented, each for 3 seconds, with 1second inter-stimulus-interval.

Immediately following the study phase, the test phase was conducted. Participants viewed the previously studied words in addition to 16 new words not previously seen. The words appeared in a small, neutral font (courier) at the centre of the screen. The first task was to make a remember/know/new judgement.

Following the instructions on remember/know/new judgements, participants were instructed on the identification task. Questions assessing the recognition for various item characteristics followed the remember/know/new judgements. The three questions asking for the recognition of levels of the three dimensions were randomised in presentation, so that for one item, font was asked first, followed by location and size, but for another, size was asked first followed by location and font, etc.; the sequence was randomised.

For both the remember/know/new judgements and the item judgements, participants made their response by selecting the first letter of the response on a computer keyboard (‘ r’ for ‘remember’, ‘t’ for times font when making font decision and top when making location decisions, and so on). The task was not timed, and participants were encouraged to consider each judgement carefully. Following the first study and test phase, three more study and test phases continued with the same instructions.

Results

Responses were collapsed across all subjects. To minimize variability due to practice (at the beginning of the session) as well as variability due to fatigue (at the end of the session), only responses from trials 2 and 3 were analysed; responses from these two trials were then combined, after no significant difference between them was observed on a chi-squared test. Due to space limitations, the results on remembering and knowing will not be discussed here, but we will only comment that near identical interactions were observed for remembered and known items; for the analysis, results associated with “remember” and “know” judgments (i.e. studied items judged as “old”) were combined.

The results are reported following Kadlec (1995). All tests of DS, PS, and PI are Z-tests with at least $p < 0.1$, unless otherwise noted. DS and PS held for all dimensions, whereas PI failed for all items.

To simplify the interpretation, the results were collapsed on to two dimensions, size and location. The resulting distribution topographies are represented in figure 2.

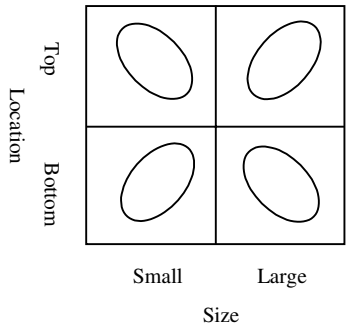

Figure 2: Schematic representation of results from experiment 1

The straight vertical and horizontal lines separating the distributions represent the decisional boundaries; they are parallel to the dimensional axese, because DS held for both dimensions. Furthermore, the distances between the distributions do not differ between the levels of each dimension, thus PS is also valid. However, PI has been violated in all instances, and in a consistent pattern: there is a strong positive tendency to remember large items as being on top and small items on the bottom, while there is a strong negative tendency to remember small items on top and large items on the bottom. Clearly, source definitions formed from these characteristics will result in a memory bias independent of decisional processes such as response biases. In other words, recolllected large words have a “topness” associated with them, and are dissociated from a “bottomness”, while the opposite is true for small words.

In order to further validate our results, we conducted a similar study, but we eliminated the presentation of a font dimension all together, as well as the remember/know judgments.

Experiment 2

Participants

Twenty-one undergraduate students enrolled in an introductory psychology course at the University of Victoria participated in the study for bonus marks.

Materials

One hundred sixty words with a frequency rating of 1 were obtained from the Francis-Kucera Word Pool and randomly divided into four lists of forty words. List presentation was fully counterbalanced. All the words were presented in random order in a study phase and were factorially manipulated on size (large and small) and location (top or bottom).

Procedure

Participants were informed that they would view a list of words on a computer screen, and that these words would vary on two dimensions, location on screen and font size. They were then instructed to do their best to 'remember' the words and how they were presented, as they would later be tested on these attributes. Firstly, in phase 1, a list of 40 words was presented for approximately 2 seconds each with an inter-stimuli interval of 1 second. Following this was a test phase in which subjects were asked 3 questions about 80 words (40 studied and 40 novel words): "Is this word old (o) or new (n)?", "Did it appear on the top (t) or bottom (b)?", and "Was it presented in a large (l) or small (s) size font?". The order of the questions was randomised. Subjects responded using a keyboard with the abbreviated letters corresponding to the responses to which they stand for (e.g. (o)=old). This task was not timed. Phase 2 followed and was a mere repetition of phase 1 but with different word lists. The whole session lasted 40 to 50 minutes.

Results

All tests of DS, PS, and PI are two-tailed Z-tests with at least $p<0.05$, unless otherwise noted. Analysis of the compiled old-correct matrix (where subjects responded "old" and were correct in doing so, whether in phase 1 or phase 2, or whether the new/old question preceded or followed the attribution questions) revealed an interaction of source characteristics, identical to that of experiment 1, represented in figure 2. Whereas DS and PS held for the two dimensions, PI failed in every case, such that there was both a positive dependency between "bottomness" and "smallness" and a positive dependency between "topness" and "largeness". Alternatively, it is also true that as words appear closer to the top of the screen, they are more likely to be remembered as having appeared in a larger size font. In analysis of unremembered items (where the item was presented, but judged as "new"), a bias was observed for words presented on top of the screen and in large size. This suggests that people have poor memory for such items; this and other result will be discussed below.

Discussion

How are source characteristics defined then? Using MSDA, we were able to separate decisional factors from memory factors. Our results are thus not based on a any decisional biases of the participant. In other words, it is not the case that participants recall an aspect of an item (e.g. having been presented in large size) and then infer from this information that the word must have been presented on top. If it were the case that participants recalled information on one dimension and inferred information on the other dimension, different criterion measures (C's) would have been observed at each level of any one dimension. However, measures of C were identical at every level of all dimensions, suggesting that decisional factors did not play a role at generating the observed patterns.

Perceptual separability also held for both dimensions, which suggest that memory for large items is no better than memory for smaller items, and that memory for items on top is no better than memory for items on the bottom. If this were not the case, d' measures for items presented on top or bottom would have differed when varied across the two sizes, and/or d' measures for items presented in large or small size fonts would have differed across the two different locations.

As both DS and PS held for both dimensions, we can infer that (1) decisional factors did not play a role in producing the observed pattern of results, and (2) that global features of the stimuli did not play such a role either. It can therefore be concluded that the interaction of the various source characteristics is a pure memory process.

This has implications for how source information is stored in memory. Our results suggest an information-compression taking place during encoding and/or storage of the source characteristics. In effect, error for the overall storage of such source information (size and location) is minimized by reducing error on the most frequently occurring instances of such a source. Source definitions composed of large items presented on the top of the screen are particularly common in all printed media such as newspapers, magazines, web pages, etc. Meanwhile, it occurs rarely that small print appears on the top part of a display, and the same is true for large items presented on the bottom of the screen. It may be the case that, in order to minimize errors on these frequently occurring source types, we are introducing biases into the process.

We believe that the compression (or consolidation) account is the most appropriate for our data; i.e. the way new information is stored is affected and directed by prior knowledge. This is analogous to perceptual illusions: perceptual illusions may exist as a consequence of a biased set of inputs which then results in a biased perception of illusory, but-otherwise-neutral items. It is likely that the same processes that cause perceptual illusions are responsible for the effects obtained here. In essence, our results may be demonstrative of a form of memory illusion, very distinct from prior studies of memory illusions with relation to eyewitness memory. In the case of eyewitness memory, some researchers (i.e. Loftus, Miller & Burns, 1978) suggest that presentation of secondary, post-event information impairs memory for an event by altering its contents. We suggest that *prior knowledge* impairs what new information

can be learned in the first place, by limiting how the new information is represented.

What is the relation between our results and multinomial models of source monitoring? We suggest that multinomial models will be unable to incorporate our data in a meaningful way, because of inherent limitations in the estimation procedure for such models. Here, we are referring to the fact that multinomial models would have to assume independence between various source characteristics and, as our results show, such assumptions would be invalid. Therefore, such modelling techniques will not be able, in the long run, to present an accurate model of source memory.

Our results do not falsify any present uses of multinomial models. Multinomial modelling is insensitive to biases for sources, thus such modelling could capture the more general nature of our results. However, such a technique inherently does not allow for any type of representation of source memory and we believe that such a representation is crucial for an accurate model of source memory.

Recall from our results that studied items that were judged as "new" were more often items that had been presented on top of the screen and in large font. Although statistical analysis of this trend was not conducted for this paper, this may be a real effect worth considering, as it suggest that certain sources (or certain combinations of source characteristics) are easier to remember, such that this source combination may even affect item detection. Again, as statistical analysis of this was not conducted, we are only speculating on this point, but it is consistent with our findings, as they suggest a form of memory consolidation taking place.

Future work in the area can thus focus on assessing how sources are defined, as the tools now exist to answer such specific questions. Modelling efforts should also attempt to incorporate this representational information, as this will, without doubt, contribute to a more complete understanding of human memory.

Acknowledgements

This research was supported in part by a grant to the third author from the National Science and Engineering Research Council of Canada (NSERC). We thank Aidan Quigley for his help in collecting data.

Abstract

We use the literature on mechanical reasoning to derive predictions about how people will test a mechanical rule. In the presence of a single rule we predict significantly more selections of tests in which the hypothesized cause is manipulated than in the presence of two rules: the original and one casting doubt on the sufficiency of the hypothesized cause for the effect. We describe an experiment using Wason's selection task that confirms our predictions and go on to discuss the implications of our results for recent work on causal cognition.

Introduction

Much of our everyday reasoning concerns the operation of mechanical devices. Many of our interactions with such devices, from figuring out how to program the VCR to mastering the newest piece of software, require us to draw inferences, make predictions and test hypotheses. Some of this reasoning is very important and, accordingly, mistakes can be costly. For example, the Chernobyl explosion (see Medvedev, 1991) has been used by Johnson-Laird (1993) to illustrate how biased interpretation of evidence relevant to an hypothesis about a device can lead to disaster. Fortunately, not all faulty mechanical reasoning leads to such calamitous consequences and sometimes we even have the luxury of experimenting with a device in order to see how it works. For example, the paradigmatic case in the literature on discovery learning (Khlar & Dunbar, 1988) is how people acquire the ability to operate a device by self-guided trial and error learning.

In this paper we will be concerned with the principles that determine the tests that people choose to carry out in order to examine an hypothesis about a mechanical device. Consider, for example, a conditional hypothesis concerning the cooling system in a factory:

(1) If the valve is open then water flows through the pipe.

Our concern is how people will go about testing such a rule rather than how they should test the rule. There are four cases which seem intuitively relevant here: the valve being open; the valve being closed; water flowing through the pipe; and water not flowing through the pipe. According to a normative theory based on the hypothetico-deductive method (Popper, 1959), in order to test the rule participants should chose to discover information about what happens both when the valve is open and when there is no water running through the pipe. Only these tests can provide evidence that falsifies the rule. Much research suggests that people do not consider these to be the best tests with which to examine a hypothesis and we do not think the case of mechanical reasoning is likely to be any different in this respect.

We suspect, however, that causal hypotheses concerning a mechanical device - such as the one above - will elicit a very specific pattern of testing behaviour amongst participants. The detail of our suspicions and a more comprehensive rationale will be presented in the next section.

Mechanical Reasoning

There is a variety of work on mechanical reasoning in the literature all of which suggests that people use representations that are in some way analog to the device being reasoned about. For example, Hegarty (1992) has proposed an account of how people think about devices claiming that mechanical reasoning processes are isomorphic to the structure of the device that is the subject of those processes. Hegarty's theory was intended to explain results obtained using a mechanical reasoning paradigm where participants are shown static images of pulley systems and are asked to predict the effect of some manipulation of the device. For example, participants might be asked how one or other of the pulleys in the image will move when a rope is pulled. Hegarty's data, both from eye-movements and gross reaction times, suggest that in making inferences about a mechanical device, people animate contiguous elements of the system piecemeal, by inferring a causal chain of events from the input of the system to its output.

Other work supports this conclusion. Schwartz & Black (1996), in showing that people can induce rules to describe a system based on mental depictions of that system, provide evidence suggesting that the initial depictions are constructed in a causal order. That is, in the absence of a rule, people appear to mentally

simulate the effects of a manipulation to the system in the direction of cause and effect.

People's piecemeal animation (Hegarty, 1992) and depiction (Schwartz & Black, 1996) of mechanical devices, suggest that their representations of mechanical devices respect the causal structure of the device. Furthermore, when people perform thought experiments involving those representations, they perform them so as to observe the effects on the system of the manipulation of a causal agent.

Testing Mechanical Hypotheses

We assume that in testing a causal hypothesis concerning a mechanical device people will form a representation of the hypothesized rule that respects its causal direction. So, given hypothesis 1:

If the valve is open then water will flow through the pipe

we expect participants to encode in their representation the information that, under this hypothesis, the valve is of causal significance with respect to water flowing through the pipe.

Given previous work on how people animate and perform mental experiments on models of devices, we expect participants, when imagining the possible consequences of performing a test on the system described in the hypothesis, to represent the consequences of the antecedent condition being in a certain state. That is, we would expect participants to be more interested in tests that respect the causal structure of the hypothesis than in tests that require backwards reasoning from changes in the effect to changes in its putative cause. Specifically, we expect participants to be more interested in cases where the cause is present or absent than in cases where the effect is present or absent.

The prediction that participants will be interested in cases where the effect is absent is a risky one, as participants are not normally interested in the false antecedent case when testing a conditional rule. Indeed, Oaksford and Chater's (1994) probabilistic account of how people test conditional rules claims that the false antecedent case is never informative. The situation for causal conditional rules is very different, however, where interest in the false antecedent case might be interpreted as being due to the use of a counterfactual strategy in testing the causal status of the antecedent. Mackie (1974) claims that we infer causality not only from repeated observations of contiguous events but also from a consideration of what might be observed in the absence of the putative cause. If the effect is also absent under these circumstances then we infer a causal relationship between the two. Harris, German & Mills (1996) have demonstrated such a strategy in the causal reasoning of children aged between 3 and 5 years.

There are, however, conditions under which we would not expect participants to be primarily interested in tests that respect the causal structure of the device. For example, if the hypothesis is presented at the same time as a second rule:

(1) If the valve is open then water will flow through the pipe
(2) *If the pipe is free from blockages then water will flow through the pipe*

where this second rule specifies an additional antecedent for the consequent, then we would expect participants to select fewer tests where the hypothesized cause is manipulated. This is because the additional antecedent introduces a potential disabling condition (Cummins et al 1991) for the hypothesized cause. This would mean that a failure to find the effect in the presence or absence of the cause might be attributable either to the hypothesized cause being insufficient to produce the effect or to the absence of the enabling condition. In the example above, the valve being open and the pipe being free from blockages might be conjointly necessary for water to flow through the pipe. If this is the case then examining the results of tests involving manipulation of the valve is unlikely to be revealing of the truth or falsity of the rule in the absence of information about the presence or absence of the enabling condition.

A Mechanical Selection Task

To test our intuitions about how causal rules about a mechanical device are represented and hence tested, we constructed a mechanical version of Wason's selection task (Wason, 1968). In our version of the task participants received a scenario (see below) which supplied a context for a conditional rule describing a causal relationship between the state of a component of the device and some output. Underneath were printed four cards representing the true antecedent, the false antecedent, the true consequent and the false consequent states of affairs. To test our hypotheses concerning the conditions under which participants would be primarily interested in tests of the hypothesis that manipulated the putative cause, we constructed a second version of the task. This second version was achieved by adding a second rule to the problem specifying an additional antecedent for the same outcome (see 1 and 2 above).

Our manipulation of number of rules is directly analogous to the presentation of additional antecedents in the conditional arguments task (Byrne, 1989). Participants who receive conditional reasoning problems that specify an additional antecedent are significantly less likely to draw the valid Modus Ponens and Modus Tollens conclusions than are participants who do not receive information about an additional

antecedent. This may be interpreted as the result of the additional antecedent causing participants to doubt the sufficiency of the first antecedent for the rule.

Byrne's work was an extension of experiments reported by Rumain, Connell & Braine (1983) who showed that presenting participants with a second conditional rule that specified an alternative antecedent for the consequent suppressed the rate at which the invalid Denial of the Antecedent and Affirmation of the Consequent inferences were drawn. Recently, Feeney and Handley (2000; Handley, Feeney & Harper, 2000) have described the results of selection task experiments where participants received a second rule specifying an alternative antecedent for the consequent in the rule to be tested. Across a series of six experiments large and reliable rates of suppression of Q card selections were found. A meta-analysis of five of the six experiments showed that the rate of not-P card selection was also significantly lower in the presence of an alternative antecedent.

The Q and not-P cards on the selection task are logically equivalent to the DA and AC inferences. Suppressing the rate at which they are selected is analogous to suppressing the rate at which the invalid inferences are made. One prediction about our mechanical selection task, therefore, is that the presence of a second rule specifying an additional antecedent should produce suppression on those cards which are logically equivalent to the MP and MT inferences i.e. the P and not-Q cards. However, we predict that this will not be the case.

Instead we expect rates of antecedent card selection (both true and false antecedent cards) to decrease in the presence of an additional antecedent. This prediction is based on our assumption that in reasoning about an hypothesis concerning a mechanical device people will incorporate into their representation the hypothesized causal status of the antecedent with respect to the consequent. Based on previous work (Hegarty, 1992; Schwartz & Black, 1996) we hypothesize that they will prefer to examine the results for the effect of manipulating the antecedent rather than vice versa. Such a testing strategy should be significantly reduced in the presence of a second rule containing an additional (and perhaps conjointly necessary) antecedent.

Method

Participants: 90 female and 21 male students at the University of Durham participated in this experiment. Participants' mean age was 20.5 years and age ranged from 17 to 42 years.

Design, Materials and Procedure: There were two groups of participants in this experiment. The first received a one-rule selection task containing a scenario and just one rule. The other group of participants received a two-rule selection task comprising of the same scenario and rule to be tested as well as a second rule specifying an additional antecedent for the consequent in the first rule. For all participants the scenario and the rule to be tested were as follows:

> *A friend of yours, who works in a factory, takes you on a tour of her place of work. She points to a large pipe and says that the cooling system in the factory obeys the following rule:*
>
> **If the valve is open then water will flow through the pipe**
>
> *You are interested in checking whether the cooling system does follow the rule your friend has told you about. Below are four cards which refer to tests that have been carried out on the cooling system. On one side of each of these cards is recorded whether the valve was open when the test was carried out whilst on the other side is recorded whether the water was flowing at the time of the test. Please indicate by circling the appropriate card or cards, which one(s) you need to turn over to decide whether the rule is true or false.*
> *Remember the rule you are testing is:*
>
> **If the valve is open then water will flow through the pipe**

The second rule received by half of the participants was as follows:

> **If the pipe is free from blockages then water will flow through the pipe**

Participants in this latter group were reminded that their task was to test the first rule. Finally, all participants saw four cards labelled 'Valve open', 'Valve closed', 'Water flowing' and 'Water not flowing'. They were asked to indicate those card(s) which were necessary in order to decide whether the rule was true or false.

Results

We performed three analyses on our results. The first examined the effects of experimental condition on individual card selection frequencies whilst the second was of the effect of number of rules on the rate at which antecedent and consequent cards were selected. In addition, we analyzed the frequency of various card combination selections.

Individual Card Selection Frequencies: Our first analysis was of the effects of our number of rules manipulation on the rate at which individual cards were selected in the experiment. These rates are presented in Table 1 below.

Chi-square analyses showed no significant effects of number of rules on the rate at which any of the cards were selected (P card: $\chi 2(1) = 1.73$, $p > .18$; not-P card: $\chi 2(1) = 1.40$, $p > .23$; Q card: $\chi 2(1) = 1.96$, $p > .16$; not-Q card: $\chi 2(1) = .15$, $p > .70$). As the presence of a

second rule has previously been found to significantly affect the total number of cards selected by participants (Feeney & Handley, 2000) we tested for an effect of our number of

Table 1: Percentage of participants selecting each card as a function of condition.

	P	Not-P	Q	Not-Q
One-Rule	84	40	37	21
Two-Rules	74	30	50	24

rules manipulation on the total selected in this experiment. This effect was not significant ($t(109) = .365$, $p > .71$). The mean total for the one rule condition was 1.82 cards (S.D. = .60) and 1.78 cards (S.D. = .74) for the two-rules condition.

Cause vs. Effect Selections: To test our predictions about cause and effect card selections we analysed the rate of cause and effect selections. For the purposes of this analysis we computed the number of cause and effect selections made by each participant, where a cause selection was defined as the selection of either of the antecedent cards and an effect selection as choosing either of the consequent cards. The mean numbers of each type of selection are shown in Figure 1 below.

We performed a 2x2 mixed design Anova on the cause and effect data. The between participants variable in this analysis was number of rules whilst the within participants factor was the number of selections concerning the hypothesized cause vs. the number of selections concerning the hypothesized effect specified in the rule. This analysis produced a non-significant main effect of number of rules ($F(1, 109) = .133$, MSE = .227), a highly significant main effect of cause vs. effect ($F(1, 109) = 33.40$, MSE = .385, $p < .001$) as well as a significant interaction between the within and between participant variables ($F(1, 109) = 4.94$, MSE = .385, $p < .028$). Tests for simple effects showed that

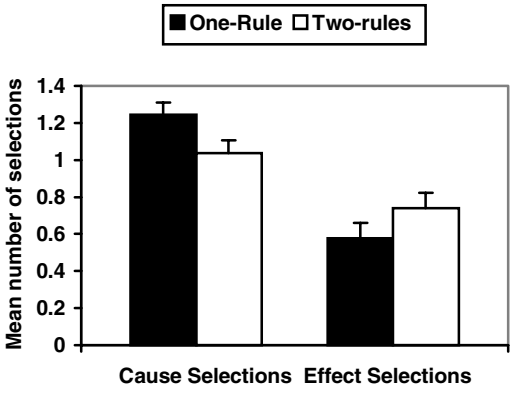

Figure 1: Mean number of cause and effect selections by condition.

there were significantly more antecedent (or cause) selections in the one-rule condition than in the two rule condition ($F(1, 109) = 4.964$, MSE = .243, $p < .028$). The difference due to number of rules on the rate of consequent (or effect) selections was not significant ($F(1, 109) = 1.965$, MSE = .369, $p > .16$).

Finally, in order to analyze the effect of our number of rules manipulation on relative rates of cause and effect card selections, we computed an index for each participant of their total of cause selections minus their total of effect selections. The effect of the number of rules manipulation on this index was significant ($t(109) = 2.22$, $p < .029$). In the one rule condition the mean score on this index was .667 (S.D. = .932) whereas in the two rule condition the mean score was .296 (S.D. = .816).

Card Combination Frequencies: Our final analysis was of the card combination frequency data from the experiment. As may be seen from Table 2, the rate of logically correct responding was not affected by our experimental manipulation with 4 out of 57 participants choosing the logically correct combination in the one-rule condition versus 5 out of 54 in the two-rule condition. The most striking effect of our number of rules manipulation on the combinations of cards that participants choose to select concerned the combined selection of the P and not-P cards only. In the one-rule condition 13 participants (23%) chose this combination whereas in the two-rule condition it was chosen by only 4 participants (7%). This difference is statistically significant ($\chi 2$ (1) = 5.07, $p < .02$) and is in the direction suggested by our hypothesis concerning how people represent and test causal rules concerning mechanical devices.

Table 2: Card combination frequencies as a function of condition.

	Condition	
Combinations	One Rule N = 57	Two Rules N = 54
p	13	13
not-p	2	1
q	0	5
not-q	0	0
p, not-q	4	5
p, not-p	13	4

not-p, q	2	2
not-p, not-q	4	5
q, not-q	1	1
p, not-p, not-q	1	1
p, q, not-q	2	0
all four	1	3

Discussion

The results of this experiment support our predictions about how people test causal rules concerning mechanical devices. Across both conditions we found a significantly greater rate of antecedent than consequent selection. This is not surprising and is probably true of most selection task experiments (although for an important exception, see below). Of much more immediate interest is the finding that the difference between the rate of antecedent and consequent card selections was significantly greater in the one-rule condition than in the two-rule condition. In addition, the rate at which people selected antecedent cards was significantly greater in the one-rule condition than in the two-rule condition although the (non-significant) rate of suppression due to the presence of a second rule was the same for each antecedent card. Finally, participants in the one-rule condition were significantly more likely to select the combination of cause present and cause absent cards than they were in the two- rule condition.

We argue that this pattern of results suggests that people's representation of the rule contains information about the putative causal status of the antecedent and when considering the possible consequences of the various tests of the rule people primarily consider tests where the hypothesized cause is manipulated. When compared to the results of selection task experiments where participants are asked to test a standard indicative rule, this experiment may be seen to have produced a very high rate (40%) of not-P card selection in the one rule condition. For example, in the meta-analysis reported by Handley and Feeney (2000) of single-rule conditions from five experiments on the standard indicative selection task, 24% of the 272 participants whose data were included were found to have selected the not-P card. We argue that the elevated rate of not-P selection found in this experiment is due to the use of a counterfactual strategy to test the causal claim made in the experimental rule. In addition to testing for the presence of the effect in the presence of the putative cause, participants were interested in looking to see whether the effect was present or absent when the hypothesized cause was absent.

Strikingly, when an additional antecedent calls the sufficiency of the putative cause into question, people are significantly less likely to select antecedent cards. A reduction in P card selections is expected given that the second rule may lead people to question the sufficiency of the antecedent for the consequent to occur. However, the selection of the not-P card may still be informative regarding the truth of the causal rule. Consider for example the two possible outcomes given the closure of the valve, the absence of water flow or the presence of flow. Assuming the device is working we may expect to observe an absence of water flow when the valve is closed. However, this absence may also be caused if the antecedent of the second conditional is not satisfied, that is if the pipe is blocked. Hence observing the absence of the effect in the absence of the cause is not informative about the truth of the rule. However, imagine instead that we observed water flowing when the valve was closed. This case would appear more informative regarding the question of whether the mechanical device is operating correctly. What our results suggest is that some participants consider only the first outcome. Hence, they regard the not-P card as uninformative and do not choose it.

Different Types of Causal Hypothesis?

Although our predictions were induced from the literature on mechanical reasoning, our results are of obvious relevance to the literature on causal cognition. For example, it is interesting to compare our results to those of Green & Over (2000) who examined decision theoretic effects in how people test causal conditional hypotheses such as the following:

(3) If you drink from the well then you will get cholera

Across all of their conditions, the rate of antecedent selections never exceeded the rate of consequent selections to the same degree as was true of our one rule condition. Collapsed across conditions, their rate of consequent selections was, in fact, marginally greater than the rate of antecedent selections (a total of 171 consequent selections vs. 169 antecedent selections). These results are in stark contrast to our own findings.

Green and Over's experiment was designed to test ideas concerning the relationship between the contingency table and causal hypothesis testing. Their results show that people are sensitive to the probabilities of the cause and the effect when deciding which cards to select. We believe that our results are different to theirs because we asked our participants to test a causal *mechanical* rule whereas their experiment concerned a causal *medical* rule. O'Brien, Costa & Overton (1986) have also found results suggesting that there are domain-specific differences in causal reasoning. In their experiment participants were asked what implications each of the four cases (*cause present + effect present*; *cause present + effect absent*; *cause absent + effect present*; *cause absent + effect absent*) had for a variety of hypotheses concerning medical and mechanical causal relationships. For all cases except the *cause absent + effect absent* case, participants were significantly less certain about the medical hypothesis than about the mechanical hypothesis.

One way to conceive of O'Brien et al's result is that people are unwilling to accept a medical hypothesis in the light of information about just a few exemplars whereas they have more confidence about the status of a mechanical hypothesis given a few confirming or disconfirming cases. In other words, causal medical

hypotheses require reasoning that is likely to be probabilistic in nature whereas causal mechanical hypotheses need not (of course it is possible to design a mechanical task that encourages probabilistic reasoning - see Kirby, 1994).

There are several factors that might be involved in causing one type of reasoning to be essentially probabilistic and the other deterministic. First, it is possible that our knowledge about organisms tells us that even in the presence of a cause, the effect might not occur. In other words, causal rules about organisms admit of many disabling conditions. In addition, illnesses have many possible causes. In Green & Over's example, someone drinking from the well might be immune to cholera or cholera might be present in the well, the local river and the nearby lake. Given all of these possibilities it makes sense that participants in O'Brien et al's study were unwilling to make decisions about the status of a medical rule in the light of information about individual exemplars. Similarly, it is unsurprising that participants in Green and Over's experiment evidenced probabilistic thinking.

Now think about testing a mechanical hypothesis. Such hypotheses are normally tested via intervention. That is, if you think that your car won't start because the plugs are dirty, you will clean the plugs and then try to start the car. If the car starts your hypothesis has been confirmed, if not then it has been disconfirmed. In either case it is unlikely that you will repeat the procedure several times in case of the operation of disabling conditions or alternative causes. Similarly, when interacting with a novel electronic device (see Klahr & Dunbar, 1988) people do not perform the same test several times in order to establish the effect of some manipulation. Their reasoning in such cases tends to be non-probabilistic.

This distinction, between probabilistic causal reasoning and consequential (or deductive) causal reasoning also relates to the literature on mechanical reasoning described in the introduction. The systems that Hegarty (1992) and Schwartz & Black (1996) required their participants to reason about were closed and so did not admit of disabling conditions or alternative causes. Of course, a particular manipulation to the system might not cause the expected effect but given the diagrams that people were shown, disabling conditions and alternative causes were unlikely to be available to reasoners. Accordingly, a strategy based on the piecemeal animation of the device in the causally appropriate direction will be adopted. For analogous reasons, our participants were interested in tests of the hypothesis about the cooling system that involved direct manipulations to the putative cause. Once the possibility of disabling conditions were introduced, they were significantly less interested in such tests.

An Influence of Spatial Language on Recognition Memory for Spatial Scenes

Abstract

Whether and how much the routine use of language influences thought is a perennially fascinating question in cognitive science. The current paper addresses this issue by examining whether the presence of spatial language influences the encoding and memory of simple pictures.

Introduction

In the last few years there has been a resurgence of interest in the question of whether and how much language influences thought. As Billman and Krych (1998) point out, this is a question that can be asked either at the level of the language system, or at the level of the linguistic form.

At the level of the language system, one can ask whether cognitive differences can be explained via cross-linguistic differences. The strong version of this hypothesis is well expressed in Whorf's (1956, p. 134) quote of Sapir: "[w]e see and hear and otherwise experience very largely as we do because the language habits of our community predispose certain choices of interpretation." Other scholars suggest a weaker version of the hypothesis, namely that language, while not determining thought, nonetheless influences how one thinks. Slobin's (1996) *thinking-for-speaking* hypothesis states that linguistic influences exist only when one performs a linguistically-mediated task (cf., Slobin, 1996).

Evaluation of the hypothesis at the level of the language system involves an examination of performance on non-linguistic tasks by speakers of different languages in order to determine whether there are language-related differences. Such examinations have yielded mixed results. Pederson and his colleagues (1998) and Levinson (1996) found that speakers of different languages performed differently on nonlinguistic tests of visual memory, including reconstruction of an array of objects, a clearly Whorfian result. Malt, Sloman, and Gennari (in press), on the other hand, found that Spanish speakers' judgments of similarity of videotaped motion events conformed to normal verb use in Spanish, but only when participants were instructed to use linguistic descriptions during the encoding phase of the experiment. This is consistent with a thinking-for-speaking (Slobin 1996) version of the Sapir-Whorf hypothesis. Furthermore, the language effect did not appear for the English-speaking participants, nor did Malt and her colleagues find a language effect on similarity judgments for artifacts, nor on recognition memory.

The other level at which language could influence thought is that of linguistic forms within a language. Evaluation of the hypothesis at this level involves comparing performance on non-linguistic tasks by speakers of the same language in conditions that invite different forms within the language. For example, Bower, Karlin, and Dueck (1975) found that participants rated new pictures as more similar to the one they had seen during encoding if they conformed to the linguistic description presented at encoding. Gentner and Loftus (1979) found an influence of the language presented at encoding on participants' recognition memory for pictures of events. Billman and Krych (1998) found effects of verbs present at encoding on recognition of videotaped motion events (but see Malt et al., in press).

Our research asks whether spatial prepositions can influence the way people encode and remember spatial relations. We chose spatial prepositions for several reasons. First, while many studies of the Whorfian question have focused on possible effects of verbs of motion on the encoding of events, there has been comparatively little work on the possible effects of prepositions on the encoding of static spatial relations. Spatial prepositions exhibit striking cross-linguistic variability, as demonstrated by Bowerman and Pederson's (in preparation) comparative study of the semantics of '*on*-terms' – terms related to contact and support. As Gentner (1981; Gentner & Boroditsky, 2001) points out, relational terms such as verbs and prepositions are a promising arena in which to seek Whorfian evidence. Relational terms are more variable cross-linguistically than nominal terms of comparable concreteness. This semantic variability suggests that there is a wide variety of plausible encodings consistent with the perceptual input. Thus, this arena may provide fruitful ground for the investigation of Whorfian effects.

In this research, we showed people spatial scenes under different linguistic encoding conditions, and later tested their recognition memory. Our goal was to determine (1) whether

spatial language influences spatial encoding and memory and (2) whether such influence occurs when there is no overt use of language, or is restricted to the case when spatial language is explicitly present. If we see language effects only when people are encouraged to utilize language at encoding, this will provide support for a thinking-for-speaking or, in our case, *thinking-for-comprehending* hypothesis. If, on the other hand, we see language effects under other conditions, this would leave open the possibility of language influencing cognition in a more comprehensive manner.

The logic of our studies is as follows. For each of the prepositions, we created a sentence and a triad of pictures that ranged in how well they fit the sentence (see Figure 1). The standard picture (the *initial* picture) was acceptably described. For each standard, there were two variants: the *plus* variant, which was a better exemplar of the spatial term, and the *minus* variant, which was a poorer exemplar (see Figure 1 below). Thus, the initial picture was somewhat ambiguous, but was designed so that the spatial term could apply to it, and the two variants were either more typical of the core prepositional category or less so. All of the pictures involved the same objects; the only source of variation was the spatial relation between the two objects. In preparing the pictures, every attempt was made to guard against a possible recognition bias for the *plus* variant (see Experiment 2).

Experiment 1a

Participants viewed pictures depicting static spatial relations - e.g., a marionette standing on a table or a coin in a hand. Half the participants read a descriptive sentence at the time that the pictures were encoded. After participating in unrelated experiments for about fifteen minutes, participants performed a recognition task that included the original pictures and two variants.

The recognition test included all three pictures - the initial picture, the plus variant, and the minus variant. If the presentation of language at encoding influences recognition memory, there should be different patterns of false alarms for the two groups. The group provided with sentences at encoding should be more likely than the control group to falsely claim that they had previously seen the plus variants of the pictures.

Method

Design. Encoding Condition (Spatial Sentences/Control), a between-subjects variable, was crossed with Recognition Item Type (Plus Variant/Initial Picture/Minus Variant), a within-subject factor.

Subjects. Thirty-six Northwestern undergraduates received course credit for their participation in this experiment. All reported being fluent speakers of English.

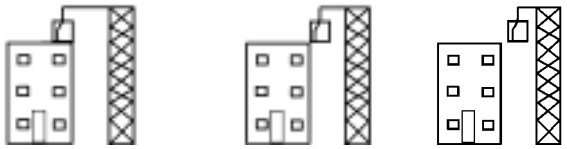
Stimuli. Thirteen triads of pictures and corresponding sets of sentences were created for this experiment. As discussed above, the pictures were created such that one might be well described by a target sentence, one passably described, and one poorly described. Each triad of pictures was associated with a pair of sentences: the target sentence that described the picture as outlined above, and a distracter sentence in which only the nouns were changed. The distracter sentence was meant to be obviously wrong; its purpose was simply to force participants to read the correct sentence and encode the target spatial relational term. For example, for the picture in Figure 1, participants chose between *The block is on the building* and *The plant is on the shelf*.

The initial picture from each triad was used for the study portion of the experiment; all three pictures in the triad were used for the recognition task.

Procedure

Part 1: Study. Twenty-five pictures (thirteen targets and twelve distracters) were randomized and presented individually for five seconds each on a computer screen. All participants were told that this was part one of a two-part experiment.

To ensure that the spatial sentences group processed the sentences we asked them to choose which of two sentences best described the picture. They were provided with answer sheets with two sentences for each picture: the target sentence and a distracter sentence. Participants in the control
condition were given no additional instructions.



Plus variant *Initial picture* *Minus variant*

Figure 1: Triad of pictures corresponding to the sentence "The block is on the building."

Part 2: Recognition. All participants received the same yes/no recognition task. All three of the pictures in each triad were presented individually in random order along with twelve distracters (six old and six new). Participants were asked to indicate on a numbered answer sheet whether or not they had seen each picture during the earlier study portion. Each picture remained on the screen until the participant pressed the "c" key, indicating that they were ready to continue.

Results

As predicted, we found that participants' recognition memory was influenced by whether a linguistic description was presented during study. Participants in the spatial sentences condition were significantly more likely to false-alarm to the *plus* variant than to the *minus* variant. (Figure 2). The difference between the false alarms in response to the *plus* variant and the false alarms in response to the *minus* variant differs significantly in the spatial sentences condition, as confirmed by a paired samples t-test ($t(17) = 5.32$, $p < .0001$). Participants in the control condition showed no such difference in their false alarm rate. Thus,

having spatial language present at encoding led to a skewing of recogntion errors towards the core of the spatial category.

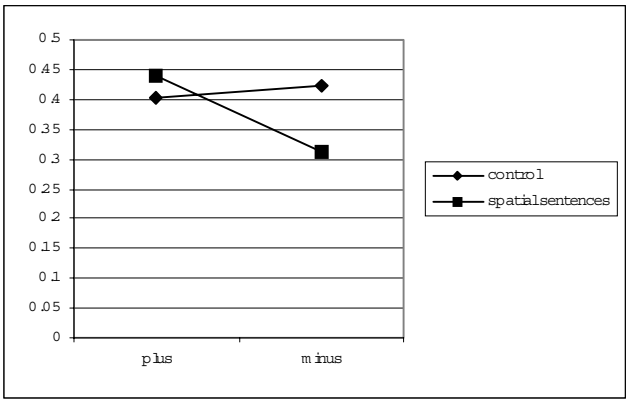


Figure 2: False alarms by condition, Experiment 1a

d' analysis To further test the claim that the presentation of sentences during study influences recognition memory for pictures, two d' measures were calculated for each individual subject. One d' indicates the discriminability of the *minus* variant and the initial picture; the other, the discriminability of the *plus* variant and the initial picture. The larger of the two was then determined, and the participants were pooled by condition, as shown in Table 1.

Table 1: Participants pooled according to the d' analysis, Experiment 1a

	Plus larger	*Minus* larger	Equal[1]
Control	4	4	10
Spatial Sentences	0	12	5

In the spatial sentences condition, but not in the control condition, the discriminability of the *minus* variant is greater than that of the *plus* variant (X^2=9.65, p<.01).

Discussion

We found that when spatial language was present at encoding, memory for the spatial relations in the pictures was systematically shifted in the direction of the spatial preposition. This is evidence for at least the moderate thinking-for- speaking version of the Whorfian hypothesis. In the next study we sought evidence for the strong version of the hypothesis. We hypothesized that if people had to attend closely to the pictures, this might evoke spontaneous linguistic descriptions as a memory aid. We thus examine the effect of more careful attention on recognition memory in Experiment 1b.

[1] d' measures within .25 of one another were considered equal for the analyses discussed in this paper.

Experiment 1b

In this study we asked whether participants instructed to pay careful attention to the pictures at study might be induced to encode the pictures linguistically and, as a result, to display an error pattern similar to that seen in the spatial sentences condition of Experiment 1a.

Method

Subjects Eighteen Northwestern undergraduates received course credit for their participation in this experiment. All reported being fluent speakers of English.

Stimuli The stimuli used were the same as those in Experiment 1a.

Procedure

Part 1: Study The procedure was identical to the control condition in Experiment 1a, except that the participants were instructed to pay careful attention to the pictures because the recognition test would be very difficult.

Part 2: Recognition The recognition task was the same as that used in Experiment 1a.

Results and Discussion

The error rate observed in Experiment 1b is lower than that observed in Experiment 1a, indicating that participants did pay more careful attention to the pictures during study. However, the pattern of false alarms is the same as that observed for the control subjects from Experiment 1a. Figure 3 shows the results of Experiment 1b along with those of Experiment 1a. These results suggest that more careful attention did not necessarily evoke linguistic encoding.

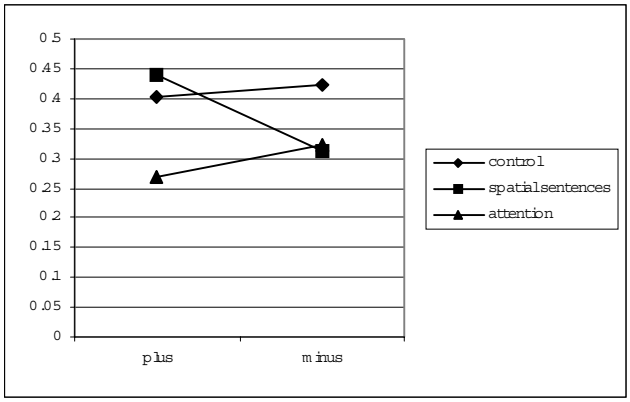

Figure 3: False alarms by condition, Experiments 1a and 1b

So far we have evidence for the influence of spatial language when it is explicitly presented, although not for the stronger possibility that language will affect cognition even when it is not overtly present. In Experiment 1c, we tested the specificity of the language effect. If, as we have assumed, the recognition shift is due to spatial language,

then we should not see this shift if participants are given verbal descriptions that do not contain spatial language.

Experiment 1c

In order to more carefully inspect the source of the language effect from Experiment 1a, we presented participants with sentences without spatial prepositions at encoding. The sentences used named only the objects in the picture. We predict that these sentences, which are missing the hypothesized source of the language effect, will not replicate the effect found in Experiment 1a.

Method

Subjects Nineteen Northwestern undergraduates received course credit for their participation in this experiment. All reported being fluent speakers of English.

Stimuli The pictures were the same as those in Experiment 1a. The sentences on participants' answer sheets were modified from those used in Experiment 1a by removing the prepositions, resulting in sentences of the following form:

The picture shows a block and a building.
The picture shows a plant and a shelf.

Procedure

Part 1: Study The procedure was identical to that in the spatial sentences condition in Experiment 1a. Participants chose which sentence best matched the picture.

Part 2: Recognition The recognition task was the same as that used in Experiment 1a.

Results and Discussion

As predicted, participants failed to show any shift towards the core spatial category designated by the preposition. The participants in Experiment 1c demonstrated the same pattern of equal *plus* and *minus* false alarms as the no-language subjects in the previous studies (the subjects in Experiment 1b and the control subjects in Experiment 1a). This pattern differed significantly from the pattern by spatial sentence subjects in Experiment 1a. Specifically, the two groups differed in their rate of false alarms in response to the minus variant (independent samples t-test: $t(34) = 3.91$, $p<.005$). This provides support for the suggestion that it is specifically the preposition that is responsible for the change in the pattern of responses observed in the spatial sentences condition in Experiment 1a. The complete set of results for Experiment 1 is presented in Figure 4.

d' analysis As in Experiment 1a, two d' measures were calculated for each individual participant in Experiment 1: one indicated the discriminability of the *minus* variant and the initial picture, and one indicated the discriminability of the *plus* variant and the initial picture. The larger of the two was then determined, and the participants were pooled by condition (Table 2).

Attention	8	4	5
Object sentences	6	3	7

In the spatial sentences condition only, the discriminability of the *minus* variant is greater than that of the *plus* variant ($X^2=19.31$, $p<.01$). Or to put it more directly, only in the spatial sentences condition is the *plus* version more confusable with the initial picture than the *minus* version.

Experiment 2

This study was done to verify that the spatial sentences applied to the three variants of each picture as expected. We asked participants to rate the applicability of the sentences from the study portion of Experiment 1a to each of the pictures.

Method

Subjects Twenty-four Northwestern undergraduates received course credit for their participation in this experiment. All reported being fluent speakers of English.

Stimuli The pictures used were the same as those in Experiment 1. The sentences used were the correct spatial sentences from Experiment 1a.

Procedure

All three of the pictures in each triad were presented individually in random order along with the twelve distracters from the recognition task from Experiment 1. Participants were asked to rate the applicability of the sentences to the pictures on a scale from one to seven, with seven being the highest rating. Each picture remained on the screen until the participant pressed the "c" key, indicating that they were ready to continue.

Results and Discussion

As expected, participants gave the highest ratings to the *plus* variants (mean rating 5.72), in-between ratings to the initial pictures (mean rating 4.47), and the lowest ratings to the *minus* variants (2.54). This distribution of the ratings suggests that the assignment of pictures to the various categories with respect to the sentences used in the spatial sentences condition of Experiment 1a was indeed appropriate. Examination of the results for individual triads showed that for two of the triads, one depicting a coin in a hand and one depicting a firefly in a dish, the sentences did not fit exactly as predicted. These sentences were adjusted accordingly for Experiment 3.

Experiment 3

This study was a replication of the spatial language condition, with a methodological improvement. In Experiment 1a, participants saw all three versions of each of the pictures (one at a time) during the yes/no recognition task. This leaves open the possibility of carryover effects from one variant to another. In Experiment 3, the study task was that of Experiment 1a, but the recognition task was designed so that each participant was tested on only one version of each picture.

Method

Design. Encoding Condition (Spatial Sentences/Control), a between-subjects variable, was crossed with Recognition Item Type (Plus Variant/Initial Picture/Minus Variant) (within-subjects) and with Assignment condition. This was a between-subjects variable determining which variant in each set was received by a given participant in the recognition test.

Subjects. One hundred eighteen Northwestern undergraduates received course credit for their participation in this experiment. All reported being fluent speakers of English.

Stimuli. The stimuli used were the same as those in Experiment 1, with minor modifications to two of the triads of pictures, and with a change of preposition (from *in* to *on*) in the sentences corresponding to two others. One of the triads used in Experiment 1, depicting a balloon on a stick, was not used for Experiment 3.

Procedure

Part 1: Study The procedure was identical to the study portion of Experiment 1a.

Part 2: Recognition Both conditions received the same yes/no recognition task. One picture from each triad was presented in random order along with twelve distracters (six old and six new). As in Experiment 1, participants were asked to indicate whether or not they had seen each picture during the earlier study portion, and each picture remained on the screen until the participant pressed the "c" key indicating readiness to continue.

Results

As in Experiment 1a, we found that participants' recognition memory was influenced by the presence or absence of spatial language during study. The pattern of false alarms for the spatial sentences condition differs from that in the control condition (Figure 5). As in Experiment 1a, participants in the spatial sentences condition were significantly more likely to false-alarm to the *plus* variant than to the *minus* variant. Participants in the control condition showed no such difference in their false alarm rate. The difference between the false alarms in response to the *plus* variant and the false alarms in response to the *minus* variant differs significantly only in the spatial sentences condition, as confirmed by a paired samples t-test ($t(57) = 2.23$, $p = .047$). In addition, the difference in the rate of false alarms between the two groups only reaches significance for the responses to the *plus* variant, as confirmed by an independent samples t-test ($t(116) = 2.20$, $p = .039$).

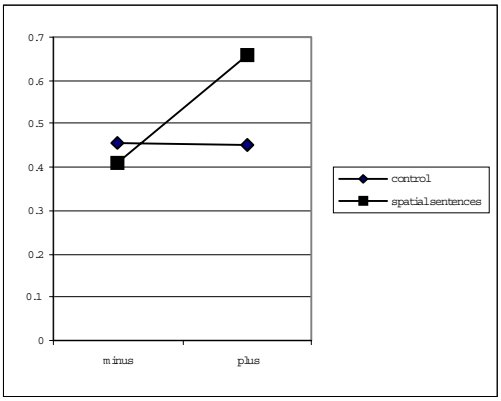

Figure 5: False alarms by condition, Experiment 3

d' analysis As in Experiment 1a, two d' measures were calculated for each individual subject. One d' indicates the discriminability of the *minus* variant and the initial picture; the other, the discriminability of the *plus* variant and the initial picture. The larger of the two was then determined, and the participants were pooled by condition (Table 3).

Table 3: Participants pooled according to the d' analysis, Experiment 3

	Plus larger	*Minus* larger	Equal
Spatial sentences	4	38	16
Control	20	20	20

The results of the d' analysis for Experiment 3 replicate those for Experiment 1: in the spatial sentences condition alone, the discriminability of the *minus* variant is greater than that of the *plus* variant ($X^2 = 16.67$, $p < .0001$).

General Discussion

In these experiments, we examined the question of whether spatial language influences the encoding and memory of spatial relations presented visually. The answer is a qualified yes. Our evidence shows that the use of spatial language during the encoding of a picture can affect recognition memory for the spatial relations in the picture. People given spatial prepositions during encoding showed a shift in recognition towards the core spatial category denoted by the preposition (Experiments 1a and 3). This effect was specific to spatial relational language (Experiment 1c); no such shift was observed for sentences that simply described the objects in the pictures.

However, our evidence that language influenced encoding was limited to the case when overt spatial language was present. We did not find a shift towards the core spatial semantic category when participants were simply instructed to pay close attention to the pictures (Experiment 1b). Thus, our evidence supports the view that language can affect encoding when it is present, but not the strong Whorfian view that non-linguistic perception is shaped by the language one speaks.

There has been much controversy in recent years over whether language exerts an effect on non-linguistic cognition. Our results suggest that language forms do exert an effect on one type of non-linguistic cognition: recognition memory for simple pictures. This suggestion must be qualified, however, as we do not show an effect of language forms in the absence of linguistic descriptions at encoding, which would suggest a stronger influence of language on everyday non-linguistic cognition. Of course, it remains an open question whether in some situations, speakers might prefer encodings that are compatible with their language, resulting in cross-linguistic differences that are habitual though not inescapable.

Our results are compatible with Slobin's (1996) thinking-for-speaking hypothesis and with the results of Malt et al. (in press). They suggest that language can have profound non-linguistic effects when it is used, but that its use is not inevitable. This is consistent with Gentner and Loewenstein's (in press) suggestion that language provides tools that potentiate forming and holding ideas -- the *tools–for-thought* hypothesis. On this view, language potentiates kinds of encodings rather than forcing them.

The Origin of Somatic Markers:
A Suggestion to Damasio's Theory Inspired by Dewey's *Ethics*

Suzanne Filipic (suzannefilipic@hotmail.com)
Université de Paris III-Sorbonne Nouvelle
39 avenue de la citadelle 21240 Talant France

Damasio vs. Dewey

My goal is not to propose a criticism of Damasio's theory, but to suggest how it might be possible to carry it further, to wipe out even more efficiently the traditional dualism opposing our reason and emotions. Damasio's theory of somatic markers is for me a very efficient means of exposing the importance of emotions on the workings of reason, but my fear is that it might lead a few to replace the old dualism opposing an efficient reason to disruptive emotions by a new one overemphasizing the power of emotions on a weak influenced reason.

An important part of Dewey's *Ethics* deals with this dualism. I suggest that, although Damasio's experiments can be seen as providing amazing clarity and precision to Dewey's philosophical intuitions, Dewey's elaboration on the reciprocal influence of reason and emotions goes one step further in questioning whatever supposedly opposes them.

Dewey's *Ethics*

Since Dewey's *Ethics* is probably much less known today than Damasio's *Descartes' Error*, let me start by presenting what interactions Dewey imagines between our emotions and our reason.

For Dewey, when we think we are making a choice between following our emotions, or following our reason, reality is always more complex:

> while there is conflict, it is not between desire and reason, but between a desire which wants a near-by object and a desire which wants an object which is seen by thought to occur in consequence of an intervening series of conditions, or in the "long run". (1932)

When facing a new situation, when are emotions necessary if thought must lead us to action ? Dewey's first intuition is that emotions provide the necessary starting point of reflection, or the energy necessary to its activity:

> Unless there is a direct, mainly unreflective appreciation of persons and deeds, the data for subsequent thought will be lacking or distorted. A person must feel the qualities of acts as one feels with the hands the qualities of roughness and smoothness in objects, before he has an inducement to deliberate or material with which to deliberate. (1932)

Dewey also thinks that any outcome of a thinking process must be emotionally "appreciated," otherwise it would not stir us to action. I quote *Ethics* again: "no matter how elaborate and how rational is the object of thought, it is impotent unless it arouses desire".

At this point, we might wonder two things. Are the emotions which stimulate reflection and those which motivate action of the same kind? And doesn't Dewey overemphasize the importance of emotions, by giving them a crucial role at the beginning and at the end of the process of thought?

In the fourteenth chapter of *Ethics*, Dewey works on distinguishing valuation, as a judgment of value, in which reason evaluates an object by its consequences, and valuing, as an immediate emotional reaction. For Dewey, valuation and valuing are not opposed, but linked: "We esteem before we estimate, and estimation comes in to consider whether and to what extent something is worthy of esteem [...]. All growth in maturity is attended with this change from a spontaneous to a reflective and critical attitude". (1932)

Therefore, even if emotional reactions always come first, reason can and should have an effect upon later ones: "judgments of value are not mere registrations [...] of previous attitudes of favor and disfavor, liking and aversion, but have a reconstructive and transforming effect upon them by determining the objects that are worthy of esteem and approbation". (1932)

Dewey thus distinguishes between primary emotions, which one has at the beginning of one's life, and adult emotions. These ones are of two different kinds: the spontaneous ones, which are immediate, but probably the result of past value judgments, and the transformed emotions, which have just evolved, as an effect of a new value-judgment.

Therefore, to go back to my two questions, we can conclude that Dewey ends up giving emotions an important influence on reason, and the two kinds of emotions he imagines in this regard might coincide with the two kinds of emotions he had noticed as necessary to reflection. The emotions providing energy to the thought process might be the spontaneous ones, occurring before the thought process, and the transformed emotions, produced by valuation, might be the ones necessary to act.

If one accepts this interpretation, we could conclude that in front of a situation, Dewey imagines that our reaction follows a pattern similar to this one: a new situation *provokes* spontaneous emotions *which stimulate* reflection *which produces* a value-judgment and a transformed emotion *which enable us to act*.

What suggestion will this theory enable us to make on Damasio's theory of somatic markers?

Damasio's Theory of the Somatic Markers

The starting point of Damasio's research is Elliot, a reasonable and intelligent man, who, because of a brain tumor, became unable to take any sound personal decision.

After running a series of tests, Damasio became convinced that Elliot was still able, in front of most situations, to imagine different action plans, but that he was never able to choose the right one in practice. To link his lack of emotions to his inability to assign values to the different plans he is still able to produce, Damasio proposes his theory of the somatic marker.

To explains what he means by a "somatic marker," Damasio asks his reader to imagine himself as an owner of a large business, "faced with the prospect of meeting or not with a possible client who can bring valuable business but also happens to be the archenemy of your best friend, and proceeding or not with a particular deal" (1994).

For Damasio, using a cost/benefit analysis of all the scenarios you imagine is not going to work; at best, it would take you too long to make a decision. However, he thinks that without reasoning about it, some of the options you imagine are automatically eliminated. If, from experience, a connection has been made between a specific response option and its bad outcome, a somatic marker will be activated. This marker would then operate either outside consciousness, by inhibiting a tendency to act, or consciously, by letting you experience an unpleasant gut feeling, thus convincing you to avoid this option.

Damasio's Theory as an Explanation of Dewey's Intuitions

Before going any further, I would like to suggest that Damasio's theory can first be read as an explanation of Dewey's relatively vague notions. When Damasio writes, " a somatic state, negative or positive, caused by the appearance of a given representation, operates not only as a *marker for the value of what is represented, but also as a booster for continued working memory and attention"* (1994), it can easily be read as an explanation of what Dewey meant when he wrote that emotions provide reflection with "material with which to deliberate," and "an inducement to deliberate" (1932).

The Origin and Evolution of Somatic Markers

Somatic markers are, according to Damasio, what enable us, in new circumstances, to experience feelings before we start evaluating the situation rationally. For Dewey, these "intuitions" which are necessary for reflection because they provide its material and its motivation, are in the long run the product of our value-judgments. Thus, he estimates that our emotions are as necessary to our reason, than our reason to our emotions.

I think that Damasio considers that only emotions are at the source of somatic markers. Since he sees them as necessary to the thinking process, it leads him to conclude that our reason is based on our emotions, but he forgets to consider whether our emotions are influenced by our reason.

At this point, my goal is to question Damasio's apparent one-sided view on the reason/emotions interaction. My first remark is simply theoretical. Following Damasio's experiments, I think we can reach different conclusions. For him, when a chosen option leads to a negative outcome, the consecutive somatic state (the painful emotion) allows a new marker to be created. Damasio thus insists on the fact that emotions are what create somatic markers.

However, I think it is just as logical to conclude that, since we also use our reason to choose an option, our reason is also an important cause of the resulting somatic state, and thus of the new marker. In other words, if our reason had enabled us to make a better choice, the final emotion would have been different, and therefore the new marker would have been different.

I think Damasio does consider reason as an important step in the decision-making process. Yet, because his experiments led him to re-evaluate the importance of emotions, he stopped at the conclusion that emotions are the foundations of reason, and it might be asked whether we should not also consider that our emotions might be just as much the products of our reason.

My second remark is about Damasio's main experiment. I think that Damasio ends up giving emotions such a one-sided influence on reason because the experiments he works from are cases in which the role of emotions is much more important than any conscious evaluation, in the production and the evolution of somatic markers. I will try to analyze the "gambling experiments" proposed in chapter 9 of *Descartes' Error.*

I think it may be necessary to distinguish between two different processes: the production, and the evolution of somatic markers. My point is not to suggest that these two processes are totally distinct, but

rather that the second one progressively distinguishes itself from the first. If these two processes are thought of as different, I think we can consider how much Damasio's experiments do reproduce real-life decision-making circumstances, and how much they differ from them.

Damasio's experiments consist of asking his patients and "normal" individuals to gamble, playing with four decks of cards, two decks giving out high rewards but also high penalties, and thus leading the players to bankruptcy, and two other decks, causing lower rewards but also much lower penalties, enabling the players to win the game. These experiments are a success since they enable Damasio to distinguish patients, who loose the game, from normal individuals, who win, because they learn to avoid the bad decks of cards.

If we consider how somatic markers are created, which means if we consider a limited number of the same kind of experiences, I think Damasio's gambling experiments reproduce what happens in real life. An experience which leads you to a success, produces a positive marker which will be activated in the future if the same circumstances are experienced again (in this case, decks C and D); whereas an experience which ends as a failure produces a negative marker (as for decks A and B).

However, if we consider the way if which markers evolve, I think these gambling experiments only allow us to study a limited category of our real-life experiences. If we consider "normal" individuals, after a few cards have been turned down, when the question comes up again to choose a deck of cards, the different stages of the decision-making process are the following. After the different response options have been produced (in this case, there will be four options, since there are four decks of cards), the negative marker associated with two of the four options allows them to be eliminated quickly, and then a choice has to be made between the two remaining ones, either automatically, or consciously. When the decision is made, the player picks up a card, experiences an emotion (positive or negative, depending on the efficiency of the preceding markers), the emotion then makes the marker evolve, reinforcing it, if the bet was successful, or modifying it, if it was not the case.

However, I think we can wonder whether this process does not permit survival only if one repeatedly faces the same sets of circumstances (a hundred cards have to be turned down, for the experiment), in which the possible response options are always exactly the same (make a choice between four decks of cards), and in which response options have very similar consequences. Is it the case in real life? Survival in our societies might require much more complex decision-making processes. Damasio was obviously trying to simplify a typical decision-making experience when he devised these gambling experiments. However, these experiments probably do not enable us to consider the importance of another "typical" decision-making experience, where conscious evaluation has a much more decisive role.

In other words, we might suggest that as long as an environment is stable, human needs do not evolve, and thus the situations or the objects that humans look for are always similar. Their survival is much more easy to achieve if an automatic process (like the action of somatic markers, if we accept Damasio's theory) enables them to predict the outcome of familiar experiences. Yet, in a constantly evolving environment, in which many experiences are unique, an automatic decision-making process might not always be the most efficient one.

Another difference seems essential between Damasio's experiment and life. Damasio says from the beginning that this game is like life because chance rules it. Then, to explain why this test enables him to measure so well his patients' errors in decision-making, he writes that, like in real-life, this test gives the possibility to make choices, but the player does not know neither how, nor when, nor what to choose.

These two passages are for me very surprising, and I think Damasio would agree with me that an individual successful "at the game of life" does not always make a good poker player, and vice versa. Why? Because successes and failures in life usually have a cause, whereas in the experiment they do not. Successes and failures in life can be analyzed, whereas the rules of the gambling experiment, because they are arbitrary, by nature resist analysis. When going through Damasio's experiment, it is necessary to choose the "wrong" decks several times before being cautious because nothing can explain that choosing a particular deck will be, on the whole, a bad option. The only way to persuade oneself is to repeat the mistake.

In life, failures probably encourage analysis a lot more easily. It is not necessary to burn oneself many times to be cautious with fire or hot objects. The first time a child burns himself, he can learn only to never touch again the same kind of object. However, the second time, he has to wonder what it is that these two objects have in common, that makes them objects to avoid.

What is it that enables us to learn from experience, in all experiences where chance is not the strongest element? Our ability to compare experiences, to analyze them, to deduce rules of behavior from individual occurrences, in a word, our reason, even if it is motivated by somatic markers.

To summarize my position, I would say that these gambling experiments are a success because they are an efficient test to distinguish normal individuals from patients. Moreover, skin conductance tests show that it

is probably because a somatic state is activated in normal individuals before they make a decision, that their actions are beneficial on the long term. These experiences thus verify that the activity of somatic markers is a necessary condition if decision-making processes are to help the organism survive. The patients do not succeed at this game, as they do not succeed "in life," because they are unable to produce new somatic markers.

However, these games do not prove that emotions are overall a more important factor than reason in influencing the evolution of somatic markers. The patients might loose the game because their emotions do not produce markers, but they might make wrong decisions in life because their emotions and value-judgments combined do not produce somatic markers either.

The Limited Value of Intuitive Appraisals

Decisions made automatically or unconsciously, on which reason does not have any influence, appear to me as of a limited value, to repeat Dewey's words.

> There is a permanent limit to the value of even the best of the intuitive appraisals [...]. These are dependable in the degree in which conditions and objects of esteem are fairly uniform and recurrent. They do not work with equal sureness in the cases in which the new and unfamiliar enters in. (1932)

The mechanism Damasio describes is probably the one which is at work in his experiments, and in all real-life experiences which have to be undergone in order to survive. (Or at least his book convinced me that this was the case). In these experiences, an automatic learning process can take place, and this mechanism probably enables us to avoid the mistakes we already made.

But what are the processes that enable us to make decisions, when survival is secured? What is the role of conscious reasoning in those processes, probably the last to have appeared in evolution, and still the least important in quantity, that enable us to imagine a solution to a new problem, or a new solution to an old problem, a melody, a new energy?

If I insist on the importance of conscious reasoning on the evolution of somatic markers, it is not to suggest that Damasio does not sufficiently consider the share of conscious reasoning in each experience, but rather to reevaluate the influence of past value-judgments on the unconscious processes that each experience activates.

I do not oppose any element of the somatic marker theory. I only suggest that Damasio might have underevaluated the importance of reason in the long-term evolution of somatic markers, and therefore in our subjective experience, probably because he mostly wanted to demonstrate how limited the influence of reason was on the short-term, when we choose to act in response to a situation.

What are the Consequences of Each Theory?

Damasio's theory can be summarized very briefly as: emotions are what enable us to produce markers, make them evolve, and thus emotions are the necessary conditions of the functioning of our reason.

We can conclude, with Damasio, that emotions have a crucial role, worry that they are given so much importance when their mechanisms are not yet understood: "What worries me is the acceptance of the importance of feelings without any effort to understand their complex biological and sociocultural machinery," and want the fragility of the "foundations" of reason to be recognized:

> The idea of the human organism outlined in this book, and the relation between feelings and reason that emerges from the findings discussed here, do suggest, however, that the strengthening of rationality probably requires that greater consideration be given to the vulnerability of the world within. (1994)

Or, with Dewey, we can estimate that if emotions do have a great influence on the workings of reason, our reason can also influence our emotions. Our rationality is probably fragile, because it is based on emotions, but it is "constructible," since our conscious choices probably have in return a strong influence on the evolution of our emotions.

This process might even be just as automatic as the first one. Our valuations end up modifying our tastes. Without even wanting to change, we do not always like as adults what we liked as children. However, Dewey thinks that some of our "intuitions" (we could probably say: markers) resist analysis:

> The very fact of the early origin and now unconscious quality of the attendant intuitions is often distorting and limiting. It is almost impossible for later reflection to get at and correct that which has become unconsciously a part of the self. (1932)

To conclude on this, I would like to suggest that the task Dewey assigns to reason, that of evaluating if our spontaneous emotions are the result of sensible evaluations, may be a feasible one if one follows the precautionary measure given by Damasio. I suspect that from education we might be able to learn either to mind our somatic states and analyze their causes, or to ignore them.

For example, in the situation imagined by Damasio where you wonder if you should meet a potential client, who happens to be the enemy of your best friend, I think that if one asks himself the question consciously, it may be possible to perceive one's somatic states, and

thus to decide whether to "follow their advice" or not. However, if one pretends to ignore them, instead of diminishing their influence, and let reason work freely--according to those who think that we should not let emotions interfere with reason, their influence will probably be even more important. If an organism learns to ignore its somatic states, the markers will influence the decision-making process anyhow, but without giving reason a chance to influence the decision.

Two Definitions of Reason

In the end, their contrasted definitions of reason seem to be what prevents Dewey and Damasio's theories to coincide. What is reason?

For Damasio, reason seems to be a faculty. When Damasio takes the example of choosing whether to meet your best friend's enemy or not, he opposes his somatic marker hypothesis, to a "pure" reason hypothesis. This is the passage I want to analyze here. For Damasio, pure reasoning will at best enable us to make a decision, but after "an inordinately long time" (1994). However, he thinks that in most cases, a decision will be impossible to make for two reasons.

First, Damasio evokes the limits of our attention and working memory. However, this does not seem to be a sufficient argument, otherwise it would suggest that the patients Damasio works with could solve their problems if they only took a paper and pencil when they need to make a decision. Their cases would probably not have inspired so many ideas to Damasio, if the solution to their problems was that simple.

His second argument is simply that reason's strategies can often be defective. What "strategies" does he have in mind? The answer is for me very surprising, it is the "humans' devastating ignorance and defective use of probability theory and statistics" (1994).

Do we mostly face pure chance? Are probability and statistics calculations our only way to evaluate how others behave, or how society works? Is the reflection on the causes of what happens to us, which should enable us to predict the consequences of what we will choose to do, an impossible task? Because somatic markers enable us to assimilate automatically and to a certain extent the recurrences of reality, can reason only face the "rest," which would be pure chaos?

Shouldn't we consider that after many experiences, we retain not only new somatic markers, which when activated will be able to arouse future somatic states, but that we also retain "markers" of a different kind, which might enable us to make positive choices, and that we call, for lack of more scientific terms, ideas, conscious value criteria?

Why doesn't Damasio write about reason's acquisitions? His theory seems to oppose not only conscious reasoning and the automatic unconscious selection process, but also reason as an empty faculty, and emotions as a content, which can be modified by experience.

Yet, this opposition seems to be more linguistic than proved experimentally. Reason is usually defined (in French as in English) as a capacity, and emotions as states, and it seems that Damasio ratifies this dualism. The fact that his patients are unable to learn from experience may prove that the memory of conscious ideas depends on the activity of somatic markers, but it does not prove that it does not exist in normal individuals.

For Dewey, our reason works from ideas, acquired through one's personal experience and through communication:

> Experience is intellectually cumulative. Out of resembling experiences general ideas develop; through language, instruction, and tradition this gathering together of experiences of value into generalized points of view is extended to take in a whole people and a race. Through intercommunication the experience of the entire human race is to some extent pooled and crystallized in general ideas. These ideas constitute principles. We bring them with us to deliberation on particular situations. (1932)

Just once, Damasio speaks of the necessity of possessing a logical strategy, that would evolve with experience. Was this remark only about our capacity to use statistics and probability better and better?

The primary task of our reason may be to help us reach goals rather than to help us avoid unfavorable situations. It seems probable to consider that in evolution, where one mechanism is sufficient (the somatic markers), a second one does not try to accomplish the same things. At the risk of oversynthetizing Dewey's and Damasio's theories, I think we can suggest that, in case of a failure as of a success, the goal of a thought process will probably be to reach by analysis a plan of future action (better than the one imagined before the just-accomplished action), or even simply to define a set of necessary conditions in hope of attaining this new goal. This would create another kind of "marker," a positive one, which would encourage action, if this set of conditions happens to be experienced in the future. Emotions would then be more efficient at composing a memory of the past, and reason better at building a memory of the future, to quote Damasio's phrase ("memories of the future").

On Strength of Will

Finally, the difference in Dewey's and Damasio's definition of strength of will seems to be very significant of how Dewey considered more than

Damasio the possible consequences of a joint activity of our capacities to reason and to experience emotions.

For Damasio, strength of will is what enables us to endure something painful short term, in exchange for positive consequences on the long term: "Willpower is just another name for the idea of choosing according to long-term outcomes rather than short-term ones" (1994). Willpower can be explained by the action of a positive marker, reason is not evoked.

However, the examples he chooses to illustrate this definition are not decisions one takes easily. On deciding whether to undergo yet another surgery, one might have to decide for it, although it might mean to need to overcome strong negative feelings. The automatic decision-making processes do not seem sufficient in this case.

For Dewey, it is neither reason alone, nor a positive somatic marker, but the product of the union of both, a well thought-of judgment and a "transformed" emotion, that enable us to think in the long term:

> In reality "strength of will" (or, to speak more advisedly, of character) consists of an abiding identification of impulse with thought, in which impulse provides the drive while thought supplies consecutiveness, patience, and persistence, leading to a unified course of conduct. (1932)

Anti-dualism

It might have seemed that I was "defending" the primacy of Reason, but it was not my goal. I think Damasio's theory is essential because it brings to light how necessary emotions are to decision-making processes. I did not intend to refute this, and to argue that reason was more important to decision-making than emotions.

It just seemed appropriate to recall its importance so that, doing away with the dualism opposing an efficient reason to disturbing emotions, we would not clear the way for a new one, opposing influent emotions to an influenced reason. Dewey's hypotheses, as vague and intuitive as they are, seem to sketch a more vague but more global scheme of the reciprocal influence of emotions on reason, and vice versa.

The exception to his theory which Damasio evokes in *The Feeling of What Happens*, the pianist Maria João Pires, who can control by will whether she experiences the emotions that music arouses in her, evokes for me the possibility that we might be considering for now only a very slight portion of the possible interactions between reason, or consciousness, willpower, and emotions.

To come back to my remarks on Damasio's theory suggested by Dewey's writings, I do not know what Damasio would think of them. The theoretic starting point of my analysis, on the "not enough" anti-dualist character of Damasio's theory can seem arbitrary. However, it was precisely the goal of this reflection, to try to show that Dewey's anti-dualism, though a theory, might well be a roundabout way to question reality without being influenced by dualisms handed down to us by culture. Even if we should hope that science will one day have exhausted the hypothesis "resources" of John Dewey's philosophy, I hope I suggested that his anti-dualism can still today inspire scientific research, and thus resolve, if only momentarily, the dualism which so frequently opposes scientific research to philosophical research.

To come back to my fear of seeing a new dualism replace an old one, I will end my discussion by noting that Dewey and Damasio agree in pointing to the dualism opposing mind and body as one of the major sources of (what Stephen Jay Gould calls) "our lamentable tendency to taxonomize complex situations as dichotomies of conflicting opposites" (2000). I think Dewey would have been delighted to hear Damasio correct Descartes' error: "We are, and then we think, and we think only inasmuch as we are, since thinking is indeed caused by the structures and operations of being". (1994)

Acknowledgments

I would like to thank Marie-Christine Lemardeley Cunci (Paris 3) for accepting this research as a possible master's degree dissertation, Christiane Chauviré (Paris 1) for her interest in this novice analysis of Dewey's works, and William Schubert (UIC) for his encouragements. I would also like to thank the French Department of the University of Illinois at Chicago for the 1999-2000 teaching assistantship they awarded me, which enabled me to complete this research.

Abstract

Are dissociations between categorization and explicit memory in tests of amnesics and normals evidence for multiple memory systems? Or could these dissociations be artifacts arising from methodologies used in some experiments? We report a series of studies exploring this issue. Using normals in various states of simulated amnesia we show that categorization at test is well above chance even in the absence of prior exposure to category members. We also show that subjects perform well when tested with items that conflict with categories they had studied earlier. We argue that subjects in some paradigms can extract information about categories from the test rather than rely on memory for studied category members. In further studies, we generalize these findings to other stimuli and other category structures that have been used in tests of amnesics and normals.

Introduction

Do categorization and explicit memory rely on independent neural memory systems? Evidence for multiple systems comes from dissociations between categorization and explicit memory in studies of normals and amnesics. Amnesics are reported to categorize at levels comparable to normals but are significantly worse at explicit memory. Such dissociations seem to imply that separate systems may exist and pose clear problems for theories that assume a single underlying memory system, such as well-known exemplar models.

The evidence is clear that amnesics have impaired explicit or declarative memory. The focus of this paper is on whether data from studies testing amnesics clearly provide evidence for intact abilities to learn new perceptual categories. Our goal is to examine whether some categorization performance can be explained in the absence of positing a separate implicit system for category learning that is spared in amnesia. Our approach has been to utilize the same paradigms and methodologies found in the amnesia literature to study normal subjects under conditions that simulate aspects of amnesia. To create "amnesia" in normals, we used a variety of techniques such as eliminating the study session altogether, introducing delays between study and test, and surreptitiously switching the test stimuli to those from an unstudied category. We follow the amnesia literature in testing these effects using a variety of stimuli, including distortions of dot patterns, object-like stimuli with discrete features, and simple forms placed in categories separated by quadratic boundaries.

In this paper, we review some behavioral evidence for dissociations from studies of amnesics and normals. For each case, we present data from studies we conducted that provide a possible alternative explanation for intact categorization by amnesics. Due to space constraints, we will only present our results in summarized form without detailed description of the methods or statistical analyses. After summarizing our initial work along these lines reported by Palmeri and Flanery (1999), we describe several new experiments that expanded upon these initial results in several important ways.

Learning Categories of Dot Patterns

A classic methodology for studying categorization and recognition has been the Posner and Keele (1968) dot pattern paradigm. To create a pattern, a small number of dots are randomly scattered on a grid. To create a category, a pattern is randomly generated and designated the prototype. Category members are generated by randomly distorting the prototype by varying degrees.

Knowlton and Squire (1993) used a variant of this paradigm to test amnesics on categorization and recognition. For categorization, subjects were exposed to 40 high distortions. Subjects were tested on judging members and nonmembers of that category. For categorization, members were 4 repetitions of the prototype, 20 low distortions, and 20 high distortions. Nonmembers were 40 randomly generated patterns. For recognition, subjects were exposed to five random patterns eight times each. In the recognition test, they were asked to discriminate between the five old patterns and five new patterns. No corrective feedback was provided in either condition. Knowlton and Squire (1993) reported a dissociation between categorization and recognition when comparing amnesics and normals. As shown in Figure 1, amnesics categorized as well as normals but were significantly impaired at recognition memory.

This dissociation seemed to provide evidence for separate systems. However, Nosofsky and Zaki (1998) showed that a single-system model could account for a

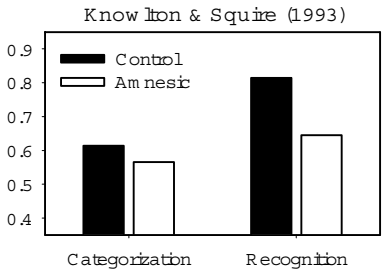

Figure 1. Categorization and recognition accuracy for controls and amnesics.

dissociation by simply assuming that amnesics had degraded memory. A challenge for this theoretical possibility was an extreme dissociation observed by Squire and Knowlton (1995). Their patient, E.P., was able to categorize as well as normals but recognition was entirely at chance. It would be very difficult to formulate a single-system model along the lines of Nosofsky and Zaki that could predict chance recognition performance in the presence of normal categorization performance.

To better understand the categorization performance of amnesics, Palmeri and Flanery (1999) investigated whether prior exposure was even necessary to categorize at test. One explanation for above-chance categorization by amnesics is that it may be possible to group items during the test that looked similar (prototypes and distortions) into the member category and group items that did not look similar (random patterns) into the nonmember category. Whereas, it is impossible to tell apart old from new patterns without memory.

Palmeri and Flanery tested this possibility by producing a state of profound amnesia in normals. As a ruse, subjects were told that patterns had been subliminally presented during an initial word identification task. No dot patterns were ever really presented. Subjects then completed the same categorization and recognition tests used by Knowlton and Squire. Similar to E.P., our simulated profound amnesics showed chance recognition. Yet, they showed above chance categorization. Apparently, our subjects were able to figure out how to categorize members versus nonmembers by picking up on the category structure clearly embedded within the test. They had no prior memories of any sort to rely on.

Experiment 1. We extended this paradigm by directly comparing the performance of simulated amnesics (No Exposure) to that of subjects who were exposed to the study items (Exposure). Half of the subjects were given subliminal exposure, as in Palmeri and Flanery, and were tested on categorization or recognition; the other half were given actual exposure, as in Knowlton and Squire, and tested on categorization or recognition. Results are shown in Figure 2. As expected, the exposure group could recognize items well above chance but the no exposure group could only guess. Replicating Palmeri and Flanery (1999), subjects in a no exposure group could categorize well above chance. Subjects receiving no exposure did not categorize significantly worse than subjects who were actually exposed to category items. Apparently, prior exposure to a category did not provide much, if any, benefit.

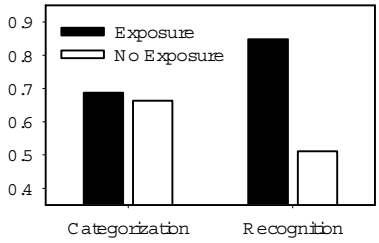

Figure 2. Categorization and recognition accuracy in Experiment 1 for subjects exposed and not exposed to category items (Palmeri & Flanery, 2001).

Experiment 2. One criticism of these studies is that the ruse used to induce amnesia may have placed subjects in a different mind set from that of subjects who were exposed to members. Our "profound amnesics" may realize they never saw any patterns and may think the task is to discover the hidden category structure, something they appear to do quite ably. So, one goal of this experiment was to use a different paradigm for demonstrating that subjects may categorize based on information they acquire during the categorization test. In this experiment, we surreptitiously switched the test stimuli for some subjects to that of an unstudied category.

In addition, we clearly do not want to draw the conclusion that people always ignore information about a previously studied category in favor of information presented during a test. A second goal was to show that when initial exposure provides evidence for a clear category structure, subjects will use that information to make category decisions irrespective of the makeup of the categorization test. To demonstrate this, we adapted a paradigm used by Squire and Knowlton (1995). In one condition, subjects were initially exposed to 40 high distortions of the prototype (40H), exactly as was done in earlier studies. In another condition, subjects were instead exposed to 40 repetitions of the prototype (40P). We reasoned that subjects in the 40P condition should have acquired clear knowledge of the category structure and should protest any surreptitious changes during a test. By contrast, subjects in the 40H condition should have acquired little knowledge of the category structure and should go along with our surreptitious changes.

To verify that different exposure conditions had a significant effect on performance, we tested subjects in the same way as our earlier studies after a one week delay. Overall, 40P subjects achieved 75.3% accuracy and 40H subjects achieved 65.1% accuracy. As expected, categorization accuracy was influenced by the type of information presented during initial category exposure, as was reported by Squire and Knowlton (1995). Overall performance of our 40H subjects was quite comparable to what we and others have observed in this para-

digm; performance of the 40P subjects was significantly better than what we have observed before. So, information presented during initial exposure can have a significant effect on categorization performance.

As a way of simulating amnesia, we tested a subset of subjects after a several weeks delay. But now we tested half on items generated from the prototype used to generate items they had seen before (Same condition) and tested half on items generated from a novel prototype (Different condition). Thus, each subject was in one of four conditions: 40P-Same, 40P-Different, 40H-Same, and 40H-Different. Since all subjects viewed a different randomly generated set of stimuli, we can characterize subjects in the Different condition as receiving a categorization test intended for another individual.

As illustrated in Figure 3, we found that subjects in 40P-Same performed quite well, correctly categorizing 77.4% of the items. However, subjects in 40P-Different were completely at chance categorizing the test items. We suspect that these subjects tried to use the category information they clearly had acquired earlier and could not apply that knowledge when given a test comprised of entirely novel items. For subjects in the 40H conditions, as we predicted, there was no significant difference in performance between subjects who were tested on the same structure they were initially exposed to and subjects who were tested on a completely different structure. Consistent with our previous results, these subjects appear to be making categorization decisions based on what they acquired during the categorization test, not on what they may have acquired during earlier phases of the experiment.

Summary. The dissociation between categorization and recognition reported by Knowlton and Squire (1993) initially appeared to present strong evidence supporting multiple memory systems theory. We reported how the observed dissociations between categorization and recognition using distorted dot patterns may be explained as a result of the particular methodologies used to test these individuals. We showed that very good categorization performance can be achieved in the absence of any prior exposure to the category members. We also showed that very good categorization performance can be achieved when people are tested on items that are

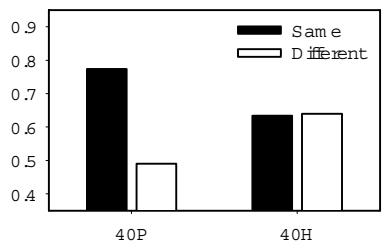

Figure 3. Categorization accuracy in Same condition and Different condition for subjects studying 40 repetitions of a prototype (40P) and 40 high distortions of prototype (40H) in Experiment 2.

different from what they had actually studied. But this seems to only occur when subjects have been initially exposed to a very diffuse category structure consisting of high distortions that are not very similar to one another. When subjects have been exposed to a clear category structure through repetition of a single prototype, they attempt to categorize items based on that acquired category knowledge, not on information presented during the categorization test.

Learning Categories of Object-Like Stimuli with Discrete Features

Reed et al. (1999) aimed to generalize the investigation of preserved categorization by amnesics by using object-like stimuli with discrete features. The stimuli they used, called Peggles, were drawings of animals that varied on nine binary-valued dimensions. To create a category, some Peggle was designated the prototype. Category members were distortions of the prototype. Low distortions shared 7 or 8 features of the prototype. High distortions shared only 1 or 2 features. In the extreme, an antiprototype had all nine features opposite to that of the prototype. Stimuli that shared 4 or 5 features of the prototype were designated neutral items that were half way between the prototype and the antiprototype.

Subjects viewed 40 low distortions of the prototype. After exposure, subjects were told that the animals they saw were all members of a category, called Peggles, and were then asked to make member/nonmember judgments, without feedback, of 96 new items. The test included 12 repetitions of the prototype, 24 low distortions, 24 neutral items, 24 high distortions, and 12 repetitions of the antiprototype. Subjects were also tested on their ability to complete a cued-recall test identifying both values of the 9 dimensions of the Peggles.

Reed et al. (1999) found that amnesics were impaired at an explicit cued-recall task but could categorize at levels comparable to normals. But, two of their amnesics actually categorized stimuli opposite to the way they should have. That is, they mistakenly called the prototype and low distortions nonmembers and called the antiprototype and high distortions members. Reed et al. suggested that amnesics had a spared implicit category learning system that partitioned members and nonmembers but that perhaps declarative memory was needed to remember which partition corresponded to the items they had previously been exposed to.

Experiment 3. Following the theme of this paper, we propose an alternative explanation. During the categorization test, subjects were shown the prototype many times and were shown low distortions that were very similar to the prototype. They were also shown the antiprototype many times and were shown high distortions that were very similar to the antiprototype. In other words, there were two clear clusters of items presented during the categorization test. If subjects could pick up on the category structure embedded within the testing

sequence to cluster stimuli into two groups, they would be able to correctly partition the stimuli into two categories. But, they would not be able to unambiguously decide which cluster corresponded to the category they were initially exposed to without relying on memory of some sort. Might this be a more reasonable explanation of the category switching by amnesics previously reported by Reed et al.?

The goal of this experiment was to test whether subjects might be categorizing in part by extracting information from the structure of the categorization test. We tested subjects in three conditions: Immediate, Delayed, and Novel. The Immediate condition was essentially a replication of Reed et al. (1999). In the Delayed condition, subjects were exposed to the category and then returned one week later to be tested in the same way as subjects in the Immediate condition. In the Novel condition, subjects were also exposed to the category and returned one week later. The stimuli presented for categorization in the Novel condition contained an embedded category structure that contradicted what was presented during initial exposure. To do this, a neutral item with respect to the prototype that was used to generate stimuli from the original exposure session was picked at random and designated the "prototype" for purposes of creating a new categorization test sequence. From this novel prototype, low distortions, neutral items, high distortions, and an antiprototype were created. Note that the "antiprototype" for this new structure would also be considered a neutral item with respect to the prototype that was used to generate items subjects were originally exposed to. The novel categorization test consisted of 12 repetitions of the novel prototype, 24 low distortions, 24 neutral items, 24 high distortions, and 12 repetitions of the novel antiprototype.

Let us generate some predictions for the Novel condition. If subjects are categorizing based on what they had been previously exposed to, they should categorize the "prototype" and the "antiprototype" in this novel test sequence equally, as half way between the member and nonmember category with respect to what they had originally studied. However, if subjects are instead picking up on the clear category structure embedded within this novel test sequence, they should group the "prototype" and its distortions in one category and group the "antiprototype" and its distortions in another category. Half of the subjects would call the "prototype" group the members and half would call the "antiprototype" group the members.

Now to the results. First, as shown in the right portion of Figure 4, performance in the recall task was significantly impaired in the Delayed and Novel condition compared to the Immediate condition. Also, as shown in the left of Figure 4, subjects in the Immediate and Delayed conditions showed comparable categorization.

Scoring categorization data for subjects in the Novel condition was somewhat more complicated (Palmeri & Flanery, 2001). Essentially, what we first did was to

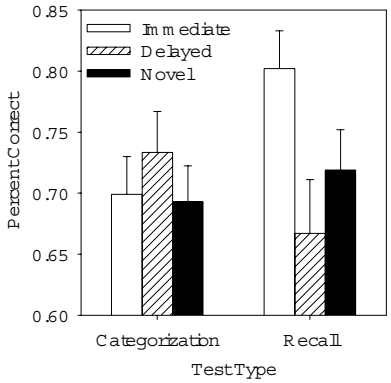

Figure 4. Categorization and cued-recall accuracy in the Immediate, Delayed, and Novel conditions of Experiment 3 (Palmeri & Flanery, 2001).

measure the difference in membership endorsements for the "prototype" and the "antiprototype." Recall that if subjects were categorizing these two critical stimuli with respect to what they had actually been exposed to, they should be indifferent at categorizing these items as members or nonmembers. To the contrary, we found a 53.6% difference in membership endorsements for the "prototypes" and the "antiprototypes." Subjects were clearly discriminating between these items when making category member judgments. Next, if a particular subject judged the "prototype" more often to be a member then we judged categorizations of the low distortions as members and high distortions as nonmembers to be "correct" responses; if a particular subject judged the "antiprototype" more often to be a member then we judged categorizations of the high distortions as members and low distortions as nonmembers to be "correct" responses. Figure 4 displays categorization accuracy for the Novel condition using this scoring method (actually, we scored the Immediate and Delayed conditions in the same way to make the reported results consistent). What should be clear from the figure is that subjects in the Novel condition discriminated between members and nonmembers in a way that was consistent with the structure embedded within the testing sequence and not on memory for what they had seen a week earlier. As with Experiment 2, we found comparable performance between subjects who were tested on categories they actually studied and subjects who were tested on categories that contradicted what they had actually studied.

Summary. In this experiment, we extended a paradigm used by Reed et al. (1999) to contrast categorization and recall by amnesics and normals. They observed impairments in cued recall by amnesics compared to normals, but there was little difference in categorization between the two groups. However, they did observe that two of their amnesic individuals categorized members of the previously studied category as nonmembers and nonmembers as members. While Reed et al. interpreted these results in terms of an implicit memory for the category, we instead provided evidence that this ability

to discriminate members from nonmembers might emerge from a clear category distinction embedded within the testing sequence.

Learning Categories Described by a Complex Quadratic Rule

Can individuals with explicit memory impairments learn to categorize stimuli in accordance with a complex categorization rule? Filoteo et al. (in press) had normals and amnesics learn categories described by what they characterized as a complex quadratic rule. Subjects learned two categories that were defined by multivariate normal distributions. Figure 5 displays the equal likelihood contours for the category structures utilized by Filoteo et al. (in press). Because the categories are defined by normal distributions, the two categories overlap, so perfect performance is impossible. Also as shown in the figure, learning the categories required subjects to integrate information across both stimulus dimensions; in the language of decision boundary theory, learning these categories required the formation of a quadratic (nonlinear) decision rule. This manipulation was of theoretical importance because some work has suggested that amnesics cannot integrate information across multiple dimensions (Rickard & Grafman, 1998).

The stimuli used by Filoteo et al. (in press) consisted of a horizontal and a vertical line connected at the top left corner. The length of the horizontal and vertical lines varied in accordance with the distributions shown in Figure 5. It is important to note that the "diagonal" distribution consisted of stimuli for which the line lengths are highly correlated; in other words, they form the left and top portions of a square (square category). The "circular" distribution consisted of stimuli for which the line lengths are uncorrelated; in other words, they form the left and top portions of various rectangles (rectangle category). On each trial of the experiment, subjects were presented with a stimulus randomly drawn from either the square or the rectangle category, categorized it as a member of category A or category B, and received corrective feedback.

Filoteo et al. observed the accuracy in the last 100 trials to be 85% for normals and 84% for amnesics. They concluded that amnesics appear to be able to acquire categories defined by a complex quadratic rule. To test whether an amnesic could retain that rule over a delay period, they tested one amnesic and one normal after a one day delay. Subjects completed a single block of 100 trials in which they received corrective feedback on every trial, just as in the original training. Accuracy was 92% for the normal individual and 89% for the amnesic. Thus, amnesics and normals appear to be able to learn and retain a quadratic categorization rule.

Experiment 4. The Filoteo et al. results suggest that amnesics can learn and retain a category described by a complex quadratic rule that requires integrating information from two stimulus dimensions, height and width. However, these stimuli can also be described in an alternative way by rotating the dimensions by 45 degrees. That is, we can alternatively describe the dimensions as shape and size. The square and rectangle categories contain stimuli of the same shape and can be categorized by a very simple shape rule rather than a complex quadratic rule. Filoteo et al. rejected this possibility, arguing that their subjects were learning a complex quadratic rule requiring an integration of information along two independent stimulus dimensions. But, we are puzzled by how these subjects were able to learn a complex categorization rule so quickly, reaching asymptotic performance after less than 100 trials, when other categorization experiments examining quadratic boundaries have required many days of training to reach asymptote.

To illustrate that subjects may not be learning a complex quadratic rule, but may instead may be learning a simple shape rule, we replicated and extended the Filoteo et al. study using three conditions. In the first condition, we used the same stimuli and category structures as Filoteo et al. (Square/Rectangle condition). In the second condition, subjects were trained on similar stimuli, but both multivariate category distributions were shifted along dimension 1. In this way, the diagonal category distribution still had height and width correlated, but their values were not equal – in other words, the stimuli were rectangles of the same shape that varied in size (Rectangle/Rectangle condition). In the third condition, we used very different stimulus dimensions of circle size and angle of a diameter line (Circle-Line/Circle-Line condition) that cannot be integrated like the height and width of line segments; these dimensions were roughly equated for discriminability with the height and width dimensions.

Performance in the Squares and Rectangles conditions were comparable (81% and 78% accuracy, respectively). Performance in the Circle-Line condition was far worse (58% accuracy). These results suggest that amnesics may not have been learning a complex quadratic categorization rule at all, but may have instead been learning a very simple shape rule.

Another issue with the Filoteo et al. (in press) results regards the retention of the categorization rule after a

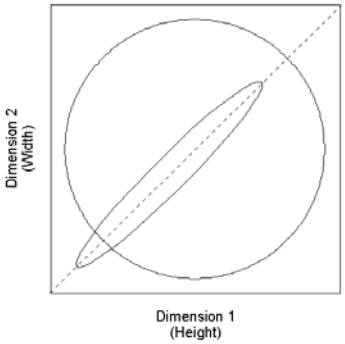

Figure 5. Equal probability contours for categories used by Filoteo et al. and used in Experiment 4.

delay. In the second session of their experiment, subjects received feedback after each trial, similar to what they had experienced during training. Did the amnesics display a real memory for the categorization rule or did they express a savings in relearning a very simple categorization rule? To show that different kinds of categorization tests can reveal different levels of knowledge about categories, we brought our subjects back after one day and tested them in three different ways. First, we tested them without feedback on stimuli drawn from a uniform distribution across the entire set of possible stimuli. Second, we tested them without feedback on stimuli drawn randomly from the two category distributions. Third, we retrained them with feedback, as was done by Filoteo et al. Although subjects reached comparable levels of performance in the Squares and Rectangles condition on the first day, subjects were much better when tested on the uniform distribution without feedback in the Squares condition (96%) than the Rectangles condition (79%). By contrast, in the other two testing conditions (without feedback and with feedback), performance was comparable for the Squares and Rectangles condition (82% and 80% accuracy, respectively). It appears that the different categorization tests can reveal differential knowledge of the categories.

Summary and Conclusions

We found evidence that normal subjects can acquire information about categories in the absence of prior study and in opposition to prior study. In our experiments, performance by subjects in these conditions was not significantly different from performance by subjects who actually received prior study and who were tested on items consistent with their prior study. Our results demonstrate that classification decisions made during a categorization test may not be based solely on information acquired during a study task, but may also be based on information acquired during the test itself. As a general point, we argue that care must be taken in selecting items for a categorization test so as not to provide additional information about the categories being tested or so as not to change the information about the categories that may have been previously acquired. In the present experiments, subjects were tested in such a way that it was possible to extract information about the categories from the tests themselves. Subjects were repeatedly tested on the category prototype (four times in Experiment 1, twelve times in Experiment 2) and were tested on many low distortions that were very similar to the category prototype, conditions particularly amendable to unsupervised category learning. A preferable way to test individuals in an neutral manner might be to sample all possible test stimuli from a uniform distribution, as we did in the last experiment. Although it may be possible to partition such test stimuli into some arbitrary set of categories, only by chance might this partition match the correct category discrimination without relying on memory for studied items.

As we stated at the outset, our results may have implications for understanding the relationship between categorization and other forms of memory. The ability of amnesics to categorize stimuli coupled with their impairment at recognizing or recalling stimuli has been taken as evidence for multiple memory systems (e.g., Knowlton & Squire, 1993; Reed et al., 1999; Squire & Knowlton, 1995; see, however, Nosofsky & Zaki, 1998). If the paradigms used by some investigators permit category acquisition from the categorization test (by contrast, the explicit memory tasks used in these experiments cannot be accurately performed without memory for the studied items), then the strength of this dissociation may be questioned. It seems prudent to forgo strong conclusions about independence or nonindependence of fundamental aspects of human cognition until more convincing paradigms are employed.

Abstract

Student responses to qualitative physics questions were analyzed with latent semantic analysis (LSA), using different text corpora. Physics potentially has a number of distinctive characteristics that are not encountered in many other knowledge domains. Physics texts exist at a variety of levels and typically involve an integrated presentation of text, figures and equations. We explore the adequacy of several text corpora and report results on vector lengths and correlations between key terms in elementary mechanics. The results suggest that a carefully constructed smaller corpus may provide a more accurate representation of fundamental physical concepts than a much larger one.

Introduction

The physics classroom has often served as a laboratory for cognitive science. Studies of students learning or failing to learn physics have influenced notions of conceptual change, question answering and tutoring strategy (Albacete & VanLehn, 2000; Van Heuvelen, 1991). The physics teaching community is now aware that conventional teaching methods often fail to make any significant change in the student's understanding of the physical world. While students in the more technical introductory courses might develop the ability to recognize certain problem templates and to manipulate equations, and those in "conceptual" physics courses learn enough set answers to pass multiple choice exams, there is ample evidence that many students retain the same misconceptions about the nature of everyday phenomena with which they began the formal study of physics (Ploetzner & VanLehn, 1997).

The study of physics allegedly places rather different demands on the student than other academic work, as is readily apparent in the texts that are used. The goal of "understanding physics" or "thinking like a physicist", to which most instructors aspire, involves a combination of declarative and procedural knowledge in which the procedural component figures far more significantly than in, for example, a survey of history or introductory computer literacy. Language is used somewhat differently in physics than in other scientific fields. While biology and chemistry resort to Greco-Roman or Germanic word forming conventions to

introduce new words with precise meanings, physics more often than not takes words from ordinary language, like force and momentum, and restricts their meaning to a single sense. In most modern physics texts (such as Hewitt, 1998), there are multiple photographs or simple sketches on every page, and much of the text is directly organized around these figures. Much of the exposition in conceptual physics courses includes questions and answers that may be separated by text. Physics texts often devote considerable space to the historical evolution of physical concepts, the cultural context of physics, and its social impact. Some authors also devote appreciable space to discussing discarded theories and chains of reasoning that lead to incorrect conclusions. Thus, a significant fraction of the text found in a physics text may, in fact, exemplify incorrect thinking.

Our group has been developing a corpus of texts about physics that will eventually be used in an intelligent tutoring system on conceptual physics. The text corpus is needed to build a latent semantic analysis (LSA) space, which will be used to process the meaning of student answers in ordinary language. This paper is concerned particularly with the best strategy to construct such a corpus. A naive approach would be to gather a number of physics texts, and combine them into one corpus. However, there are unusual challenges taking this approach. What should be done about the diagrams in the text? What about the text that was written to illustrate incorrect reasoning? Does the inclusion of texts at different levels strengthen or dilute the accuracy with which physics concepts are represented in the LSA space? In short, how much special preparation of the corpus is needed, if it is to provide a reliable representation of the physics that students are expected to learn?

Latent Semantic Analysis

LSA has recently been proposed as a statistical representation of a large body of world knowledge (Kintsch, 1998; Landauer & Dumais, 1997). LSA provides the foundation for grading essays, even essays that are not well formed grammatically, semantically, and rhetorically; in fact, LSA-based essay graders assign grades to assays as reliably as experts in composition (Foltz, Gilliam, & Kendall, 2000). LSA has been used to evaluate the quality of student contributions in interactive dialogs between college students and AutoTutor, a tutoring system in the domain of computer literacy; the LSA module evaluates the quality of student answers to questions almost as reliably as graduate student research assistants (Graesser, P. Wiemer-Hastings, K. Wiemer-Hastings, Harter, Person, & TRG, 2000; P. Wiemer-Hastings, K. Wiemer-Hastings, Graesser, & TRG, 1999). Given these successes in using LSA to evaluate the quality of student essays and contributions in tutoring systems, on a variety of topics, we were interested in exploring how LSA would fare in the domain of qualitative physics.

LSA is a mathematical technique in which the information contained in the co-occurrences of words in a body of text is compressed into a set of vectors in N-dimensional space. The input to LSA is word co-occurrence matrix M, where the individual elements Mij is the number of times that the ith word occurs in the jth document. A document is an arbitrarily defined unit, but normally is a sentence, paragraph, or section in a text. The rows and columns of the matrix are then subjected to mathematical transformations that take into account the frequency of word use in the document (Berry, Dumais, & O'Brien, 1995; Landauer, Foltz, & Laham, 1998). Using the mathematical process of singular value decomposition, the matrix is then expressed as the product of three matrices, the second of which contains the singular values on the diagonal. Changing all but the largest N singular values to zero sets the dimensionality N of the vector space representing the text. The matrices are then re-multiplied to produce a matrix of the same dimensions of the original matrix.

At first glance it might seem that by discarding some of the singular values we are discarding information. However, it turns out in practice that the lower dimensional representation better captures the meaning of the text. For instance, there ends up being a positive relationship between the coefficients in the rows corresponding to different words, if the words have similar or associated meanings. The reduced number of dimensions are sufficient for evaluating the conceptual relatedness between any two bags of words. A bag is an unordered set of one or more words. The match (i.e., similarity in meaning, conceptual relatedness) between two bags of words is computed as the geometric cosine (or dot product) between the two associated vectors, with values that normally range from 0 to 1. LSA successfully predicts the coherence of successive sentences in text (Foltz, Kintsch, & Landauer, 1998), the similarity between student answers and ideal answers to questions (Graesser, P. Wiemer-Hastings, et al., 2000; Wiemer-Hastings et al., 1999), and the structural distance between nodes in conceptual graph structures (Graesser, Karnavat, Pomeroy, Wiemer-Hastings, & TRG, 2000). At this point, researchers are exploring the strengths and limitations of LSA in representing world knowledge.

Constructing an LSA Corpus That Knows About Physics

We have assembled several different physics corpora to test the effect of the content of the subject matter on the

quality of the LSA solutions. The documents in the texts were classified into different rhetorical categories, such as exposition, example problems, historico-cultural material, incorrect reasoning, and so on. The fundamental research question is whether the inclusion of different texts and categories of content have an impact on the representation of core concepts in the mechanics portion of a conceptual physics course. All the corpora include text materials from the mechanics portion of Paul Hewitt's *Conceptual Physics* (1998), a text that is widely used in conceptual physics courses at the college level; these were used with permission from the publisher. The "Omnibus" corpus included chapters 2-9 of the Hewitt book plus six volumes of a comprehensive text aimed at students in technical or life science majors, two advanced texts in electromagnetism, and another physics text that was available electronically. The "Large" corpus was constructed from the former by deleting the three latter texts. A "Small" corpus further deleted the texts that did not cover mechanics. A "Restricted Small" corpus further deleted any text identified as primarily historico-cultural or involving misconceptions. In the "Restricted Hewitt" corpus, we included only those texts from Hewitt in the restricted small corpus. Each of the corpora was thus a proper subset of the preceding one, with the goal of further refining or sanitizing the text corpus to handle the core concepts in mechanics. The time needed to "restrict" a text was minimal once the text was converted to electronic form.

Vector Lengths and Similarity

Kintsch (1998) proposed that the length of the vectors representing key terms provides a measure of the extent to which the LSA has captured the meaning (or importance, centrality) of the word with respect to the subject matter. The vector length increases to the extent that the set of values in the vector deviate from zero. Words like *force*, *momentum* and *gravitation* should have reasonably large vector lengths in any corpus that represented basic physics concepts well.

LSA spaces of 100, 200, 300, 400, and 500 dimensions were created for each of the above five corpora. Each text paragraph was treated as a document. Figure captions were eliminated. Questions & answers were lumped in the same document. Based on the vector lengths computed for the key mechanics words listed in Table 1, it was decided that little improvement would be achieved by going beyond 500 dimensions. The restricted Hewitt corpus was so small that only a 400 dimensional representation could be obtained. The vector lengths for selected physics words in a 300 dimensional space are shown in Table 1.

A number of conclusions can readily be drawn from Table 1. There is a general correlation between vector lengths of the first two corpora and between those of the two smallest corpora. When we eliminated the material not pertinent to mechanics as presently understood, some vectors ended up increasing in length. For example, the *impulse* concept, which occurs only in mechanics, had a significantly larger vector length in the smaller corpora than in the larger corpora. The same can be said for *tension*, which is the force transmitted by a rope or cable, and is useful only in mechanics. Even a concept like *energy*, which pervades all areas of physics, appears to be more crisply represented in the smaller corpus.

Table 1. Vector Lengths for Physics Words.

Word	Omnibus	Large	Small	R-small	R-Hewitt
Gravity	.288	.281	.262	.242	.240
Gravitational	.256	.250	.223	.256	.283
Mass	.300	.293	.269	.239	.288
Acceleration	.300	.296	.266	.270	.284
Force	.186	.179	.155	.128	.153
Momentum	.267	.263	.258	.283	.288
Energy	.222	.219	.228	.238	.313
Impulse	.367	.371	.400	.432	.466
Friction	.320	.314	.301	.313	.375
Velocity	.252	.250	.240	.236	.291
Vector	.285	.305	.292	.382	.455
Potential	.323	.328	.361	.386	.464
Tension	.266	.271	.302	.390	.475
Kinetic	.298	.294	.301	.312	.422
Normal	.315	.314	.352	.414	.373
Newton	.347	.242	.211	.206	.265
Aristotle	.309	.309	.318	.409	.436
Galileo	.324	.326	.325	.338	.355
Newtonian	.242	.223	.221	.339	.000

The names of the key physicists, *Galileo* and *Newton*, along with that of *Aristotle*, whose notions of physics are now largely discarded, were also included in our study of vector lengths. Interestingly, our efforts to eliminate material of only historical value in the two restricted corpora did not eliminate a rather well represented *Aristotle*. LSA did pick up stylistic characteristics of individual authors.

The similarity between concepts in LSA is represented by the cosine values in corresponding vectors. We computed the cosines between the physics terms in Table 1 and these appear in Table 2. The greatest similarity appeared for *kinetic energy*, which is in effect a composite word and for *impulse-momentum*, which would appear as a composite in the "impulse-momentum theorem" and the exposition of it, in that impulse equals the net change of momentum in a collision. We note that the similarities between *mass* and *acceleration* and between *force* and *acceleration*, which would be expected in any exposition based on Newton's second law (the net force on an object equals

the mass times its acceleration). The similarity scores are appreciably more apparent in the smaller corpora with the irrelevant text removed.

Table 2. Largest magnitude cosines between key physics terms. (Corpora titles are abbreviated)

Correlation	Om	Lge	Sm	R-Sm	R-H
Gravitational force	.084	.083	.093	.146	.029
Gravitational potential	.058	.091	.097	.107	.032
Force acceleration	.006	.009	.009	.048	.087
Mass acceleration	.033	.035	.044	.070	.066
Normal force	.080	.084	.125	.096	.043
Mass momentum	.010	.013	.028	.040	.077
Impulse momentum	.182	.187	.176	.196	.148
Kinetic energy	.209	.228	.265	.267	.267
Tension friction	.052	.052	.020	.066	.001
Vector Velocity	.052	.055	.053	.065	.059
Kinetic friction	.081	.083	.020	.066	.026

Summary

We have developed a number of alternative physics text corpora for use in the evaluation of student answers to physics questions. Comparisons of word length and word similarity suggest that both the elimination of material from other areas of physics and other levels of exposition, as well as the elimination of material not dealing with the exposition of the physical concepts, allows an improved representation of core physics terms and the relationships between them, even with a rather small corpus. However, this conclusion is currently being tested on a large body of student and expert answers to physics questions. The preliminary results suggest that although vector lengths increase for individual words with a refined selection of texts, it is a large corpus that works best when the entire sentence is used to evaluate the match of student and expert answers. In other words, individual words may have a crisper representation when a smaller, well-defined text is used but when analyzing an answer formed around the integration of several complex concepts, a broader selection of texts is more beneficial. Furthermore, it is our contention that a regression could be used to capitalize on the unique information provided by both types of LSA spaces. In future work, we will examine the feasibility of adding picture descriptions in natural language to the corpus and alternative treatments of equations and composite words.

Abstract

We propose the use of autonomous software agents as cognitive models that generate testable hypotheses about human cognition. While such agents are typically produced to automate practical human tasks, they can be designed within the constraints of a psychological theory. As an example we describe an agent designed within global workspace theory that accommodates several other theories as well. We discuss various resulting hypotheses, including a new interpretation of the readiness potential data of Libet.

Introduction

Computational models have long been a major, and perhaps indispensable, tool in cognitive science. Many of these model some psychological theory of a particular aspect of cognition, attempting to account for experimental data. Others aspire to be a general computational model of cognition, such as the construction-integration model (Kintsch 1998), SOAR (Laird et al. 1987), and ACT-R (Anderson 1990). Most of these computational models are computer simulations of subjects in psychological laboratories, and are capable of performing tasks at a fine-grain level of detail. The simulated data ideally fit the human data like a glove. The theories on which the simulations are based are periodically revised so that new simulations conform more closely to the data. The computational models are judged on how closely they predict the data. A model may also be judged by the amount of change required in core, as opposed to peripheral, parameters that are needed to fit the data. Alternatively, the models are evaluated on a course-grain level, by observing whether a number of qualitative predictions (i.e., directional predications, such as condition A > B) fit the data. And finally, all of the models have been evaluated by observing how well they fit data in practical, everyday tasks in real-world environments. For example, some such agents, based on SOAR, simulate battlefield performers such as fighter pilots and tank commanders (Hirst & Kalus 1998). These data fitting approaches to testing theories have been hugely successful, and account for a large body of what is now known in cognitive science.

In this paper, we propose another class of computational models, which fall under the general heading of autonomous software agents (Franklin & Graesser 1997). These agents are designed to implement a theory of cognition and attempt to automate practical tasks typically performed by humans. We have been developing two such agents that implement global workspace theory Baars 1988), one with a relatively simple clerical task (Zhang et al. 1998b) and the other with a rather complex personnel assignment task (Franklin et al. 1998). These models do not merely produce output that solves a specific engineering problem, as do typical software agents like web bots. They have mechanisms that simulate human cognition and their design decisions generate hopefully testable hypotheses (Franklin 1997), thus potentially providing research direction for cognitive scientists and neuroscientists.

This paper briefly describes the architecture and mechanisms of one such agent. In Table 1 we point out examples of relevant hypotheses that arise from our design decisions. It is beyond the scope of this article to specify all of the hypotheses and associated support.

Theoretical Frameworks

According to *global workspace (GW) theory* (Baars 1988), one principal function of consciousness is to recruit the relevant resources needed for dealing with novel or problematic situations. These resources may include both knowledge and procedures. They are recruited internally, but partially driven by stimulus input. GW theory postulates that human cognition is implemented by a multitude of relatively small, special purpose processes, almost always unconscious. Communication between them is rare since they mostly communicate through working memory and over a narrow bandwidth. They are individually quite simple and incapable of dealing with complex messages. Coalitions of such processes compete for access to a global workspace. This limited capacity workspace serves to broadcast the message of the coalition to all the unconscious processors (bringing it to consciousness) in order to recruit relevant processors to join in handling the current novel situation, or in solving the current problem. Thus consciousness allows us to deal with novel or problematic situations that cannot be dealt with efficiently, if at all, by automated unconscious processes. Consciousness recruits appropriately useful resources, and thereby manages to solve the relevance problem.

An *autonomous agent* (Franklin & Graesser 1997) is a system situated in, and part of, an environment, which senses that environment, and acts on it, over time, in pursuit of its own agenda. In biological agents, this agenda arises from drives that evolve over generations; in artificial agents its designer builds in the drives. Such drives, which act as motive generators (Sloman 1987), must be present, whether explicitly represented or derived from the processing trajectory. The agent also acts in such a way as to possibly influence what it senses at a later time. In other words, it is structurally coupled to its environment (Maturana 1975). Examples include humans, most animals some mobile robots, and various computational agents, including artificial life agents, software agents and many computer viruses. Here we are immediately concerned with autonomous software agents, designed for specific tasks, and 'living' in real world computing systems such as operating systems, databases, or networks.

A *"conscious" software agent* is one that implements GW theory. In addition to modeling this theory (Franklin & Graesser 1999), such "conscious" software agents should be capable of more adaptive, more human-like operations, including being capable of creative problem solving in the face of novel and unexpected situations. However, there is no claim that the agent is a sentient being. What, if anything, the agent truly feels or what the conscious experience actually is are not the relevant concerns.

IDA (Intelligent Distribution Agent) is a "conscious" software agent being developed for the US Navy (Franklin et al. 1998). At the end of each sailor's tour of duty, the sailor is assigned to a new billet.. The Navy employs some 280 people, called detailers, to effect these new assignments. IDA's task is to completely automate the role of detailer. IDA must communicate with sailors via email in natural language, by understanding the content and producing life-like responses. Sometimes she will initiate conversations. She must access several databases, again understanding the content. She must adher to some ninety Navy policies. She must hold down moving costs, but also cater to the needs and desires of the sailor. This includes negotiating with the sailor and eventually writing the orders. A partial prototype of IDA with most of the functionality described is now up and running. It should be complete before the beginning of the year.

Architecture and Mechanisms

Table 1 specifies several of the underlying hypotheses that guided the design of IDA Many of these hypotheses are not directly addressed in this paper. Others will be discussed in some detail.

IDA is intended to model a broad range of human cognitive function. Her architecture is comprised of modules each devoted to a particular cognitive process. Table 2 lists most of these modules and gives pointers to the sources of their computational mechanisms, and to the psychological theories they support.

The processors postulated by GW theory are implemented by codelets, small pieces of code, each an independent thread. These are specialized for some simple task and often play the role of demons waiting for appropriate conditions under which to act. From a biological point of view, these codelets may well correspond to Edelman's neuronal groups (1987).

Perception in IDA consists mostly of processing incoming email messages in natural language. In sufficiently narrow domains, natural language understanding may be achieved via an analysis of surface features called complex, template-based matching (Allen 1995, Jurafsky & Martin 2000). Ida's relatively limited domain requires her to deal with only a few dozen or so distinct message types, each with relatively predictable content. This allows for surface level natural language processing. Her language-processing module has been implemented as a Copycat-like architecture (Hofstadter & Mitchell 1994) with codelets that are triggered by surface features. The mechanism includes a slipnet that stores domain knowledge, a pool of codelets (processors) specialized for recognizing particular pieces of text, and production templates for building and verifying understanding. Together they allow her to recognize, categorize and understand. IDA must also perceive content read from databases, a much easier task. An underlying hypothesis motivating our design decisions about perception appears in Table 1.

Suppose, for example, that IDA receives a message from a sailor saying that his projected rotation date (PRD) is approaching and asking that a job be found for him. The perception module would recognize the sailor's name and social security number, and that the message is of the please-find-job type. This information would then be written to working memory. The hypothesis here is that the contents of perception are written to working memory before becoming conscious. IDA employs sparse distributed memory (SDM) as her major associative memory (Kanerva 1988). SDM is a content addressable memory that, in many ways, is an ideal computational mechanism for use as a long-term associative memory (LTM). Any item written to working memory cues a retrieval from LTM, returning prior activity associated with the current entry. In our example, LTM will be accessed as soon as the message information reaches the workspace, and the retrieved associations will be also written to the workspace.

Table 1. Hypotheses from Design Decisions

Module	Hypotheses from Design Decisions
Perception	Much of human language understanding employs a combined bottom up/top down passing of activation through a hierarchical conceptual net, with the most abstract concepts in the middle.
Working Memory	The contents of perception are written to working memory before becoming conscious.
Long-term Memory	Part, but not all, of working memory, the focus, is set aside as an interface with long-term associative memory (LTM). Reads from LTM are made with cues taken from the focus and the resulting associations are written there. Writes to LTM are also made from the focus.
Consciousness	Human consciousness must have a mechanism for gathering processors (neuronal groups) into coalitions, another for conducting the competition, and yet another for broadcasting
Motivation	The hierarchy of goal contexts is fueled at the top by drives, that is by primitive motivators, and at the bottom by input from the environment, both external and internal
Goal Contexts	In humans, processors (neuronal groups) bring perceptions and thoughts to consciousness. Other processors, aware of the contents of consciousness, instantiate an appropriate goal context hierarchy, which motivates yet other processors to perform internal or external actions.
Emotions	Action selection will be influenced by emotions via their effect on drives. Emotions also influence attention and the strength with which items are stored in associative memory.
Voluntary Action	Voluntary action in humans is controlled by a timekeeper who becomes less patient as the time for a decision increases. Each time a proposal or objection reaches consciousness, its chance of becoming conscious again diminishes.
Language Production	Much of human language production results from filling in blanks in scripts, and concatenating the results.

At a given moment IDA's workspace may contain, ready for use, a current entry from perception or elsewhere, prior entries in various states of decay, and associations instigated by the current entry, i.e. activated elements of LTM.. IDA's workspace thus consists of both short-term working memory (STM) and something very similar to the long-term working memory (LT-WM) of Ericsson and Kintsch (1995).

Since most of IDA's cognition deals with performing routine tasks with novel content, most of her workspace is structured into registers for particular kinds of data. Part of the workspace, the *focus*, is set aside as an interface with long-term LTM. Retrievals from LTM are made with cues taken from the focus and the resulting associations are written to other registers in the focus. The contents of still other registers in the focus are stored in (written to) associative memory. All this leads to the perception hypothesis in Table 1.

Not all of the contents of the workspace eventually make their way into consciousness. The apparatus for "consciousness" consists of a coalition manager, a spotlight controller, a broadcast manager, and a collection of attention codelets who recognize novel or problematic situations (Bogner et al. 2000).

Each attention codelet keeps a watchful eye out for some particular situation to occur that might call for "conscious" intervention. In most cases the attention codelet is watching the workspace, which will likely contain both perceptual information and data created internally, the products of "thoughts." Upon encountering such a situation, the appropriate attention codelet will be associated with the small number of codelets that carry the information describing the situation. (In the example of our message, these codelets would carry the sailor's name, his or her social security number, and the message type.) This association should lead to these information codelets, together with the attention codelet that collected them, becoming a coalition. Codelets also have activations measuring their current relevance. The attention codelet increases its activation in order that the coalition might compete for the spotlight of "consciousness". Upon winning the competition, the contents of the coalition is then broadcast to all codelets. This leads us to the consciousness hypothesis in Table 1.

Baars addresses the question of how content arrives in consciousness (1988, pp. 98-99), offering two possible high-level mechanisms both consistent with neurophysiological timing findings. He also devotes an entire chapter (1988 Chapter 3) to neurophysiological evidence consistent with the basic concept of a global workspace. Yet no mechanisms are proposed for the three distinct processes identified as being needed in our hypothesis above. Here we have a good example of engineering, as well as psychological, considerations giving direction to neurophysiological research.

Summarizing our example, an attention codelet will note the please-find-job message type, gather information codelets carrying name, ssn and message type, be formed into a coalition, and will compete for consciousness. If or when successful, its contents will be broadcast.

IDA depends on a behavior net (Maes 1989) for high-level action selection in the service of built-in

drives. She has several distinct drives operating in parallel that vary in urgency as time passes and the environment changes. Behaviors are typically mid-level actions, many depending on several behavior codelets for their execution. A behavior net is composed of behaviors, corresponding to goal contexts in GW theory, and their various links. A behavior looks very much like a production rule,

Table 2. IDA's Modules and Mechanisms and the Theories they Accommodate

Module	Computational Mechanism motivated by	Theories Accommodated
Perception	Copycat architecture (Hofstadter & Mitchell 1994)	Perceptual Symbol System (Barsalou 1999)
Working Memory	Sparse Distributed Memory (Kanerva 1988)	Long-term Working Memory (Erricsson & Kintsch 1995)
Emotions	Neural Networks (McCellland & Rumelhart 1986)	(Damasio 1999, Rolls 1999)
Associative Memory	Sparse Distributed Memory (Kanerva 1988)	
Consciousness	Pandemonium Theory (Jackson 1987)	Global Workspace Theory (Baars 1988)
Action Selection	Behavior Nets (Maes 1989)	Global Workspace Theory (Baars 1988)
Constraint Satisfaction	Linear Functional (standard operations research)	
Deliberation	Pandemonium Theory (Jackson 1987)	Human-Like Agent Architecture (Sloman 1999)
Voluntary Action	Pandemonium Theory (Jackson 1987)	Ideomotor Theory (James 1890)
Language Generation	Pandemonium Theory (Jackson 1987)	
Metacognition	Fuzzy Classifers	Human-Like Agent Architecture (Sloman 1999)

having preconditions as well as additions and deletions. It typically requires the efforts of several codelets to effect its action.

. Each behavior occupies a node in a digraph. As in connectionist models (McClelland et al. 1986), this digraph spreads activation. The activation comes from that stored in the behaviors themselves, from the environment, from drives, and from internal states. More relevant behaviors receive more activation from the environment. Each drive awards activation to those behaviors that will satisfy it. Certain internal states of the agent can also activate behaviors. One example might be activation from a coalition of codelets responding to a "conscious" broadcast. Activation spreads from behavior to behavior along both excitatory and inhibitory links and a behavior is chosen to execute based on activation. IDA's behavior net produces flexible, tunable action selection. This hierarchy of goal contexts is fueled at the top by drives, that is, by primitive motivators, and at the bottom by input from the environment, both external and internal.

Returning to our example, the broadcast is received by appropriate behavior-priming codelets who know to instantiate a behavior stream for reading the sailor's personnel record. They also bind appropriate variables with name and ssn, and send activation to a behavior that knows how to access the database. When that behavior is executed, behavior codelets associated with it begin to read data from the sailor's file into. the workspace. Each such write results in another round of associations, the triggering of an attention codelet, the resulting information coming to "consciousness," additional binding of variables and passing of activation, and the execution of the next behavior. As long as it's the most important activity going, this process is continued until all the relevant personnel data is written to the workspace. In a similar fashion, repeated runs through "consciousness" and the behavior net result in a course selection of possible suitable jobs being made from the job requisition database.

The process just described leads us to speculate that in humans, like in IDA, processors (neuronal groups) bring perceptions and thoughts to consciousness. Other processors, aware of the contents of consciousness, instantiate an appropriate goal context hierarchy, which in turn, motivates yet other processors to perform internal or external actions.

IDA is provided with a constraint satisfaction module designed around a linear functional. It provides a numerical measure of the suitability, or fitness, of a specific job for a given sailor. For each issue (say moving costs) or policy (say sea duty following shore duty) there's a function that measures suitability in that respect. Coefficients indicate the relative importance of each issue or policy. The weighted sum measures the job's fitness for this sailor at this time. The same process, beginning with an attention codelet and ending with behavior codelets, brings each function value to "consciousness" and writes the next into the workspace. At last, the job's fitness value is written to the workspace.

Since IDA's domain is fairly complex, she requires *deliberation* in the sense of creating possible scenarios, partial plans of actions, and choosing between them (Sloman 1999). In our example, IDA now has a list of a number of possible jobs in her workspace, together with their fitness values. She must construct a temporal scenario for at least a few of these possible billets to see if the timing will work out (say if the sailor can be

aboard ship before the departure date). In each scenario the sailor leaves his or her current post during a prescribed time interval, spends a specified length of time on leave, possibly reports to a training facility on a certain date, uses travel time, and arrives at the new billet with in a specified time frame. Such scenarios are valued on how well they fit the temporal constraints (the gap) and on moving and training costs. These scenarios are composed of scenes organized around events, and are constructed in the workspace by the same process of attention codelet to "consciousness" to behavior net to behavior codelets as described previously.

We humans most often select actions subconsciously, but we also make voluntary choices of action, often as a result of the kind of deliberation described above. Baars argues that such voluntary choice is the same a conscious choice (1997, p. 131). We must carefully distinguish between being conscious of the results of an action and consciously deciding to take that action, that is, of consciously deliberating on the decision. The latter case constitutes voluntary action. William James proposed the *ideomotor theory* of voluntary action (James 1890). James suggests that any idea (internal proposal) for an action that comes to mind (to consciousness) is acted upon unless it provokes some opposing idea or some counter proposal. GW theory adopts James' ideomotor theory as is (1988, Chapter 7), and provides a functional architecture for it. The IDA model furnishes an underlying mechanism that implements that theory of volition and its architecture in a software agent.

Suppose that in our example at least one scenario has been successfully constructed in the workspace. The players in this decision making process include several proposing attention codelets and a timekeeper codelet. A proposing attention codelet's task is to propose that a certain job be offered to the sailor. Choosing a job to propose on the basis of the codelet's particular pattern of preferences, it brings information about itself and the proposed job to "consciousness" so that the timekeeper codelet can know of it. Its preference pattern may include several different issues (say priority, moving cost, gap, etc) with differing weights assigned to each. For example, our proposing attention codelet may place great weight on low moving cost, some weight on fitness value, and little weight on the others. This codelet may propose the second job on the scenario list because of its low cost and high fitness, in spite of low priority and a sizable gap. If no other proposing attention codelet objects (by bringing itself to "consciousness" with an objecting message) and no other such codelet proposes a different job within a prescribed span of time, the timekeeper codelet will mark the proposed job as being one to be offered. If an objection or a new proposal is made in a timely fashion, it will not do so.

Two proposing attention codelets may alternatively propose the same two jobs several times. Several mechanisms tend to prevent continuing oscillation. Each time a codelet proposes the same job it does so with less activation and, so, has less chance of coming to "consciousness." Also, the timekeeper loses patience as the process continues, thereby diminishing the time span required for a decision. A job proposal may also alternate with an objection, rather than with another proposal, with the same kinds of consequences. These occurrences may also be interspersed with the creation of new scenarios. If a job is proposed but objected to, and no other is proposed, the scenario building may be expected to continue yielding the possibility of finding a job that can be agreed upon.

Experimental work of neuroscientist Benjamin Libet lends support to this implementation of voluntary action as mirroring what happens in humans (Libet et al. 1983). He writes, "Freely voluntary acts are preceded by a specific electrical change in the brain (the 'readiness potential', RP) that begins 550 ms before the act. Human subjects became aware of intention to act 350-400 ms after RP starts, but 200 ms. before the motor act. The volitional process is therefore initiated unconsciously. But the conscious function could still control the outcome; it can veto the act." Libet interprets the onset of the readiness potential as the time of the decision to act. Suppose we interpret it, instead, as the time a neuronal group (attention codelet) decides to propose the action (job). The next 350-400 ms would be the time required for the neuronal group (attention codelet) to gather its information (information codelets) and win the competition for consciousness. The next 200 ms would be the time during which another neuronal group (timekeeper) would wait for objections or alternative proposals from some third neuronal group (attention codelet) before initiating the action. This scenario gets the sequence right, but begs the question of the timing. Why should it take 350 ms for the first neuronal group (attention codelet) to reach consciousness and only 200 ms for the next? Our model would require such extra time during the first pass to set up the appropriate goal context hierarchy (behavior stream) for the voluntary decision making process, but would not require it again during the second. The problem with this explanation is that we identify the moment of "consciousness" with the broadcast, which occurs before instantiation of the behavior stream. So the relevant question is whether consciousness occurs in humans only after a responding goal structure is in place? This leads us to the voluntary action hypothesis in Table 1.

Future Work

Though the IDA model cuts a broad swath, human cognition is far too rich to be easily encompassed. Still, we plan to extend the model in several ways. An alteration to the behavior net will allow automation of actions. A capacity for learning from conversations with detailers is planned (Ramamurthy et al. 1998). A development/training period utilizing that ability is also anticipated for IDA (Franklin 2000). We're also working on giving her the ability to report "conscious" activity in natural language. Though IDA deals intelligently with novel instances of routine situations, she should be able to also handle unexpected, and problematic non-routine situations. We're working on it. In modeling human cognition, there's always much left to do.

Abstract

Three- to four-month-old infants presented with a series of cat or dog photographs show an unusual asymmetry in the exclusivity of the perceptual category representations formed. We have previously accounted for this asymmetry in terms of an inclusion asymmetry in the distribution of features present in the cat and dog images used during familiarization (Mareschal, French, & Quinn, 2000). We use a combination of connectionist modeling and experimental testing of infants to show that the asymmetry can be reversed by an appropriate pre-selection and minor image modification of cat and dog exemplars used for familiarization. The reversal of the asymmetry adds weight to the feature distribution explanation put forward by Mareschal et al. (2000).

Introduction

The ability to categorize is, without question, one of the central pillars of cognition. It is, therefore, not surprising that categorization abilities are present in humans from the very earliest age. Indeed, infants only a few months old are able to separate complex visual stimuli into generic object categories (e.g., Quinn & Eimas, 1996). In previous work, we have presented a simple connectionist model of perceptual categorization during early infancy (Mareschal & French, 1997; Mareschal & French, 2000; Mareschal et al., 2000). The model provided a mechanistic account of early infant category learning in terms of the data compression properties of connectionist autoencoder networks. Not only did this model capture standard infant categorization phenomena such as prototype formation and the use of feature co-variation information to form categories (Mareschal & French, 2000), but it also captured some of the more subtle idiosyncratic characteristics of infants' categorization behavior.

In particular, 3- to 4-month-olds show an unexpected asymmetry in the exclusivity of the perceptual category representations formed for cats versus dogs (Quinn, Eimas, & Rosenkrantz, 1993; Eimas, Quinn, & Cowan, 1994). Following exposure to a series of cat photographs, these infants will form a perceptual representation for cats that excludes dogs. In contrast, following exposure to a series of dog photographs, the same infants will form a category representation for dogs that does NOT exclude cats. Thus, there is an asymmetry in the exclusivity of the cat and dog categories: dogs are excluded from the representation for cats, whereas dog do not exclude cats.

We extend these results by showing how an opposite exclusivity asymmetry can be induced in 3- to 4-month-olds by a judicious choice of cat and dog exemplars presented to the infants prior to testing. Success in reversing the asymmetry between the Cat and Dog categories would lend strong support to a bottom-up account of early infant perceptual categorization.

Asymmetric exclusivity in infant categorization

Quinn et al. (1993) reported the following surprising categorization asymmetry. When 3- to 4-month-old infants were shown different photographs of either cats or dogs, they formed perceptual category representations for either groups of pictures. Infants were first shown a number of different photographs of cats and were then shown a picture of a dog paired with a novel picture of a cat. During the preference trials, the infants were much more attentive to the dog than to the novel cat. This was interpreted as showing that the infants had formed a category representation of Cat that excludes dogs. The dog, in other words, was perceived by the infants as not belonging to the category of cats. In sharp contrast, infants who were first shown a series of photographs of different dogs and were then shown a picture of a cat along with a novel dog were not preferentially attentive to either picture. When coupled with the finding that infants did not show a prior preference for cat photographs over dog photographs, and that infants familiarized with either cats or dogs looked longer at a bird photograph, the overall pattern of results was interpreted as showing that infants had formed a category representation of Dog that did not exclude cats. In short, the Dog category included cats, but the Cat category did not include dogs.

Infant perceptual categorization tasks frequently rely on preferential looking techniques based on the finding that infants direct attention more to unfamiliar or unexpected stimuli (e.g., Sokolov, 1963; Charlesworth, 1969; Cohen, 1973). While it is true that infants may sometimes have a preference for familiar stimuli, such as word stress patterns (Jusczyk, Cutler, & Redanz, 1993), it has been repeatedly shown that there is preferential attention directed to *novel* visual stimuli. The standard interpretation of this behavior is that the infants are comparing the input stimuli to an internal representation of those stimuli. As long as there is a discrepancy between the information stored in the internal representation and the visual input the infant continues to attend to the stimuli. While attending to the stimuli the infant updates its internal representation. When the information in the internal representation is no longer discrepant with the visual input, attention is switched elsewhere. When a familiar object is presented there is little or no attending because the infant already has a reliable internal representation of that object. In contrast, when an unfamiliar or unexpected object is presented, there is a lot of attending because an internal representation has to be constructed or adjusted.

When a series of exemplars can be grouped into a consistent category, this account of representation construction implies a progressive decrease in looking time with successive exemplars encountered. Although each exemplar encountered is novel (and therefore attracts the infant's attention), the process of representation construction gradually leads to the extraction of key dimensions of the category. Thus, after some time, a reliable category representation is constructed and new exemplars encountered (although still novel), take little time to be assimilated to the internal category representation and therefore only briefly capture the infant's attention.

A model of infant perceptual categorization

We used a three-layer autoencoder to model infant categorization behaviors (Mareschal & French, 1997; Mareschal & French, 2000; Mareschal et al., 2000). Learning in an autoencoder consists of developing an internal representation of the input (at the hidden unit level) that is sufficiently reliable to reproduce all the information in the original input (Cottrell, Munro, & Zipser, 1988). Information is first compressed into an internal representation and then expanded to reproduce the original input. The successive cycles of training in the autoencoder are an iterative process by which a reliable internal representation of the input is developed. The reliability of the internal representation is tested by expanding it and comparing the resulting predictions to the actual stimulus being encoded.

The degree to which network error increases on presentation of a novel object depends on the similarity between the novel object and previously seen (i.e., familiar) objects. Presenting a series of similar objects leads to a progressive drop in error on future similar objects. The modeling assumption that we have therefore made is that network error and infant attention levels correlate: the higher the network error, the longer the looking time of the infant This is true of both autoassociators (where output error is the measurable quantity) and infants (where looking time is the measurable quantity).

To model the Cat/Dog findings, we obtained data for the networks from measurements of the original cat and dog pictures used by Quinn et al. (1993). There were 18 dogs and 18 cats classified according to the following ten traits: head length, head width, eye separation, ear separation, ear length, nose length, nose width, leg length vertical extent, and horizontal extent. The feature values were normalized over all pictures in both training sets to be within 0 and 1.

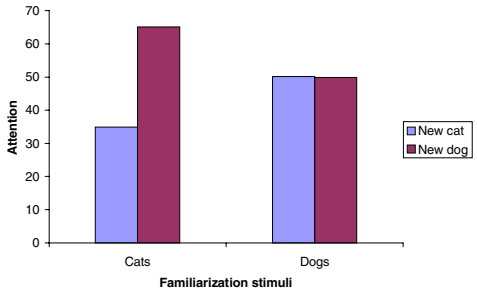

Figure 1. Generalization errors for networks trained on cats and dogs (Mareschal *et al*. 2000).

Figure 1 shows what happens when networks trained on cats are presented with a novel cat and a dog, and when networks trained on dogs are tested with a novel dog and a cat. When the networks are initially trained (i.e., familiarized) on cats, the presentation of a dog results in a large error score (corresponding to infants' longer looking time). Dogs are not included in the category representation of cats. In contrast, when the networks are initially trained on dogs, the presentation of a cat will result in essentially the same error as a novel dog, suggesting that the cats have been included in the category representation for dogs.

Because auotencoders extract the distribution statistics of the exemplars they have encountered, this led us to explore the distribution of feature values in the data measured from the original photographs in order to explain the asymmetry. Figure 2 shows the probability distributions of the 10 traits for both cats and dogs. Some of the traits are very similar in terms of their means and distribution of both cats and dogs (e.g., head length and head width). Others, especially nose length and nose width, are very different and will provide the crucial explanation of the unexpected attentional asymmetries reported by Quinn et al. (1993) and Eimas

et al. (1994). It is clear that in almost all cases the distribution for each Dog trait (represented by the dark line) subsumes the distribution for corresponding trait for cats. The narrower distributions for most Cat traits, on the other hand, do not subsume the range of values for the corresponding Dog traits. In other words, cats are possible dogs but the reverse is not the case: most dogs are not possible cats. Specifically, when we examine all of the members of the two populations, we see that the values of all ten traits for 9 (i.e., 50%) of the members of the Cat category fall within a 2σ cut-off for those traits for the Dog category. Fully half of the cats in the population could be reasonably classified as dogs. In contrast, the smaller means and lower variances of a number of traits (especially, nose length and nose width) for cats compared to dogs means that only 2 of the 18 dogs could conceivably be classified as being members of the Cat category.

Hence, it seems that the exclusivity asymmetry is driven by (1) an associative learning mechanism that is sensitive to feature distributions, and (2) a distribution

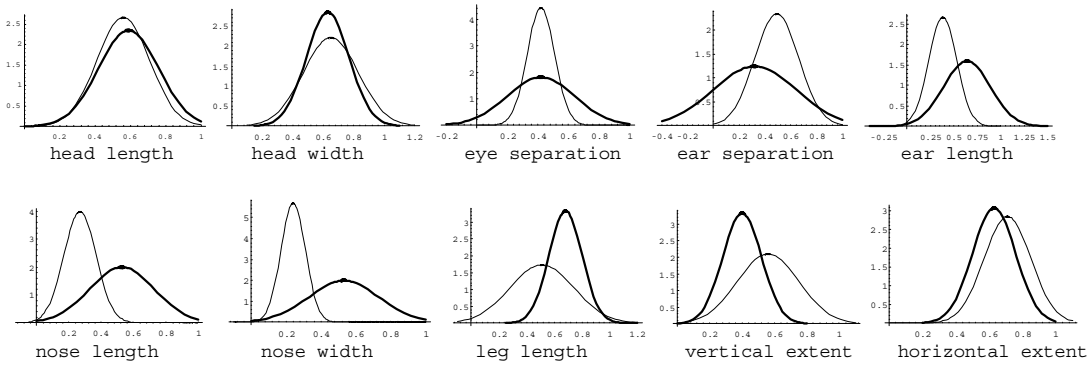

Figure 2. Frequency distributions for the ten defining traits of 18 dogs and 18 cats in Mareschal et al., 2000. The variance of Dog traits is, on average, 1.6 times that of Cats. Dogs' features largely subsume by cats'.

profile in which the Dog feature values largely subsume the Cat feature values. A direct implication of this is that if the distribution statistics were reversed, then we should observe a reversed categorization asymmetry. In this new case, infants should develop a perceptual category representation of Dog that excludes cats and a perceptual category representation of Cat that does not exclude dogs. The simulation and experiments reported below test this prediction directly.

Reversing asymmetric exclusivity

To explore whether the asymmetry could be experimentally reversed, we began by artificially manipulating the naturally occurring variance of the two categories. In the original experiment the within-category variability of the dog photographs was greater than that of the cat photographs and, crucially, the feature set for dogs largely subsumed that of cats. However, by carefully selecting sets of cat and dog photographs and then morphing a number of these images, we were able to reverse the variance of the categories In the original experiment (Mareschal et al., 2000) the average variance over all ten features of the Dogs was 1.63 times that of the Cats, whereas for the modified images the average variance of Cats was 3.12 times that of Dogs. Figure 3 shows the feature distributions for these modified exemplar sets. A comparison with the original data plotted in Fig. 2 shows how the distributions have been reversed. This is especially clear for features such as "Leg length." There were an identical number of morphed images (8 out of 18) in both the Dog and Cat stimuli sets.

Reversing the network's learning

The simulation reported was done on a standard 10-8-10 feedforward backpropagation autoencoder network (learning rate: 0.1, momentum: 0.9, Fahlman offset: 0.1). Training was identical to that in Mareschal et. al. (2000). Networks were trained in batches of 2 patterns for a maximum of 250 epochs. This simulated familiarization with pairs of pictures for a fixed period before being presented with a new familiarization pair. Results were averaged over 50 runs.

Figure 4 shows the model's generalization error to novel exemplars of cats and dogs as a function of whether they were trained on cats or on dogs. Networks trained with cats show no difference in error (hence predict no difference in looking times) when tested with a novel cat or a dog. In contrast, the networks originally trained with dogs show much greater error when tested with a novel cat than when tested with a novel dog (suggesting a strong preference for looking at a cat vs. a novel dog). This asymmetry is exactly the opposite of the one found in the original Mareschal et al. (2000) study and constitutes an explicit prediction of the autoencoder model.

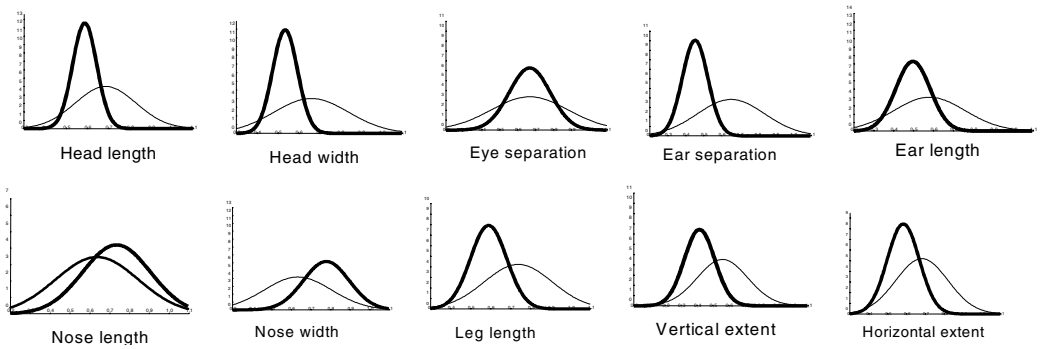

Figure 3. Frequency distributions for Exp. 1 for the 18 dogs and 18 cats. The variance has been artificially reversed and, crucially, Dog features are largely subsumed by Cat features. Compare with Figure 2

Experiment 1: Reversal of exclusivity

This prediction was tested with two groups of 3- and 4-month-old infants that were presented with a set of 12 exemplars from the same category, cats or dogs, during a series of familiarization trials, and were then presented with preference test trials consisting of a novel cat paired with a novel dog. The model predicts that infants familiarized with dogs should display a novel category preference for cats on the preference test trials, whereas infants familiarized with cats should display looking times divided evenly between the dogs and cats displayed on the preference test trials.

Method

Participants. The participants in Exp. 1 were 12 infants approximating 3 and 4 months of age (M = 3 months, 20 days; SD = 8.30 days). Seven of the infants were females and five were males.

Stimuli. The stimuli were 36 colored photographs of cats and dogs (18 exemplars per category, representing 18 different breeds for each category). The photographs were obtained from Siegal (1983) and Schuler (1980). In order to obtain dogs with low perceptual variance and cats with high variance, certain stimuli were slightly modified using computer imaging processing software (Rubber v.2.0). None of the stimuli were "morphed" to the point of giving the impression of a strange animal. The same number of animals (8) were morphed in both groups. The variance of the Cat category was modified so that the average variance of Cats was 3.1 times that of Dogs (compared to the original experiment where the average variance of Dogs was 1.6 times that of Cats). As in Quinn et al. (1993) and Mareschal et al. (2000), the pictures selected were chosen to represent a variety of shapes, colors, and orientations of each type of animal. The size of the animal in each picture was nearly the same, and thus not a reflection of its actual size (so that any categorization effects observed would not be the result of simple size discrimination.)

Each stimulus contained a single animal, cut away from its background, centered, and mounted onto a white 17.7 x 17.7 cm posterboard for presentation.

Apparatus. Infants were tested in a visual preference apparatus, modeled on the one described by Fagan (1970). The apparatus is a large, three-sided gray viewing chamber that is on wheels. It has a hinged, gray display panel (85 cm high and 29 cm wide) onto which were attached two compartments to hold the posterboard stimuli. The stimuli were illuminated by a 60-Hz fluorescent lamp that was shielded from the infant's view. The center-to-center distance between compartments was 30.5 cm and on all trials the display panel was situated approximately 30.5 cm in front of the infant's face. There was a 0.625 cm peephole midway between the two display compartments allowing observation of the infant's visual fixations.

Procedure. In both experiments, infants were placed in a reclining position on their seated parent's lap. An experimenter positioned the apparatus such that the midline of the infant's head was aligned with the midline of the display panel. The experimenter loaded the appropriate stimuli into the display panel, elicited the infant's attention and exposed the stimuli to the infant. During the course of a trial, the experimenter observed the infant through the peephole and recorded visual fixations to the left and right stimuli by means of two 605 XE Accusplit electronic stop watches, one of which was held in each hand. Interobserver reliability for this procedure was determined by comparing the looking times measured by the experimenter using the center peephole and additional observers using peepholes to the left of the left stimulus compartment and to the right of the right stimulus compartment is high (Pearson r = .97), a value comparable to values obtained in other laboratories that measured visual fixation duration with the corneal reflection procedure (e.g., O'Neil, Jacobson, & Jacobson, 1994). Two experimenters recorded fixations, one during familiarization and another during preference test trials. Importantly, the person recording during preference test trials was unaware of the category information that was presented during the familiarization trials.

Each infant was assigned twelve randomly selected

pictures of cats or dogs. On each of six 15s familiarization trials, two of the twelve stimuli, again randomly selected, were presented. Six infants were randomly assigned to each group, defined by the familiarization category, cats or dogs. Immediately after the familiarization trials, two 10s preference test trials were administered in which a novel cat was presented with a novel dog. There were six such pairs, randomly selected, and each pair, which was seen on both test trials, was assigned to one infant who had seen dogs and one infant who had seen cats during the familiarization trials. The test-trial stimuli were thus identical for both groups of infants. The left-right positioning of the novel animal from the novel category was appropriately counterbalanced across infants.

	Familiarization phase (average fixation time in secs.)		Novelty preference (% of viewing time for unfamiliar category)	t
Familiarization category	First 3 trials	Last 3 trials		
Cats	7.8(3.8)	6.9(3.6)	49.5% (16.7)	-0.08
Dogs	7.9(1.4)	9.2(3.1)	70.4% (9.7)	5.1*

t for mean vs. chance *p < .005, one-tailed.

Table 1. Mean fixation times in Experiment 1.

Results and Discussion

Familiarization trials. Individual looking times were summed over the two stimuli that were presented on each trial and then averaged across the first three and the last three trials. The mean looking times and standard deviations are shown in Table 1. Novelty preference is expressed in percentage of time that the infant looks at the exemplar from the unfamiliar category compared to the total time regarding the pair of test stimuli. An analysis of variance, familiar category (cats vs. dogs) x trial block (1-3 vs. 4-6), performed on the individual scores, revealed no significant effects, $F(1, 10) < 2.28$, $p > .15$, in each instance. As has been the case in previous infant categorization studies using the same procedures and similar stimuli (Eimas & Quinn, 1994; Eimas, et al. 1994; Mareschal et al., 2000; Quinn & Eimas, 1996, 1998; Quinn, et al., 1993), no evidence of habituation was obtained. We believe the complexity and variety of stimuli were sufficient to maintain infant attention during the familiarization trials.

Preference test trials.
The total looking time of each infant across the two test trials to the novel stimulus from the novel category was divided by the total looking time to both test stimuli and converted to a percentage score. Mean novel category preference scores are shown in Table 1 and in Figure 5. t tests versus chance, which were one-tailed because of the predicted preference in the direction of novelty, revealed that infants familiarized with dogs preferred the novel cat, but infants familiarized with cats did not prefer the novel dog. In addition, the two means were significantly different from each other, $t(10) = 2.65$, $p < .05$, two-tailed. As was predicted by the model, infants familiarized with dogs formed a category representation that excluded cats, but infants familiarized with cats did not form a category representation that excluded dogs. The findings are exactly the opposite of those reported in Exp. 4 of Quinn et al. (1993). Thus, we can reasonably conclude that the stimulus manipulations were successful in reversing the inclusion relation between dogs and cats reported by Mareschal et al. (2000).

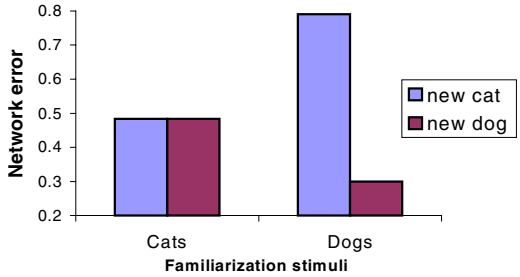

Figure 4. Network generalization errors when Cat features largely subsume Dog features

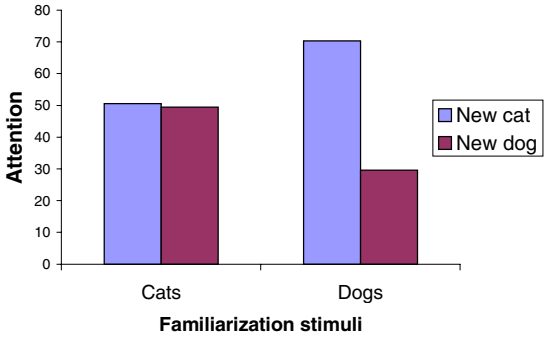

Figure 5. Infant attention when Cat feature distributions largely subsume those for Dogs.

Experiment 2: No prior preference

An alternative explanation for the outcome of Exp. 1 is that infants might have spontaneously preferred the cats over the dogs. Although no such spontaneous preference was found in Quinn et al. (1993) or Quinn and Eimas (1996), it is possible that the stimulus manipulations could have inadvertently produced one. If there was a preference for cats over dogs in Exp. 1, then it would have facilitated (if not fully explained) any presumed novel category preference for cats after familiarization with dogs, and it would have interfered with any novel category preference for dogs after familiarization with cats. Exp. 2 was thus replication of Exp. 1, but conducted without the familiarization trials.

Method

Participants. 6 infants approximately 3 and 4 months old (M = 3 months, 17 days; SD = 12.71 days). Three of the infants were females and three were males.

Stimuli and apparatus. Same as Exp. 1.

Procedure. All infants were presented with the preference test trials described for Exp. 1, but without the prior familiarization trials.

Results and Discussion

A preference score for cats was determined for each infant for the two trials by dividing the looking time that the cat was observed by the total looking time to both the cat and dog. The score was then converted into a percentage. The mean preference for cats was 48.34%, SD =22.03. This preference was not significantly different from chance, $t(5) = -0.18$, $p > .20$, two-tailed. Further, the preference for cats after familiarization with dogs in Exp. 1 was found to be reliably higher than the spontaneous preference for cats with no familiarization with dogs, $t(10) = 2.24$, $p < .05$, two-tailed. The preference results from Exp. 1 are thus unlikely to be reflective of a spontaneous preference for cats and more likely are a consequence of the reversal of the inclusion relation between cats and dogs.

Conclusion

Quinn, Eimas, & Rosenkrantz (1993) observed a striking asymmetry in the infant categorization of photos of cats and dogs. An initial simulation by Mareschal and French (1997) and Mareschal et al. (2000) was able to reproduce the original experimental results by focusing on the *within-category variability and inclusion relation* of the two categories of animals. This simulation led to a prediction — namely, that if the degree of variability and overlap of shared feature distributions was the key to explaining this categorization asymmetry, then artificially reversing the order of the within-category variability for shared features should reverse the infant categorization asymmetry. We were able to reverse this categorical variability and, as predicted by the model, we observed the reverse categorization asymmetry in the infants.

The reversal of the asymmetry makes the point that infants form at least some category representations on-line, rather than tapping into pre-existing concepts that had been formed prior to arriving at the laboratory. If the infants been relying on previously acquired categories, then their responsiveness should not have varied with the variations in the familiar category information presented. The fact that infant responsiveness did vary across experiments suggests that the categories were being formed on-line and that the boundaries can be pushed around depending on the information presented during familiarization.

Abstract

The issue of strategy selection in solving the Tower of Hanoi (TOH) problem is investigated by focusing on the critical issues of whether the selection process is contingent and adaptive. The results of an experiment in which participants solved a series of different four-disk TOH problems under instructions requiring accuracy maximization vs. effort minimization are presented. A computer simulation, comparing a number of known strategies to the experimental data, has been carried out to try to identify the strategies used by the participants. The findings support the hypothesis of adaptive and contingent strategy selection in the TOH domain.

Introduction

Much work in the problem solving arena has dealt with the Tower of Hanoi (TOH) – considered as a typical well-structured problem – producing important theoretical and empirical results. Researchers have discovered interesting phenomena and tried to provide explanations for them. Several solution strategies have been described (Simon, 1975), and various models have been proposed to simulate human performance on this task (Karat, 1982; Ruiz & Newell, 1989; Anderson, Kushmerick & Lebiere, 1993; Anderson & Lebiere, 1998; Altmann & Trafton, 2000). Detailed accounts of learning how to solve the TOH on a trial-by-trial basis (Anzai & Simon, 1979) have been put forward together with hypotheses concerning the strategies and the heuristics people seem to learn in successive attempts to solve the problem (VanLehn, 1991).

Despite these achievements, many issues are still unresolved and many topics are currently investigated. Two recent examples involve the role of goal encoding and retrieving in memory (Altmann & Trafton, 2000), and the possible use of active planning to avoid previously visited states (Davies, 2000).

Given that different models and strategies have been proposed in different experimental settings, it seems important to try to identify the factors affecting the selection of solution strategies in this domain.

We propose the hypothesis that strategy selection in the TOH is a contingent processes, i.e., it is sensitive to task and contextual factors. Following a widely accepted idea about human problem solving (Simon, 1975; Anderson, 1990; Christensen-Szalanski, 1998) and decision-making (Payne, Bettman & Johnson, 1993), it is further hypothesized that strategy selection is adaptive. Given a specific task and context, it is functional to the achievement of a good trade-off between accuracy and cognitive effort (Christensen-Szalanski, 1998; Fum & Del Missier, 2000).

These two strategy-related questions (i.e., is the process of strategy selection contingent? is it adaptive?) are the main topics of this work. In the paper we briefly discuss some issues concerning research on the TOH strategies. Then we present the results of an experiment in which participants solved a series of different four-disk TOH problems under instructions requiring accuracy maximization vs. effort minimization. A computer simulation, comparing several solution strategies to the experimental data, has been carried out to try to identify the strategies used by participants in the two instruction groups.

Issues on Strategy Research

Research on strategies in TOH, and related problem solving tasks, must deal with several theoretical and empirical issues.

A first issue concerns identificability (Anderson, 1990): patterns of behavioral data are used as a trace to induce the existence of a given strategy, but in many cases the data do not allow discriminating among distinct models of strategic behavior. In our specific domain, however, very few attempts (an exception being represented by Altmann & Trafton, 2000) of directly comparing different models on the same data set have been done.

Other theoretical problems deal with the under-specification and the low generalizability of some of the proposed strategies. With underspecification we mean

*The order of authorship is arbitrary; each author contributed equally to all phases of this project.

the fact that the description of a strategy does not allow a unique identification of the move to be done for every problem state. With low generalizability we mean the fact that the proposed strategy results ad hoc and cannot be extended to deal with some classes of TOH problems people are able to solve.

A further theoretical limitation is constituted by the fact that some strategies are willfully optimal (Anderson & Lebiere, 1998), while people seldom achieve such a brilliant performance (Goel & Grafman, 1995; Miyake et al., 2000; Karat, 1982).

On the empirical side, there is the problem of the intrusiveness of the methods utilized to identify the existence of a given strategy. Verbal protocols, for instance, (Anzai & Simon, 1979; Van Lehn, 1991) have proved to be a useful exploratory tool, but there is evidence (Stinessen, 1985; Ahlum-Heath & DiVesta, 1986) that participants verbalizing during the task perform differently from participants that do not verbalize. The very use of verbal protocols could prompt the adoption of different solution strategies.

A related issue deals with the suggestiveness of the experimental instructions. For instance, Anderson, Kushmerick & Lebiere (1993) gave hints that deliberately encouraged the adoption of a particular strategy. The generalizability of their model is, therefore, directly related to the way the same strategy is spontaneously adopted by the participants when no hints are given.

Another concern is constituted by the fact that strategy selection in the TOH has often been studied by having people perform many trials over the same problem. In this way it cannot be excluded that the improvement in the participants performance could be attribute to rote memorization instead of genuine learning. To control for this factor, Anderson, Kushmerick & Lebiere (1993) presented a wider range of problems to their participants preventing them from evolving special-case strategies.

In our experiment we investigated a factor that could possibly affect the adoption of different solution strategies, and we ran a simulation study to try to identify them. To do this, we had to make some underspecified strategies computationally workable by postulating a few additional assumptions. We concentrated our attention on general strategies – i.e. on strategies capable of solving problems put not only in their standard (i.e., tower-to-tower) form – and on strategies that do not prescribe an optimal solution. Furthermore, we refrained to force participants to justify and comment on their moves, and carefully avoided suggesting any specific solution procedure. Finally, we utilized a set of different problem types.

The Experiment

The main goal of the experiment was to test the hypotheses of contingent and adaptive strategy selection. We manipulated the experimental instructions to modify the importance participants gave to the distinct goals of accuracy maximization vs. effort minimization.

According to the contingent and adaptive hypothesis, we expected to find a rational use of different strategies in different experimental groups. The strategies used by participants in the accuracy group should increase the accuracy of the solutions by paying a higher temporal cost. The strategies used in the effort group should yield effort savings but less accurate solutions.

Method

Participants The participants were 34 undergraduates students, aged between 18 and 24. None of them was suffering from any perceptual, cognitive or motor deficiency. The sample was balanced for gender. All the participants had a basic familiarity with computers and were able to use the mouse.

Procedure Participants read an instruction document that explained the basic rules of the TOH, showed the interface used by the computer program, and described how to use it. The instructions required the participants to solve the problem "in the fewest possible number of moves" or "in the shortest possible time", depending on the group (accuracy vs. effort, respectively) to which they were randomly assigned. The experimenter (always one of the authors) asked the participants about their knowledge of the task and was willing to answer possible questions about the procedure. After going through a short training session, participants started to solve the series of test problems.

Materials A number of different three- and four-disk TOH problems were randomly generated for the experiment. The problems comprised four possible configurations of disks obtained by combining a flat vs. tower disposition in the start state with a flat vs. tower disposition in the goal state.

Two randomly generated three-disk problems, with an optimal solution path of seven moves and with a flat-to-flat configuration, were used for training and presented to the participants in casual order.

The test set comprised eight randomly generated four-disk problems, two for each possible configuration. Each problem had an optimal solution path of 15 moves. The test set was delivered using block randomization.

Apparatus A PowerMacintosh 9500 computer was used for the experiment. A program implementing the

TOH task was written using MCL 4.3 and CLIM 2. The program recorded each participant move (including the moves violating the TOH rules) with the associated time.

The interface was composed by two identical windows, vertically stacked and centered. The upper window showed the initial state of the problem and could be acted upon by the participants. The lower window, which showed the goal state, presented a fixed display. The participants had to perform a drag-and-drop operation with the mouse to move disks from peg to peg in the upper window. In case of an illegal move, an auditory warning was delivered, and the dragged disk was forced back to its source peg.

Experimental Design Two independent variables – one between-subjects (instruction type) and one within-subjects (trial number) – were manipulated in a 2x8 mixed design. The number of trials in the test session (eight) was chosen to obtain an acceptable balance between the possibility of obtaining learning effects and that of inducing fatigue effects. The basic dependent variables were the number of errors (i.e. illegal moves in addition to minimum path length), the number of attempted illegal moves, the total time to solve the problem, the mean move latency (excluding the first move), and the time necessary to execute the first move.

Results

All the data analyses were performed on 31 cases[1] (15 in the accuracy, 16 in the effort group) either on transformed and untransformed variables[2]. Given the absence of any difference, we will present only the results obtained using the untransformed variables.

Errors A 2x8 analysis of variance (ANOVA) on the number of errors (Figure 1) showed the significant main effects of instruction type ($F(1,29)=6.57$, $MSE=173.53$, $p<.05$), and trial ($F(7,203)=4.95$, $MSE=69.33$, $p<.001$). The interaction was not significant. The participants in the accuracy group made fewer errors that those in the effort group ($M=6.73$ for accuracy; $M=11.02$ for effort). In both groups the number of errors decreased from the first block of four trials to the second block ($M=11.38$ for the first block, $M=6.38$ for the second one). A post hoc analysis carried out with the Tukey HSD test showed significant differences between the following pairs of trials: 1-5 ($p<.05$), 1-6 ($p<.01$), 1-8 ($p<.05$), 2-5 ($p<.01$), 2-6 ($p<.001$) and 2-8 ($p<.01$). The Bonferroni procedure confirmed the results.

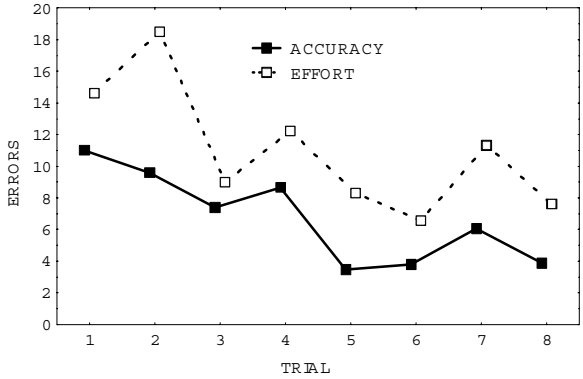

Figure 1: Number of errors for each trial in the accuracy and effort conditions.

Illegal Moves Participants attempted to execute very few illegal moves. The number of such moves was however lower in the accuracy group than in the effort group ($M=0.77$ for accuracy, $M=1.87$ for effort), and decreased from the first to the second block of trials ($M=2.00$ for the first; $M=0.65$ for the second block). Both the effects, but not the interaction, were statistically significant ($F(1,29)=6.71$, $MSE=11.17$, $p<.05$ and $F(7,203)=6.37$, $MSE=3.76$, $p<.001$, respectively).

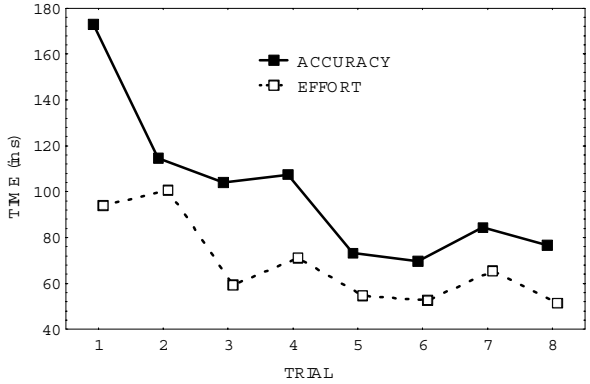

Figure 2: Solution times for each trial in the accuracy and effort conditions.

Solution Times A 2x8 ANOVA on the solution times (Figure 2) revealed the significant main effects of the instruction type ($F(1,29)=7.83$, $MSE=7947.67$, $p<.01$) and of the trial ($F(7,203)=8.68$, $MSE=2259.27$, $p<.001$), while their interaction was not significant. The participants needed more time to solve the problems in the accuracy than in the effort group ($M=100$ s for accuracy, $M=69$ s for effort). The time necessary to complete the task decreased from the first to the second block of trials ($M=103$ s for the first, $M=66$ s for the

[1] Two cases were excluded because the participants needed more than the maximum allowed time (45 min) to complete the first two problems in the test session. One case was excluded because the participant said, only at the end of the session, that she had previously written a program capable of solving this kind of task.

[2] A logarithmic transformation was performed on all the variables measuring time, while a square-root transformation was applied to all the variables recording the number of moves.

second). The Tukey test and the Bonferroni procedure highlighted significant differences between the first trial and the last six and between the second trial and the last four (with the exception of the pair 2-7).

Move Latencies A 2x8 ANOVA on move latency times showed a significant interaction ($F(7,203)=3.10$, $MSE = 946783$, $p< .01$) between instructions and trial.

The main effects were also significant: $F(1,29)=14.85$, $MSE=9131212$, $p< .001$ for instructions, $F(7,203)=8.00$, $MSE=946783$, $p< .001$ for the trial. A 2x7 ANOVA with the exclusion of the first trial confirmed the main effects but not the interaction ($F(6,174)=1.29$, $MSE=745583$, $p=.26$). This result suggests that the interaction could be attributed to the extremely high latencies of the participants in the accuracy group on the first trial. This was confirmed by the post hoc tests on the first ANOVA. The move latency was higher in the accuracy group than in the effort group ($M=3.82$ s for accuracy, $M=2.34$ s for effort), and decreased from the first to the second ($M=3.46$ s first block; $M=2.71$ s second block). The Tukey post hoc analysis on the second ANOVA showed significant differences between the pairs 2-5 ($p< .05$), 2-6 ($p< .05$) and 2-8 ($p< .05$). The Bonferroni procedure confirmed only the difference between the trials 2 and 8 ($p< .05$).

First Move Latency A 2x8 ANOVA on the first move latency showed only the significant main effect of the instruction type ($F(1,29)= 13.18$, $MSE=583.18$, $p< .01$) with latency higher for participants in the accuracy group ($M=14.78$ s for accuracy, $M=3.64$ s for effort).

Cluster Analysis of Move Latencies We performed also a k-means cluster analysis to determine whether the means of the move latencies and the mean percentages of moves within given latency boundaries were different between the two instruction groups. The cluster analysis was performed on all the moves that required less than 4 s to be executed[3]. For each subject a solution with 2 clusters (moves having an almost exclusive motor component vs. moves requiring more relevant cognitive processes) was looked for.

A 2x2 (Move x Instruction) ANOVA on the cluster means showed a significant interaction ($F(1,29)=9.46$, $MSE=80919$, $p< .01$) and significant main effects of the move kind ($F(1,29)=2499.81$, $MSE=10229$, $p< .001$) and of the instruction type ($F(1,29)=10.31$, $MSE=10229$, $p< .01$). The interaction is explained by the fact that the difference of 140 ms between participants in the two instruction groups for the "cognitive" moves ($M=3.08$ s for accuracy and $M=2.94$ for effort) was significantly smaller than the difference of 305 ms found between the groups for the simplest "execution" moves ($M=1.87$ for accuracy vs. $M=1.57$ for effort). These results confirm the indications obtained from the previous move latency analysis, but suggest also a potential execution speed-up for the participants in the effort group.

A further analysis was focused on the mean percentages of cases belonging to the two move clusters and to the moves requiring 4 s or more (the third cluster of "long" moves) in both instruction groups. The results showed significant differences between the accuracy and effort groups for the execution moves (Mann-Whitney U test, $U=57$, $z=2.49$, $p< .05$) and long ones ($U=32$, $z=3.47851$, $p< .001$). In particular, the mean percentage of cases belonging to execution moves was greater in the effort group ($M=61.77$, $SD=8.35$) than in the accuracy group ($M=50.94$, $SD=12.11$). The reverse was true for the long moves (accuracy: $M=24.82$, $SD=10.26$; effort: $M=12.08$, $SD=5.98$). This could mean that participants in the effort group made a higher percentage of execution moves and a lower percentage of cognitive moves in comparison with the moves made by the participants in the accuracy group.

Discussion

There is clear evidence that the experimental manipulation has been very effective in changing the way the TOH problems are solved. As expected, participants are able to achieve their respective goals of minimizing effort and maximizing accuracy, and they are forced by the instructions to trade a lower number of moves with a higher solution time.

There is also clear evidence of the existence of a learning effect. Participants in both groups learn to perform better in successive trials, making fewer errors and using less time. The learning profiles for the two groups remain however distinct across all the trials. The difference concerns not only the errors made and the times needed for solution, but extends to all the dependent variables suggesting that participants in the two groups were selecting and using different solution strategies.

The Simulation

The goal of the simulation was to try to identify the strategies used in each trial by participants in the two instruction groups by comparing several known TOH solution strategies on their capacity to fit the data.

[3] Given an independent estimate of 2.15 s for the time needed to move a disk using a TOH program with a direct-manipulation user interface (Anderson, & Lebiere, 1998), we assume that moves requiring 4 s or more are also affected by some kind of higher-order cognitive operation.

The Implemented Strategies

For the simulation we developed a series of ACT-R (Anderson & Lebiere, 1998) models implementing the following solution strategies:

SS1 The selective search strategy described by Anzai & Simon (1979), and subsequently studied by Van Lehn (1991). At each step only disks that are free to move in the current state are considered. The choice of which disk to move and where is guided by two heuristics: "(1) do not move the same disk on consecutive moves, and (2) do not move the smallest disk back to the peg it was on just before it was moved to its current peg" (Van Lehn, 1991, p. 6). Because the strategy is under-specified, an additional assumption has been made: "(3) whenever possible, choose the move which has the effect to put the largest out of place disk (the LOOP disk) into the target peg", which gives the strategy a more goal-oriented attitude. Because the participants did not always follow the directives of the don't-move-twice and don't-undo-move heuristics, the model employs them probabilistically according to two empirically-derived parameters (93% of the cases in which they could be applied when modeling the participants in the accuracy condition, and 90% of the times for the effort condition). Finally, whenever there is still uncertainty about which move to make, the model chooses randomly.

SS2 The selective search strategy previously described augmented with the new one-follows-two heuristics that states that if you have just moved the disk of dimension two, you should now put the smallest disk on top of it.

SP The (simple) perceptual strategy described in Simon (1975) and rephrased as follows: "(1) if all n disks are placed on the target peg, stop; else (2) find the next disk (i) to be placed on the target peg (3) if there are smaller disks on top of disk i, clear them (4) clear disks smaller than i off the target peg (5) move disk i to the target peg (6) go to 1." (Goel & Grafman, 1995, p. 633). In order to avoid being stuck into an infinite loop, because clearing the source peg to move disk i will block the target peg and vice versa, a stack of subgoals is maintained which allows the strategy to be rescued.

KR The strategy described in Karat (1982) which combines elements of domain-specific knowledge into a general problem-solving framework. The strategy adopts a limited look-ahead: if the movement of the LOOP disk from its source to the target peg is blocked by only the smallest two disks, the task of moving the small disks on the third peg is considered as trivial, and the moves are immediately executed.

AT In addition to implementing the above mentioned strategies, we utilized also the activation-based model of memory for goals (Altmann & Trafton, 2000)[4]. The model adopts the strategy of Anderson & Lebiere (1998), but stores goals as ordinary declarative memory elements instead of caching them in the architectural goal stack, and uses a strengthening process for encoding and priming from cues for retrieval.

As previously mentioned, all the strategies are sub-optimal, i.e. they do not generally reach the solution with the minimum number of moves, a performance that also our participants were seldom (i.e., 12% of the times in the accuracy, and 5% in the effort condition) able to make.

Procedure and Results

We executed a simulation of all the strategies on the TOH problems used in the experiment.

We decided to compare the strategies only on their capacity to predict the number of errors made by the participants. Additional assumptions and parameter tuning would be required to model also the times. Therefore, we preferred to stick to a very conservative simulation policy.

The trial-by-trial results of the simulation are presented in Table 1. The table shows the strategies that, in each trial, predicted a number of errors falling into the 99% confidence intervals (CI) computed from the experimental data.

Table 1: Trial-by-trial simulation results.

Group	Trial							
	1	2	3	4	5	6	7	8
Accuracy	KR SP AT	KR SP	SP AT	KR SP	SP	SP AT	KR SP	KR SP AT
Effort	S2 KR SP	KR SP	KR SP	KR	KR	KR		KR SP

The global fit of the three best strategies (SP, KR and AT)— measured using the mean absolute difference (MAD), the root mean square error (RMSE) and the percentage of trials in which the prediction of the model is within the 99% CI (P99CI)— is presented in Table 2.

Table 2: Simulation results for the best strategies.

Strategy	Group	MAD	RMSE	P99CI
KR	accuracy	3.098	3.615	62.5%
SP	accuracy	2.899	3.239	100%
AT	accuracy	5.093	5.763	50%
KR	effort	2.264	3.074	87.5%
SP	effort	5.992	7.111	50%
AT	effort	9.382	10.112	0%

The best fitting strategies are SP in the accuracy condition and KR in the effort condition. The AT

[4] We thank Erik Altmann for making the model available and allowing us to use it in the simulation study

strategy yields good results on half of the trials in the accuracy condition. The selective search strategies are notable to achieve a good fit: only the use of SS2 in the first trial of the effort condition cannot be excluded.

Discussion

The basic conclusion that can be drawn from the simulation is that the results are mainly in compliance with the contingent and adaptive selection hypotheses.

The perceptual strategy is actually more accurate but probably more effortful than the Karat's strategy (that does not require expensive recursive operations). The Altmann & Trafton's model is more accurate than the other two strategies, but probably more expensive than the Karat's model.

Further simulations, using model-tracing and time data, should provide additional supporting evidence.

Conclusions

A preliminary support has been gained for the contingent and adaptive nature of strategy selection in the TOH. On this basis, we suggest that it is important to pay attention to the problem solving factors affecting the accuracy vs. effort trade-off, due to their influence on the strategy selection.

Many other issues must be cleared to obtain a deeper understanding of the selection processes in the TOH and in similar well-structured problems. In this context, we regard as especially important the transition towards more detailed, cognitively grounded strategies to further constrain and specify the existing models, and to allow more detailed comparisons.

This process could yield both the redesign of old strategies and the definition of new ones. Altmann & Trafton (2000) offered a first important contribution with their memory-based model of the Anderson & Lebiere (1998) strategy. We think that a closer analysis and experimental investigation of the attentional and perceptual processes in the TOH could produce significative advances in our understanding of the cognitive processes underlying the solution strategies.

Abstract

An understanding of language processing in humans is critical if realistic computerised systems are to be produced to perform various language operations. The examination of aphasia in individuals has provided a large amount of information on the organisation of language processing, with particular reference to the regions in the brain where processing occurs and the ability to regain language functionality despite damage to the brain. Given the importance played by aphasic studies an approach that can distinguish between aphasic forms was devised by using a Kohonen self-organising network to classify sentences from the CAP (Comparative Aphasia Project) Corpus. We demonstrate that the different distributions of words in aphasics types may lead to grammatical systems which inhabit different areas in self-organising maps.

Introduction

The examination of neural language processing is of importance as it offers the opportunity for producing realistic computerised language systems and a comprehension of the underlying biological mechanisms and constraints involved. One technique that has proved useful for identifying the organisational arrangement of language processing is the examination of aphasia. Aphasia is the inability to perform one or more cognitive language functions due to damage to the brain. The typical causes of aphasia are brain tumours, strokes, head injuries and infections. Although this is a rough simplification, the two most common types of aphasia are Broca's and Wernicke's aphasia.

Broca's Aphasia: Subjects with damage to the Broca's area of the cerebral cortex have problems creating spoken responses. These responses are often grammatically incorrect, effortful, laboured, come in bursts and have a restricted vocabulary. Furthermore, verbs are often missed out or replaced by the nominal form in spontaneous speech. However, many individuals with this condition can perform language processing functions such as language comprehension, dealing with non-reversible sentences, object and verb recognition and the identification of semantic and verb errors. Table 1 provides examples of typical spontaneous speech from Broca's aphasics [Wermter, Panchev and Houlsby (1999), Marshall, Pring and Chait (1998) and Brendt and Caramazza (1999)].

Wernicke's Aphasia: Although individuals with Wernicke's aphasia have problems understanding language and producing sentences that are meaningful, they can produce fluent phrases that have a reasonable syntactic, grammatical and symbolic structure [Chen and Bates (1998) and Wermter, Panchev and Houlsby (1999)]. Table 2 provides examples of spontaneous speech from Wernicke's aphasics.

An approach previously used to distinguish aphasic forms is recurrent neural networks [Wermter, Panchev and Houlsby (1999)]. Such networks can represent long term memory and context using recurrent connections and extracting the appropriate context from inputs. In the simple recurrent network outlined by Elman (1990) the context layer stores the activations of the hidden layer units for one time step and passes them back to the hidden layer units on the next step. Typically there is a one-to-one relationship between the number of units in the context layer and in the hidden layer [Spitzer (1999)]. This offers the opportunity to recycle information from multiple time steps and to identify temporal relationships. As the hidden layer receives inputs from both the input and the context layer, patterns should have an impact across time and context be learned.

However, there are certain drawbacks with recurrent neural networks which led us to consider an alternative approach. Recurrent neural networks are a *supervised* learning approach that do not perform in a manner that is close to neural networks in the human brain. Therefore in this paper we used *unsupervised* self-organising networks that can identify categories, features and regularities using unsupervised learning in a manner closer to the cerebral cortex. In this paper we analyse spoken language from Broca's aphasics, Wernicke's aphasics and normal patients. We demonstrate that the different distributions of words in aphasics types may lead to grammatical systems which inhabit different areas in self-organising maps.

Location of Aphasia and Language Function

The examination of aphasics provides some indication of how language processing is organised and the form that language recovery takes. A language processing model that has been established from studying the location of damage in the cerebral cortex of aphasics is that the human brain performs diverse language processing opera-

Table 1: Typical spontaneous speech from Broca's aphasics.

Normal phrase	Broca's aphasic response
A boy is giving the ball to the man	A boy is ... the ball
A monkey is eating a banana	Monkey ... banana
Chrysanthemum	Chrysa...mum...mum
Cat cries	Cat tears

Table 2: Typical spontaneous speech from Wernicke's aphasics.

Typical Wernicke's aphasic responses
They are running a swimming water and snow
The boy is running he is talking to the it is a cat
It is a cat and he is talking the flower

tions. According to Taylor (1999) and Dodel, Hermann and Geisel (1999) the cortex is made up of various somewhat overlapping regions which are responsible for cognitive language sub-operations. In order to produce the final language functions there is a need to coordinate and combine the outcomes of the appropriate regions. According to Reilly (2001) the brain performs as a group of collaborating specialists, none of which can deal with a difficulty alone, but only do so when each cooperates. In the brain it is possible to deal with a complex difficulty by splitting the task into smaller elements and coordinating these elements. The uniqueness of the human brain does not come from the number of neurons but the structural complexity. It has been identified that the module approach can offer re-usability by having a region of the brain doing the same processing activity as part of many different cognitive functions [Reilly (2001)].

In terms of the actual functions that are associated with diverse regions of the cerebral cortex a few examples will now be outlined. When Binder, Frost, Hammeke, Cox, Rao and Prieto (1997) required individuals to state whether an animal was native of America and used by humans, different principal regions of the cerebral cortex were established as responsible for the language processing involved: (i) an area incorporating the superior temporal sulcus, middle temporal gyrus and parts of the inferior temporal gyrus; (ii) sections of the inferior and superior frontal gyri, the middle frontal gyrus and the anterior cingulate; (iii) angular gyrus; and (iv) a region containing the posterior cingulate and gyrus zones.

Silent word generation starting with a certain letter takes place in Broca's and Wernicke's areas and sections of the left frontal, temporal and parietal lobes [Papke, Hellmann, Renger, Morgenroth, Knetcht, Schuierer and Petersen (1999)] and the resolution of whether two words belong to the same semantic group involves increased activity in the superior frontal gyrus and frontal gyrus [Shaywitz, Shaywitz, Pugh, Constable, Skudlarski, Fulbright, Bronen, Fletcher, Shankweiler, Katz, Gore (1995)]. Finally, the process of generating verbs out loud was found by Xiong, Rao, Gae, Woldroff, Fox (1998) and Raichle, Fiez, Videen, Macleod, Pardo, Fox, Petersen (1994) to be associated with areas of the left posterior temporal cortex, right anterior cingulate, inferior frontal gyrus, Broca's area, left superior temporal gyrus, cingulate gyrus, inferior temporal gyrus and the occipital gyri.

The examination of aphasia has assisted in creating models of the form that the recovery of language processing takes in the brain. Examinations of the brain following death have identified injuries to parts of the cerebral cortex in normally functioning individuals which should have produced aphasia. This led to the view from Karbe, Thiel, Weber-Luxenburger, Herholz and Heiss (1998), Basso, Gardelli, Grassi and Mariotti (1989) and Capp, Perani, Grassi, Bressi, Alberoni, Franceschi, Bettinardi, Todde, and Frazio (1997) that language functions are recovered through regeneration of the damaged tissue or the redistribution of functionality to other regions of the brain that are operationally linked but not required in healthy individuals.

There is mixed research evidence for the time it normally takes for repair of injured tissue. However, researchers have found than redistribution of functionality to new regions of the brain can take longer and repair of the left superior temporal gyrus occurs over numerous months following the injury [Mimura, Kato, Kato, Santo, Kojima, Naeser and Kashima (1998) and Weiller, Isensee, Rijntjes, Huber, Müller, Bier, Dutschka, Woods, Noth and Diener (1995)]. As early as in the 19th Century Gower determined that individuals who lost speech due to damage to the left hemisphere were able to recover it through interaction with the right hemisphere. The region of the right hemisphere analogous to Broca's area and the right perisylvian have taken over the functions associated with the Broca's and Wernicke's areas respectively when they are injured. According to Reggia, Shkuro and Shevtsova (2000) the reorganisation of the brain regions responsible for language explains the remarkable capacity to recover from injury and robust,

fault-tolerant processing. So in summary several brain regions may be involved with aphasia, even though at a highest level often a distinction of Broca's and Wernicke's aphasia has been made in the past.

Classification of Aphasia using Self-Organising Networks

As aphasia studies provide a significant amount of relevant information regarding the organisation of brain processing, there is a motivation to develop an approach to classify interviewed subjects to distinguish the aphasia form they have.

Method Overview

The language transcripts used for the training and test data sets for a self-organising network were obtained from the CAP Corpus [Bates, Fredrici and Wulfeck (1987a and 1987b)]. The CAP Corpus is made up of transcripts of English-speaking subjects that are divided into three groups: Broca's aphasia, Wernicke's aphasia and a control group of healthy people. The language transcripts were produced using a variation of the "given-new" picture description task of MacWhinney and Bates. In this task subjects were shown nine sets of three pictures and were asked to describe them (see Table 3). The transcripts contained the subject's response and the morphemic coding. We used the coding from a previous study by Wermter, Panchev and Houlsby (1999). This maps the morphemic coding of the corpus patterns using the following syntactic descriptors: DET (Determiner), N (Noun), N-PL (Plural), PRO (Pronoun), PREP (Preposition), ADJ (Adjective), CONJ (Conjunction), V (Verb), V-PROG (Progressive), AUX (Auxiliary Verb), ADV (Adverb), ADJ-N (Numeric).

Unsupervised Learning

The self-organising network that was used consists of an input and an output layer, with every input neuron linked to all the neurons in the output layer [Spitzer (1999), Hecht-Nielsen (1990), Kohonen (1997) and Anderson (1999)]. A self-organising network can be used by itself or as a layer of another neural network. Input data is presented one sample at a time and the nodes compete against each other. The Kohonen layer creates a topographical representation of the critical characteristics of the input by creating a pattern of active and inactive units (see Figure 1). The activation of the units are calculated by multiplying the input from each input unit by its related synaptic weight and summing all the inputs for a specific unit.

Learning in self-organising networks is performed by updating the links between the input layer and the output layer via a form of Hebbian learning. Self-organising networks attempt to depict the input data with a set of models, with similar words and concepts producing models that activate the units in the output layer that are close together.

Fitting of model sectors is performed by a sequential regression procedure, where $t = 1, 2, \ldots$ is the step index: For every sample $x(t)$, the winner index c is established by the condition

$$i, \;\; x(t) - m_c(t) \qquad x(t) - m_i(t)$$

Once this has occurred, every model vector m_i or a subgroup of them that belong to units centred around unit $c = c(x)$ are altered as

$$m_i(t \quad 1) = m_i(t) \quad h_{c(x),i}(x(t) - m_i(t))$$

The 'neighbourhood function' $h_{c(x),i}$ defines those units that are to be updated.

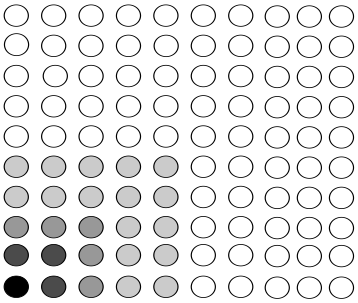

Figure 1: A representation of the activity maps of a self-organising network - The darker the neuron the greater the activation.

The self-organising network architecture considered to classify aphasic types contained 100 units (10 x 10) in the output layer. Using a different training/test set pair a self-organising network was trained and tested using the following approach. A network was trained over 1000 epochs using 80 phrases for each of the three aphasic types (Wernicke's aphasics, Broca's aphasics and a healthy control group) that were produced from the CAP Corpus. So in total there were 240 phrases. The location of each of these training phrases on the self-organising maps was identified based on the units that had the highest activation. The trained network was then tested by identifying where on the map 80 unseen phrases per aphasic type are positioned and the degree of symmetry between the training and test samples. The objective was to test if the phrases for Broca's and non-Broca's aphasics are located in different regions of the map and whether the network is able to generalise by placing the test phrases for the two groups in the same regions as the training ones. If the same unit has the highest activation level for phrases from both groups the unit is allocated to the aphasic type that has the most phrases associated with it. The grouping of Wernicke's aphasics with the healthy control group is motivated by the observation that Wernicke's aphasics often use correct syntax like the healthy control group while Broca's aphasics do not.

To remove any bias in classification and clustering the test/training phrases are based on the first six words of

Table 3: Picture series.

Syntactic Description	Sentences
DET N AUX V-PROG	A bear/mouse/bunny is crying.
DET N AUX V-PROG	A boy is running/swimming/skiing.
DET N AUX V-PROG DET N	A monkey/squirrel/bunny is eating a banana.
DET N AUX V-PROG DET N	A boy is kissing/hugging/kicking a dog.
DET N AUX V-PROG DET N	A girl is eating an apple/cookie/ice-cream.
DET N V PREP DET N	A dog is in/on/under a car.
DET N V PREP DET N	A cat is on a table/bed/chair.
DET N AUX V-PROG DET N PREP DET N	A lady is giving a present/truck/mouse to a girl.
DET N AUX V-PROG DET N PREP DET N	A cat is giving a flower to a boy/bunny/dog.

Table 4: Three word phrases for the aphasic types and their numeric representation.

Aphasic Type	Phrases	Syntactic Description	Numeric Represention
Broca's Aphasic	Banana three eat	NOUN ADJ-N VERB	1100 1010 0010
Broca's Aphasic	Boy is sport	NOUN AUX NOUN	1100 0100 1100
Wernicke's Aphasic	Little small here	ADJ ADJ PREP	0101 0101 1001
Wernicke's Aphasic	Squirrel with banana	NOUN PREP NOUN	1100 1001 1100
Healthy Control	The banana eating	DET NOUN V-PROG	0110 1100 1000
Healthy Control	A young boy	DET ADJ NOUN	0110 0101 1100

the sentences. A sliding window of three words that moves along one word at a time is used to create the final training/test three word phrases. Hence, if a transcript includes a sentence *"The monkey is sitting down eating a small yellow banana."* the first six words obtained are *"the monkey is sitting down eating"* and two of the training/test phrases are *"the monkey is"* and *"monkey is sitting"*. Since every word of these phrases is represented by a four digit binary number, the input layer for the network architecture has twelve units. The binary representations for the word are Determiner (0110), Noun (1100), Plural (0011), Pronoun (0111), Preposition (1001), Adjective (0101), Conjunction (1011), Verb (0010), Progressive (1000), Auxiliary Verb (0100), Adverb (0001) and Numeric (1010). Table 4 shows typical reponses of the aphasic types and the numeric representations that were input for the self-organising networks.

Results

Figures 2 and 3 show that it is possible to identify clear regions of the self-organising networks that are associated with the Broca's aphasic test phrases for both the test and training data. For Broca's aphasics there are two clear regions of the map, which is an indication that two forms of the condition might exist. For the two maps the Wernicke's aphasic/healthy control group are distributed around the rest of the map. When considering the test and training sample locations it is clear that the areas of the map associated with the test Broca's aphasics are very similar to the training ones. In many cases the cells with the highest activiation are exactly the same for the training and test samples. Therefore, unsupervised self-organising networks are a suitable alternative to supervised approaches for classifying aphasic types.

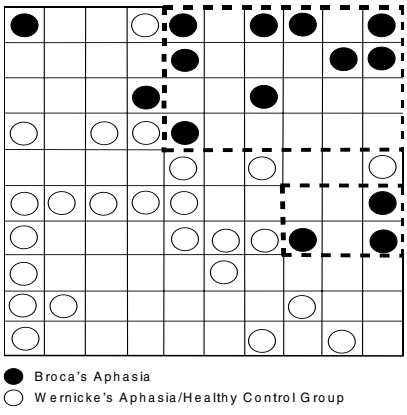

Figure 2: The regions on the self-organising map for a network based on 12 input and 100 output layer units associated with the second training set phrases for the aphasic types.

It is often the case when neural networks are trained to learn grammatical structures that two classes of examples are used; grammatically correct and incorrect phrases. The self-organising network architecture used in this paper is more general than these networks as it can identify three grammatical phrase structures, where the

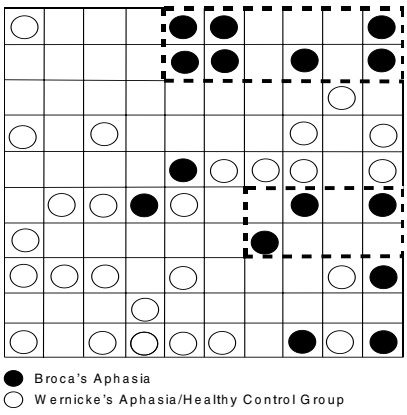

Figure 3: The regions on the self-organising map for a network based on 12 input and 100 output layer units associated with the second test set phrases for the aphasic types.

test phrases contain both typical and non-typical grammatical structures. Since phrases for the healthy control group/Wernicke's aphasics and Broca's aphasics are located at different regions on the self-organising maps it may be possible to develop a model of how the brain represents and processes grammatical structures of different individual types [Zurif, Swinny, Parther, Solomon, and Bushell (1993), Hartsuiker and Kolk (1998) and Marshall, Pring and Chiat (1998)].

The results in our experiments indicate that unsupervised networks are a suitable alternative to supervised approaches for classifying aphasic types. In terms of cognitive science the results show that while the spoken output of Broca's aphasics has a very distinct grammatical structure, healthy individuals and Wernicke's aphasics are much closer. This supports the view that language production may be based on a modular but interactive approach associated with particular regions of the brain and that correct grammatical construction is dependent on Broca's area.

By identifying two clear zones of the output maps associated with Broca's aphasics these could be associated with different degrees of injury and performance. If this is the case the different individuals in the two groups could provide the basis of a computational model of different levels of Broca's injury and hence of recovery. A final issue for consideration is why those classified as Broca's aphasic by the self-organising network failed to recover functionality by either tissue recovery or functional redistribution. A case examination of these individuals might provide information on the factors that are significant in functional recovery such as age, extent of injury and the type and level of medical intervention following injury.

The approach in this paper for classifying different aphasic types using a self-organising network was based on the difference between the grammatical constructs produced. This is an important step in our research with our overall aim being to incorporate other spoken language characteristics such as semantics and vocabulary level into the classification process by using a set of self-organising nets. The impact of that would be to produce a benchmark approach to classify many more aphasic types using a self-organisation approach and so provide cognitive scientists with a powerful diagnostic tool.

An additional advantage to cognitive scientists from the extented classifier is the removal of the subjective manner by which researchers include and exclude aphasics from pooled studies. For example, when considering if Broca's aphasics can deal with reversable sentences Brendt and Caramazza (1999) state that the percentage that cannot deal with these sentences is much less than those identified by Grodzinsky, Piñango, Zurif and Drai (1999) from the examination of the same pooled studies. Brendt and Caramazza (1999) add that the difference comes from Grodzinsky, Piñango, Zurif and Drai (1999) willingness to exclude Broca's aphasics. It is argued that they are not true Broca's aphasics. Finally, this system should offer an indication of the underlying organisational properties of language in the brain and so assist with the development of computational hybrid neural processing models [Wermter and Sun (2000) and Wermter and Meurer (1997)].

Conclusion

Studying individuals that have aphasia has provided a great deal of information connected with the nature of language processing and how the brain is able to recover language functionality following injury. By using self-organising network architectures it is possible to distinguish between a control group of healthy individuals/Wernicke's aphasics and Broca's aphasics using sentences from the CAP Corpus. One possible reason for the self-organising network's ability to separate the inputs into these two groups is their capacity to learn the grammatical structure produced by these aphasic types, which typically for Broca's aphasics are grammatically incorrect and for Wernicke's aphasics/healthy individuals are grammatically correct.

Abstract

The study sheds new light on the nature of imitative learning in 14-month-olds. It is demonstrated that while infants of this age can indeed imitate a novel means modelled to them, they do so only if the action is seen by them as the most rational alternative to the goal available within the constraints of the situation. The findings support the 'rational imitation' account over current 'imitative learning' or 'emulative learning' accounts in explaining re-enactment of goal-directed action in 14-month-olds.

Introduction

In a well-known study Meltzoff (1988, 1999) demonstrated that 14-month-olds are already capable of delayed imitation of a novel goal-directed action. Infants observed a salient novel action performed by an adult model on a black box with a translucent orange plastic panel for a top surface. The box had a light bulb hidden in it. The model leaned forward from the waist and touched the panel with his/her forehead as a result of which the box was illuminated. The infants were given the box only on a separate visit a week later when 67% of them imitated the salient novel action: they leaned forward themselves to touch the box with their forehead (see Figure 1); an action they would not spontaneously perform (as shown by a control base-line condition). This demonstration indicates the remarkably early presence of imitative learning. Meltzoff argues that 14-month-olds differentiate between the actor's goal (the visible outcome of the box lighting up) and the specific means (head-on-box) performed and "they imitate the means used, not solely the general ends achieved" (1995, p. 509). The present study addresses two important questions that arise in relation to Meltzoff's intriguing demonstration: 1) Why do infants imitate the specific novel action modelled? 2) Why don't they simply push the panel with their hand to achieve the outcome (this being a simpler, more familiar, and easier-to-perform action alternative available to them)?

In his work on the social transmission of tool use in chimpanzees, Tomasello (1999) differentiated between 'imitative learning' – which seems to be a human-specific capacity – and 'emulation learning' that is characteristic of nonhuman primates.

Figure 1: Touching the box with the forehead

Briefly, when primates observe a novel instrumental action that brings about an interesting outcome, they seem to focus on the salient outcome only without differentiating it from the particular means used. This is suggested by the fact that when they attempt to bring about the same outcome themselves – in contrast to young children – they do not directly imitate the specific means modelled. Rather, they perform a series of motor actions directed to the outcome that are already available in their motor repertoire, until – through a process of trial-and-error learning - they hit upon the same effective means that was modelled for them, as if 'reinventing' it by chance.

Tomasello (1999) points out that if infants used emulation learning in the Meltzoff situation, one could expect that instead of imitating the novel and unfamiliar

'head-on-box' action, they would tend to perform a simpler, more natural, and already familiar motor action to achieve the outcome: they would touch the box with their hand (but, apparently, they did not). Therefore, Tomasello (1999) argues that infants in the Meltzoff study "understood a) that the adult had the goal of illuminating the light; b) that he chose one means for doing so, from among other possible means; and c) that if they had the same goal they could choose the same means – an act in which the child imagines herself in the place of the other" According to this simulationist account "imitative learning of this type thus relies fundamentally on infants' tendency to identify with adults…" (p. 82).

At first sight, infants' readiness to faithfully imitate the novel and unfamiliar 'head-on-box' action also seems unexpected in the light of Gergely and Csibra's recent theory of the one-year-old's 'naïve theory of rational action' (Gergely, Nádasdy, Csibra, & Bíró, 1995; Gergely & Csibra, 1997; Csibra & Gergely, 1998). In a series of habituation studies these authors and their colleagues (Gergely et al., 1995; Csibra, Gergely, Bíró, Koós, & Brockbank, 1999) demonstrated that 9 to 12-month-old infants (but not 6-month-olds) can already interpret the behaviour of an abstract computer-animated figure as a goal-directed rational action. For example, infants were habituated to a visual event in which a small circle repeatedly approached and contacted a larger circle by jumping over a rectangular figure (the 'obstacle') that was placed in between them. During the test phase, the 'obstacle' was removed, and infants were presented with either of two events. In the 'old action' event (non-rational approach) the small circle performed the same jumping approach as before to get to the large circle, even though - for adult observers – this jumping-over-nothing action did not seem a 'sensible' goal approach given the absence of the 'obstacle'. In the 'new action' event (rational approach) the small circle performed a novel but (for adults) 'sensible' action: it approached the large circle by following the most direct horizontal straight-line pathway that has become available leading to the large circle. Corresponding to adult intuitions, 9- and 12-month-olds looked longer at the non-rational 'old action' event than at the (rational) 'new action' event, while showing no dishabituation to the latter.

According to Gergely and Csibra's theory this finding demonstrates that when interpreting a goal-directed behaviour, one-year-olds evaluate the rationality of the particular action as a function of the visible goal and the physical constraints of the actor's situation (here the presence of the 'obstacle'). When the situational constraints change (i. e., when the 'obstacle' is removed), infants can infer what particular novel action the actor ought to perform in the new situation to achieve the goal in the most rational or efficient manner. It is hypothesised that in doing so infants rely on the inferential principle of rational action that assumes that to achieve its goal an agent will choose to perform the most rational action available given the constraints of the situation (Gergely & Csibra, 1997; Csibra & Gergely, 1998).

Extending this theory to imitative learning situations one would expect infants to imitate the model's novel means only if it appeared to them to be the most rational or efficient alternative to the goal within the constraints of reality. On this assumption, however, it is not immediately clear why Meltzoff's subjects would consider the novel 'head-on-box' action as the most rational means to the goal, when clearly there is a much simpler, more familiar and for them obviously easier-to-perform motor alternative: they could touch the box simply by placing their hands on it ('hand-on-box' action). Why do they imitate the novel 'head-on-box' action then?

To solve this riddle, we hypothesised that it is possible that the action modelled by Meltzoff contained certain situational features that allowed infants to 'rationalize' the 'head-on-box' action as the most efficient alternative available to the goal. In particular, it seems possible that infants noticed and interpreted the fact that while the model's hands were free to act, s/he nevertheless chose to touch the box with his/her forehead rather than with his/her hands. Assuming that the adult is a 'rational agent', the infants may have concluded that 'there must be a good reason' for this choice, and that the 'head-on-box' action must have advantages over the simpler-looking 'hand-on-box' action in achieving the goal. Therefore, when getting a chance to reproduce the effect, the infants themselves would opt to perform the novel 'head-on-box' action that had been inferred to be the most rational alternative to the goal.

What would happen if the model's hands were visibly occupied while s/he was performing the 'head-on-box' action? This would make it explicit that in the given situation the simpler 'hand-on-box' action is not available to the model, and so the performed 'head-on-box' action would clearly appear to be the most rational alternative to the goal. What would infants do in this case, if after having observed the modelled 'head-on-box' action, we made the box available for them to act on? Note that here the situational constraints on available means would be different in the infant's case than in the case of the adult model, since, unlike the adult's, the hands of the infants would remain free to act. Therefore, while the modelled 'head-on-box' action may have seemed rational for the adult to perform, in case of the infants it would cease to be the most rational alternative available. For them there would clearly be a simpler and more rational means accessible in the form of the familiar and well-practiced 'hand-on-box' action.

Therefore, on the basis of the 'principle of rational action' we would expect that in this situation infants would not faithfully imitate the adult's 'head-on-box' action, but rather they would be more likely to touch the box with their hands: an action that is more rational given the constraints of their own situation.

In sum: our 'rational imitation' account outlined above differs from Meltzoff's and Tomasello's 'imitative learning' accounts in two significant respects. First, the 'imitative learning' model, as it stands, predicts that infants would imitate the particular means modelled by an adult irrespective of whether the specific action is seen as the most rational alternative to the goal or not (cf. Nagell, Olguin, & Tomasello, 1993). In contrast, our 'rational imitation' account emphasizes that infants do not imitate faithfully or automatically an adult model's goal-directed action. Rather, they would first evaluate the modelled behaviour from the point of view of the 'principle of rational action' and imitate it only if they managed to 'rationalize' it as the most efficient alternative to the goal available given the constraints of the particular situation. Second, the 'rational imitation' model predicts that infants will imitate the model's means that was judged to be rational only if the situational constraints of the adult model are similar to those of the infants. If the situational constraints are different, however, and there is a more rational alternative available to the infant that was not available to the model, infants are expected to perform this more rational means rather than imitating faithfully and automatically the specific action modelled by the adult.

We have modified the original Meltzoff (1988) situation in such a way that would allow us to test the above predictions.

Method

Subjects

We tested 30 14-month-old infants (+/- 1 week) in two experimental conditions. Three babies were dropped because they were not brought back for the second test, so overall we report data from 27 infants.

Procedure

The infants were brought to our lab twice with a one-week delay in between. On the first visit infants were seated in their mother's lap in front of a table that had 3 toy objects covered with cloths. (Here we are reporting data only for the 'magic box' object.) The experimenter sat at the other side of the table, while the infants were seated about one meter away from the table so that they could not reach the toys. The sessions were video taped from behind a one-way mirror. On the first visit the experimenter modelled the target act three times making sure that the infant paid attention.

The 'Hands free' condition (n=13) was a slightly modified[1] version of Meltzoff's (1988) original study. In this condition, even though the model's hands were visibly free, she did not use them. Instead, by leaning forward from the waist she touched the lamp on the box with her forehead ('head-on-box' action) and the lamp lit up. Note that in this situation the actor's reason for not using his free hands to touch the box is not directly demonstrated: it is only implied by her choice to use her head rather than her hand to light up the lamp.

In the 'Hands occupied' condition (n=14), before presenting the 'head-on-lamp' action the model, pretending to be freezing, told another experimenter that "she was cold and would like to have her blanket". After it was handed over to her, she wrapped it around her shoulders and held it tightly with both hands. (In the 'Hands free' condition the model also asked for her blanket, but then she put the blanket around her shoulders leaving her hands visibly free in front of her.) Note that in this condition the relevant situational constraints are different in the case of the model than in the case of the infant: while the hands of the adult were occupied, the hands of the infant were free. In both conditions the model went on to perform the very same 'head-on-box' action lighting the lamp by touching it with her forehead. (She repeated this three times.)

The test phase: Infants returned a week later. Sitting in their mother's lap they were allowed to act on the 'magic lamp' themselves. The model sat on the other side of the table as before. The infants actions were videotaped from behind a one-way mirror.

Data analysis and scoring

The video records of the test phase were scored by two independent observers who were uninformed as to which of the two conditions the subject belonged to. If the infant attempted to imitate the 'head-on-box' target action within a 20 sec time window s/he received 1 point, if s/he did not, s/he got 0 point. An attempt was defined as either touching the lamp with the head, or leaning forward in such a way that the subject's head approached the lamp within 10 cm or less (this is

[1] Our 'magic box' was slightly different from the one used by Meltzoff (1988) in that we have mounted a circular translucent table lamp on top of the box that could be activated by touch (see Figure 1). We have used this arrangement because in a pilot study identical to Meltzoff's experiment we noticed that the head and hair of the adult model often blocked the light effect from the infants when she touched the surface of the box with her forehead leaning over it. As a result some of the infants seemed to notice the light effect (showing surprise) only when they themselves touched the box during their second visit. By mounting the circular touch-sensitive table lamp on the box the resulting light effect was clearly visible to all infants already during the modeled action.

identical to Meltzoff's (1988) original criterion). The observers also coded the number of 'hand-on-box' actions and the number of times infants pointed to the model within the 20 sec time window. There was a 97% agreement between the two independent coders.

Results

To test our hypothesis that the different situational constraints on action in the two conditions influence the likelihood of the target action being imitated, we first compared the relative amount of imitated 'head-on-box' target acts in the two conditions. As Figure 2 shows, the two conditions differed significantly in this respect (Chi-square = 6.238 (df=1) p<.013). In the 'Hands free' condition 75% of the infants imitated the modelled 'head-on-lamp' action replicating Meltzoff's original result (he found 67% imitation). In contrast, when the model's hands were occupied ('Hands occupied' condition), only 27% of infants imitated the target act. The rest of the infants tried to light the lamp by touching it with their hands only.

Furthermore, there was a clear indication that the majority of infants who did not imitate the target act in the 'Hands occupied' condition did not fail to do so because they forgot the target act after the one week delay.

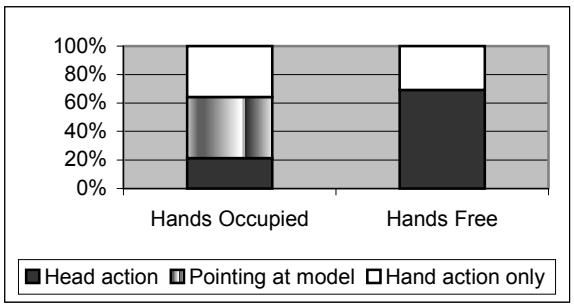

Figure 2:The amount of head and other types of actions in the two conditions

This is shown by the fact that 6 out of the 11 subjects (55%) not imitating the target act in this group produced a playful pointing gesture, pointing to the model (often smiling or giggling) (Figure 3a). This clearly indicates that they did recall the salient 'head-on-box' action of the model. In spite of this, however, they chose not to imitate, but proceeded to make the lamp light up by touching it with their hand (Figure 3b): a means that was simpler and more rational alternativa in their situation than the novel target act modelled. Furthermore, we found that all subjects in both conditions did produce at least once the 'hand-on-box' action within the 20 sec time window. In fact, the 'hand-on-box' action was typically performed more than once (Mean=2.1) by most subjects.

Figure 3a: Pointing to the model

Figure 3b: Touching with hand

Moreover, the large majority of infants (9 out of 12) who re-enacted the modelled action, performed the 'hand-on-box' action before imitating the 'head-on-box' action (Figure 4). Finally, in all cases where a 'hand-on-box' action was performed before the 'head-on-box' action, the hand-on-box' action was successful in bringing about the goal (i.e. the light was illuminated).

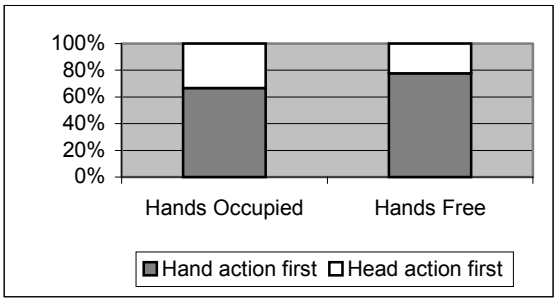

Figure 4: Relative order of hand action vs. head action among imitators

Discussion

The results provide support for the assumptions of the 'rational imitation' account. The differential degree of imitating the same target act found in the two conditions demonstrates that novel goal-directed actions modelled by an adult are not automatically imitated by 14-month-olds. The likelihood of reenacting a novel means observed was clearly a function of the infants'

interpretation of the rationality of the instrumental act in relation to the situational constraints on the actor's possible actions. We found that infants only imitated the 'head-on-box' action, if the contextual constraints of the adult's situation were the same as those of the infants themselves ('Hands free' condition). In this case 75% of the infants imitated the novel action, replicating Meltzoff's (1988) original finding. In contrast, when the model's hands were occupied ('Hands occupied' condition), the very same 'head-on-box' target act was imitated only by 27% of the infants. Given that their own hands were free to act, 73% of the 14-month-olds chose not to imitate the model in this condition, but performed a more rational alternative action available to them: they simply touched the lamp with their hand (Figure 3b).

We find especially informative the fact that in the 'Hands occupied' condition, in which the majority (73%) of the infants did not imitate the novel 'head-on-box' action, more than half of the non-imitating subjects pointed at the model while showing amusement (Figure 3a). This pointing gesture clearly indicates that after a week delay these infants successfully recalled the modelled 'head-on-box' action. Nevertheless, they chose to perform the (non-modelled) 'hand-on-box' action that was seen as a more rational means available to them in their own situation.

But why did the majority of infants reenact the novel 'head-on-box- action after having succeeded in lighting up the lamp by simply pushing it with their hands (Figure 4)? One possibility is that this imitative act served a communicative function: maybe to remind the model after a week that they remembered his funny action or to make him repeat his act. Alternatively, the reenactment may have served an epistemic function. Our data suggest that the infants inferred from seeing the model's free hands that 'there must be some reason' behind his choice to use his head instead of his hands to touch the box. Therefore, they may have expected the 'head-on-box' action to be in some (yet unknown) ways more advantageous. So maybe they reenacted the novel head action to discover the 'reason' behind the model's choice by experiencing the potential differences between the two alternative means. (We are currently running studies to test these hypotheses.)

To conclude:

1. The results successfully extend our 'naive theory of rational action' from the domain of action interpretation to the domain of action production and imitative learning.

2. We have demonstrated that evaluating the rationality of intentional action in relation to visible goals and situational constraints takes place at two different levels: a) during interpreting goal-directed actions performed by others (*ENCODING)*, and b) during selecting an appropriate motor response to achieve the same goal by the self (*RESPONSE GENERATION).*

3. Our findings show that re-enactment of a modelled goal-directed action is not an automatic process triggered by identification with a human actor. While identification may be involved in imitation, it is not sufficient to account for the differential pattern of re-enactment in our two conditions.

4. Instead, re-enactment of intentional action is a selective interpretative process driven by the inferential principle of rational action. Re-enactment takes place only a) if the action is judged as rational given the situational constraints of the *model*, and b) if the action is judged as potentially more rational than other available alternatives given the situational constraints of the *infant herself***.**

Abstract

Smith and Minda (2000) showed that mathematical approximations of several popular categorization theories could be fit equally well to the average "percentage of 'A' responses" in their meta-analysis of studies that used the 5-4 category structure. They conclude that the 5-4 category structure is not a useful paradigm for explaining categorization in terms of cognitive processes. We disagree with their conclusion, and contend instead that the problem lies with the data collection and analysis methods typically used to study categorization (in this and other category structures). To support this claim, we describe a recently completed study in which we collected and used a variety of converging data to reveal the details of participants' cognitive processes in a 5-4 category structure task.

The Smith and Minda (2000) Meta-Analysis

Recently, Smith and Minda (2000) reanalyzed 29 data sets (each set a particular condition in an experiment) collected from the experimental literature on categorization that used the 5-4 category structure.[1] Eight of the sets employed the stimuli called Brunswik faces. Others used yearbook photos (4 sets), geometric shapes (11 sets), verbal descriptions (3 sets), and rocketships (3 sets).

As shown in Table 1, each stimulus in this category structure has 4 binary features, whose combination creates 16 (2^4) different stimuli. The 5-4 structure splits this set into two linearly-separable groups.

In the acquisition phase of a typical category learning study, participants first learn to classify 9 of the 16 stimuli, 5 as A and 4 as B, as shown in the table. Each trial presents the 9 learning items, one at a time, in a random sequence, and the order changes from trial to trial. Participants classify each as "A" or "B" and the correct assignment for each stimulus is given as feedback. Typically, learning proceeds until a participant classifies all 9 stimuli correctly in a single trial. In the transfer test that follows, all 16 stimuli are presented to the participants and they classify each, now without feedback.

Table 1: The 5-4 category structure.

Stimulus (M&S, 1981)	Stimulus (S&M, 2000)	Feature F1	F2	F3	F4
Category A					
4A	A1	1	1	1	0
7A	A2	1	0	1	0
15A	A3	1	0	1	1
13A	A4	1	1	0	1
5A	A5	0	1	1	1
Category B					
12B	B6	1	1	0	0
2B	B7	0	1	1	0
14B	B8	0	0	0	1
10B	B9	0	0	0	0
Transfer					
1A	T10	1	0	0	1
3B	T11	1	0	0	0
6A	T12	1	1	1	1
8B	T13	0	0	1	0
9A	T14	0	1	0	1
11A	T15	0	0	1	1
16B	T16	0	1	0	0

Note. M&S = Medin & Smith; S&M = Smith & Minda. The feature structure for Medin & Smith's stimulus 4 is identical to that in Smith & Minda's stimulus A1, and so on.

Fitting the Data

For purposes of their meta-analysis, Smith and Minda (2000) used data from the transfer trial in each of these 29

[1] They speak of 30 sets, but two of their sets are obviously a duplication from an experiment by Medin and Smith (1981), for all 16 data points are identical for both sets.

data sets. Specifically, for each of the 16 stimuli, they computed the percentage of participants in each study who classified a stimulus as an 'A' stimulus. They then averaged these percentages over all 29 data sets to provide a global average, containing 16 data points, one for each stimulus. Thus, each data point represents the average percentage of participants (in those 29 studies) who categorized a particular stimulus as an 'A' stimulus. These data are displayed in Figure 1.

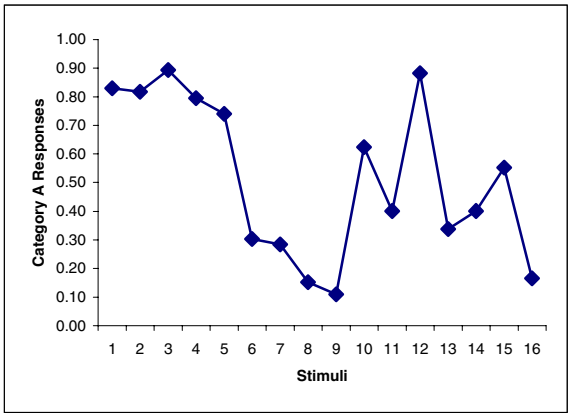

Figure 1. Average percentage of category 'A' responses from the Smith and Minda (2000) meta-analysis.

Smith and Minda (2000) next built a set of eight mathematical models, one for each of the theories they evaluated, and fitted each to the data for the 16 stimuli, adjusting the available parameters (4-6 free parameters per model) separately for best fit to each set of data. Then they averaged the set of 29 predicted performance profiles, to provide a set of 16 data points for comparison with the aggregated average of the actual data over all 29 studies. As Smith and Minda give a very clear and complete account of the functions they used and the fitting procedure, we need not repeat that information here. Table 2, adapted from Smith and Minda's Table 2, summarizes the fits to the data and the number of free parameters available to each model.

Table 2: Measures of Fit for Mathematical Models in Smith and Minda (2000)

Model	AAD	PVA	FP's
Additive prototype	0.091	0.838	4
Multiplicative prototype	0.069	0.890	5
Context	0.047	0.941	5
Additive exemplar	0.144	0.664	4
Fixed low sensitivity	0.149	0.637	5
Gamma	0.045	0.944	6
Twin sensitivity	0.043	0.946	6
Mixture	0.046	0.944	5

Note. AAD = Average Absolute Deviation; PVA = Percentage of Variance Accounted for (R^2); FP's = free parameters.

Models of the Experimental Materials

In the 5-4 category structure, individual features of value 1 (assignment of 1 and 0 is arbitrary in a particular experiment) dominate the five A stimuli and features of value 0 dominate the B stimuli: A stimuli average 2.8 1-features; B stimuli average 1.25. It is reasonable that participants would learn that 1-values indicate probable A membership, and 0 values, probable B membership. We refer to this characteristic of stimuli in the 5-4 category structure as "A-proneness."

Suppose we assign to each stimulus a value corresponding to its "A-proneness." For example, we could assign a stimulus 4 points for a 1 in F1, 3 points for a 1 in F2, 4 points for a 1 in F3, and 3 points for a 1 in F4, corresponding to the frequency with which these feature values are associated with category A in the learning set. Then take the sum of these values as the measure of A-proneness for a particular stimulus. By this method, stimulus 4A gets a score of 11, and stimulus 12B gets a score of 7.

We can fit this measure of A-proneness to the Smith and Minda (2000) data (percentage of category A responses for each stimulus) using a linear regression. The result is a 2-parameter model ($y = .034x + .069$) that predicts the percentage of category 'A' responses for all 16 stimuli with an R^2 of .81 and an AAD of .098. This simple linear regression, with only two free parameters, and derived strictly from the feature structure of the stimuli, accounts for the lion's share of the performance variability.

This analysis does not instill confidence that the more elaborate models have much to say about the actual psychological processes of the participants in these experiments. The only thing any of these models (including our strawman model) tell us about participants in these studies is that they are capable of tuning their behavior to the feature structure of the stimuli. These are more models of the experimental materials than they are models of psychological processes.

Indeed, Smith and Minda (2000) observe that the best of the mathematical models all produced such good fits to the data that it was impossible to choose between the very different process models motivating them:

> ". . . the underlying representation and process remains undetermined and unknown. Therefore, one sees that the [29] 5-4 data sets, when described by formal models, are silent on the matter of whether categories are represented in a way that is based on prototypes or in a way that is based on exemplars." (p. 17)

Smith and Minda (2000) conclude from this that the 5-4 category structure is too limited in its properties for general conclusions to be drawn from it about the processes that people use to learn new categories.

We do not agree that the 5-4 category structure is inherently too limited to reveal the underlying cognitive processes. We propose instead that the methods dominating this area of research are too limited. You've got to have the right tool for the job. In this case, the job is to uncover the processes underlying category learning and categorization

performance. We claim that the right tool (methodology) for this job is fine-grained information-processing analyses, using a variety of converging measures. We have found that detailed analysis of the trial-by-trial behaviors of individual participants reveals rich complexity in their categorization processes. In the next section, we describe the completed study, our approach to data analysis, and the lessons we have learned about the complexity and variability of categorization processes in the 5-4 paradigm.

An Information-Processing Analysis

The study we completed involved a partial replication of Medin and Smith (1981), whose category learning study implemented the 5-4 category structure using Brunswik faces. The four binary features of Brunswik faces are Eye Height (EH – High and Low), Eye Spacing (ES – Wide and Narrow), Nose Length (NL – Long and Short), and Mouth Height (MH – High and Low). These features – EH, ES, NL, and MH – correspond to features F1-F4, respectively, in Table 1. Like Medin and Smith, we used three instruction conditions (Standard, Prototype, and Rule-X), a learning phase, and a transfer phase. After that, participants were presented each of the 16 faces and its associated category, one at a time, and they rated the extent to which the face was typical for that category on a 1-to-9 scale. At the end, participants gave retrospective reports describing the processes they used to categorize the stimuli. Thirty-six Carnegie Mellon University undergraduates participated in this study. Half gave concurrent verbal protocols during the entire learning phase. Our analyses focus on these 18 participants.

A Variety of Measures

The data we have focused on in our process analyses include (1) errors, (2) concurrent verbal protocols, (3) typicality ratings, and (4) retrospective reports. Data analysis were not limited to measuring the frequency with which participants choose A or B responses to the 16 stimuli during a transfer trial. Instead, we relied on analysis of the detailed behavior of participants while they were performing both the learning and the transfer task: data that revealed a great deal about the processes they were using.

In performing these analyses, we have been guided by the idiographic data analysis methods typified by Newell and Simon (1972) and by a general theory of perception and memory, EPAM, that has previously been applied to aggregate data on the 5-4 task (Gobet, Richman, Staszewski, & Simon, 1997). EPAM is a computer program that uses a discrimination net architecture to simulate the participants' behavior in responding to each stimulus. In fact, EPAM was used to simulate the aggregate data from Medin and Smith (1981) that comprises three of the 29 Smith and Minda (2000) data sets.

Following are descriptions of our data analysis procedures, accompanied by illustrations of how analysis at this level of detail can reveal participants' categorization processes.

Errors. Participants may use from one to four features to classify a face, and they exercise most of these options at one time or another. Table 3 shows the likely errors that arise (out of ambiguities) when the nine faces used in the learning trials are categorized only on the basis of particular features, or particular pairs, or triplets of features.

The four rows and the first four columns of the table name the features. Each of the cells in the first four columns corresponds to a classification of the faces on the corresponding pair of features. For convenience of reference, we have designated the cells of the table corresponding to particular combinations of feature tests with letters from M through Z.

For example cell V, which is at the intersection of row EH and column NL, shows on the first line that 5A and 2B cannot be distinguished using only these two features, for both faces have identical eye heights and nose lengths (EH=0; NL=1). Similarly (second line), 13A and 12B are identical on EH (1) and NL (0), so a discrimination process that relied only on those two features would not be able to discriminate stimuli 13A and 12B. The other five faces form two classes: A's with high eyes and long noses, and B's with low eyes and short noses. So, for this particular pair of tests, four faces are ambiguous or "hard," and likely to be misclassified during learning. If, instead of EH:NL, the features attended to were nose length and mouth height (NL:MH), then 4A, 7A and 2B would fall in a single class, as would 13A and 14B, and these five would be the hard faces in this case. Thus, when participants use a particular pair of features to classify faces, they will make the greatest number of errors in classifying the faces that are hard for that pair.

The column of Table 11 marked "EXCEPT" indicates which faces would be error-prone if the three features *except* the one labeling the corresponding row were tested (i.e., a discrimination net using the three remaining features); the column marked "SOLE" indicates which faces would be error-prone if *only* the feature on that row were tested. The EXCEPT column shows that all nine faces can be categorized perfectly without the use of ES, but the three other features, EH:NL:MH, must all be used. Notice that each of the three triads of features that includes ES produces a different set of hard faces, as does each net using only a particular single feature.

By assessing which were the hardest faces during the learning phase, we identified the dominant discrimination strategy for each participant. Participants in the Prototype instruction condition showed the most between-subject variability in process, with strategies V, W, Y, P, and R inferred from their errors in the learning phase. Standard participants also showed considerable variability, with evidence of strategies V, W, Y, and Z in their data. The Rule-X participants, who were told explicitly to attend to nose length, used strategies R and V.

Table 3: Error patterns predicted by feature selection in the 5-4 categorization paradigm

	EH (F1)	ES (F2)	NL (F3)	MH (F4)	EXCEPT	SOLE
EH (F1)		5A,2B 4A,13A,12B **U**	5A, 2B 13A,12B **V**	5A,14B 4A,7A,12B **W**	4A,2B **M**	5A, 12B **N**
ES (F2)			4A,5A,2B 13A,12B **X**	15A,14B 7A,10B 4A,2B,12B **Y**	**O**	7A,15A 2B,12B **P**
NL (F3)				4A,7A,2B 13A,14B **Z**	4A,12B **Q**	13A,2B **R**
MH (F4)					13A,12B 5A,2B **S**	4A,7A 14B **T**

Note. Stimuli listed in each cell (e.g., 5A, 12B) are those for which errors are expected if the participant is attending to that conjunction or disjunction of features. Bold code letters (e.g., **U**, **V**, **W**) are used in the text as an economical means of referring to specific categorization strategies, as indicated by increased attention to specific features. F1-F4 = Features 1-4 in Table 1. EH = Eye Height; ES = Eye Spacing; NL = Nose Length; MH = Mouth Height. EXCEPT = attention to all features except the feature in that row. SOLE = attention to only the feature in that row.

Verbal Protocols. We assume that the features used in discriminating and categorizing the faces are verbalizable. The claim is not that participants will verbalize every feature to which they attend, or even that discrimination is always a verbal process; the claim is that the process of encoding features can create a verbalizable representation, and that patterns of verbalization of features are correlated with patterns of attention to the stimuli.

The Brunswik faces are easy to distinguish visually, and to describe verbally, using either the “official” features (eye height, eye spacing, nose length, mouth height) mentioned in the experimental instructions, or other descriptors that may be already familiar to individual participants(e.g., "long face", "small distance between nose and mouth," "wide face," or even "monkey-like"). The official descriptors, rather than idiosyncratic ones, are by far the more frequent in the protocols.

Participants' protocols mainly reported values of features of the face they were currently categorizing, sometimes supplemented with a reason for assigning the face to a particular class, and sometimes with a comparison with a previous face. The following (each preceded by identifier of participant and experimental condition) are examples of verbal responses to stimuli that described features in the language of the instructions:

MS (prototype). "High eyes; short nose; low mouth. Let's go with B, because the last one had high eyes and low mouth."

ML (prototype). "I'll say this is A because of the nose length and the eye height and the separation between the eyes and the mouth."

Rather more austere and more typical are:

MK (standard). "close and high eyes, small nose, middle mouth." *(Chooses A.)*

RB (prototype). "The eyes are low and the nose is big." (*Chooses B*.)

The discrimination processes of participants who use idiosyncratic descriptive terms are harder to identify, but the descriptors they actually used were generally related to the "official" ones in simple ways. For example, "long" faces were faces with high eyes, and sometimes also with low mouths. Faces with "eyes close to the nose" were faces with low, close eyes. The meaning, in terms of features, of these non-standard descriptors can usually be determined by checking the characteristics of the faces to which participants applied them.

Typicality Ratings. Following the transfer phase of the experiment, participants were shown each face along with its correct category. Their task was to rate the extent to which each face was typical for its category. The verbal protocol participants also provided explanations for their ratings. These proved to be informative as additional converging evidence regarding how participants were discriminating the stimuli. Following are several examples from the typicality rating explanations:

JIS (standard). “This one is pretty typical of A because the eyes are way up high and spread out in this one.”

RB (prototype). “That one, I think, is typical because the eyes are high and far apart, and the nose is little.”

MB (rule-x). “Typical. Short nose.”

In addition to lists of features as justification for the ratings, participants occasionally referred to Gestalt characteristics of the faces, using terms like "long" or "wide". For instance, "This one doesn't look like a B face. The eyes are high, and it looks like a kind of long face." The majority of explanations, however, were feature lists that revealed the various ways participants used combinations of feature values to categorize the stimuli.

Retrospective Reports. After the typicality ratings, the experimenter asked each participant, "On what basis were you making your classifications?" Following are two example responses:

RB (prototype). "Most of the type A had high eyes, and it didn't matter where the nose is or the mouth. And most of the B's had eyes in the middle, but there was a type B that had really high eyes. And then there was a type A that had eyes in the middle with a little nose and a long mouth."

MK (standard). "Basically, small nose was A, big nose was B. Basically, except small nose if the mouth was low, I looked at the eyes, and if the eyes were low, then it was B. If it was a big nose with little mouth and high up, then I checked the eyes, and if the eyes were high, then the face was A."

Note that both RB's and MK's retrospective reports are consistent with their concurrent verbalizations from the learning trials. It is converging evidence of this sort that increases our confidence in conclusions regarding participants' categorization processes.

Comparison of VP and NVP Errors

An assumption that is required in drawing generalizations from the verbal protocol participants is that the requirement to give protocols does not itself have a direct impact on categorization processes in this task. It would be reassuring if the performance of the verbal protocol (VP) participants and the non-verbal protocol (NVP) participants were in fact similar.

Following the logic in Table 3, to the extent participants in the VP and NVP conditions found similar faces difficult during the learning phase, there is evidence for similar categorization strategies across those conditions.

In both conditions, the four most difficult stimuli are 2, 5, 12, and 13. These are difficult stimuli because they are exceptions on features that are highly predictive of category membership. Table 1 shows that stimuli 2 and 13 are exceptions on Nose Length, while 5 and 12 are exceptions on Eye Height. Additionally, pairs of those stimuli are confusable if one ignores Mouth Height. That is, 2 and 5 are identical except for mouth height, as are 12 and 13. The fact that these four stimuli are always the most difficult, suggests that most participants, regardless of verbal protocol condition, found it difficult to learn the exceptions.

Looking at error rates across all of the stimuli, we find that VP and NVP error rates correlate $r = .82$, indicating a high degree of similarity in the error patterns between the two conditions. In terms of overall error rate, VP participants tended to make more errors (Mean = 50.2) than NVP participants (Mean = 39.7), although an ANOVA reveals that this difference is not significant: $F(1, 36) = 1.219$, $p = .277$).

Summary of Findings

Due to space limitations, and because of the massiveness and complexity of the body of data we are examining, we must briefly summarize our most important findings. Additionally, we feel that a general description of the results will be more useful, in terms of distinguishing the information processing approach from the more typical, aggregate-level, nomothetic approach, than the specific frequencies and percentages in our findings would be. Therefore, we will finish the paper with an account of our main findings.

One lesson that emerges from these rich data is that the task structure itself was a major determinant of the outcomes we measured. The influence of task structure on performance is apparent in Figure 2, and we found similar effects in our data. Because nearly all of our participants achieved the learning criterion, we infer that they discovered the implicit task structure.

A second finding is that most of the participants, regardless of their instructional condition, interpreted the task as one of forming rules that could be used to assign faces to a category. This generally took the form of learning what *features* were associated with the A or B categories, then using this knowledge to classify *faces* by means of their features, rather than defining prototypic faces or cycling through comparisons with previous exemplars. Feature-based rule following is apparent in the verbal protocols presented earlier.

Regarding rule-based behaviors, some (but not all) participants discovered that it was also useful to recognize certain individual faces and associate their categories directly with them. These were almost always the "hard" faces that did not fit the simple rules they used to discriminate the others. This was particularly apparent in statements like, "Ah, this is the one that tricks me." This phenomenon is consistent with the model of Nosofsky, Palmeri, and McKinley (1994), but the inconsistent appearance of this phenomenon in our data also suggests that model's limitations.

Another finding is that the numerous differences in the behaviors of different participants could be traced in large measure to different strategies of attention, and different strategies for retaining and combining information about features and combinations of features upon which rules of choice could be built. Strategies were effective to the extent that they made only modest demands on memory, including demands on short-term memory and demands for transferring information to long-term memory and retaining it for use in building up the structure of decision rules.

Perhaps the most consistent phenomenon we observed in the data was the high degree of within-participant variability in process. Examination of participants' stimulus-by-stimulus category responses and corresponding

verbalizations reveals that the dominant rule-based processes are sprinkled with instances of comparing the current stimulus to the immediately preceding stimulus, and also increasing evidence of recognition-based processes (especially for the hard faces) with experience. Even within the rule-based processes, there was a good deal of variability, as participants had varying degrees of success with the feature-based rules they generated and tested.

Conclusion

Sciences are concerned with discovering and testing laws that describe the invariant features of their domains. Invariance is a complex concept. Even the gravitational constant is not an invariant once one strays from the Earth or ascends a mountain. So science has laws, like the law of gravitational attraction, but it has parameters and variables that specify the workings of each law as a function of various circumstances.

Matters become especially complex when we consider laws of biology, with its immense variety of living forms, and still more complex when we consider the laws of psychology, which seeks the regularities in the behavior of an organism that has enormous capabilities for adaptation and learning. Not only will the behavior vary with the innumerable features of the environment in which the person performs the task, but even leaving genetic differences aside, it will vary as a function of each individual's previous history of experience and instruction.

The experimental data we have analyzed here illustrate a number of such complexities. No unitary set of laws, taken by itself, governs the precise way in which a set of people go about solving a simple categorization task, not even if all of them are drawn from the same university population. Covering variation by averaging conceals it but does not banish it or explain it. Siegler (1987) made the same point about the "Perils of Averaging," but in the context of analyzing children's arithmetic. With this paper we illustrate the value of a fine-grained, multivariate approach for advancing our understanding of categorization and category learning in terms of their underlying cognitive processes.

It was almost a half century ago that Bruner, Goodnow, and Austin (1956) published their seminal work on categorization, *A Study of Thinking*. In the introduction to that book, they wrote:

> ". . . we have come gradually to the conclusion that what is most needed in the analysis of categorizing phenomena . . . is an adequate analytic description of the actual behavior that goes on when a person learns how to use defining cues as a basis for grouping the events of his environment." (p. 23)

To understand participants' actual behaviors during categorization and category learning processes, not only did we need to analyze the behavior of individual participants, but the data obtained from each had to be of a grain size fine enough to capture some detail of ongoing learning processes. We examined errors and concurrent verbalizations stimulus-by-stimulus, then looked for converging evidence in participants' typicality ratings and their retrospective reports. The requirement that conclusions about participants' processes should be based on the convergence of multiple measures provided strong tests of the validity of our findings. In the end, our approach yielded a rich, descriptive understanding of the underlying representations and processes employed by participants in our study.

The challenge to explain the phenomena observed remains. Because of the variety of measures used in our analyses, and the variation among them in granularity, we advocate the development of simulation models. We submit that detailed, multivariate information-processing analyses and simulation modeling are tools that are well-suited for the job of advancing understanding of category learning and categorization. The data help us come to a better understanding of actual cognitive processes in category learning, and simulation models allow for the possibility of accounting for the enormous variability in process within and between participants.

Is Experts' Knowledge Modular?

Abstract

This paper explores, both with empirical data and with computer simulations, the extent to which modularity characterises experts' knowledge. We discuss a replication of Chase and Simon's (1973) classic method of identifying 'chunks', i.e., perceptual patterns stored in memory and used as units. This method uses data about the placement of pairs of items in a memory task and consists of comparing latencies between these items and the number and type of relations they share. We then compare the human data with simulations carried out with CHREST, a computer model of perception and memory. We show that the model, based upon the acquisition of a large number of chunks, accounts for the human data well. This is taken as evidence that human knowledge is organised in a modular fashion.

Introduction

An important goal of cognitive science is to understand the characteristics of knowledge, in particular the way it is acquired and used. To achieve this goal, research has employed a number of methods, including artificial laboratory experiments, such as nonsense syllable learning, and collection of naturalistic data, such as experts functioning in their natural environments. It is generally accepted that knowledge consists of different types (declarative, procedural, episodic) and that its acquisition follows a power law of learning. In addition, it has often been proposed that knowledge is modular, consisting, for example, of productions (e.g., Newell, 1990) or of perceptual chunks (e.g., Chase & Simon, 1973).

The goal of this paper is to explore, both with empirical data and with computer simulations, the extent to which modularity characterises human knowledge, and in particular experts' knowledge. We first describe the concept of modularity, and then show how it has been used in expertise research. This leads us to describe the CHREST architecture, which acquires knowledge by growing a discrimination net encoding chunks. Next, we present data aimed at characterising the properties of experts' chunks, and compare them with those acquired by CHREST. The comparison results in an excellent fit between the model and the human data. In the conclusion, implications for the modularity of human knowledge in general are drawn.

Modularity of Knowledge

Several formalisms, both modular and non-modular, have been developed in cognitive science to explain how humans represent and implement knowledge. Examples of modular representations are production systems, semantic networks, and discrimination nets. Examples of non-modular representations are distributed neural networks, holograms, and various mathematical representations based on matrix algebra. This classification should be considered with caution, however. On the one hand, production rules, for example, are typically organised in problem spaces (e.g., Newell, 1990), and their interdependence can be considerable, which counts against strict modularity. On the other hand, it could be argued that, in non-modular representations, modules emerge as the system develops or learns (e.g., Rumelhart & McClelland, 1986).

Modular knowledge organisation has attracted much interest in computer science and artificial intelligence, given the importance of how knowledge is indexed, structured, organised, and retrieved (e.g., Lane et al., 2000). In artificial intelligence, modularity has been defined as "the ability to add, modify, or delete individual data structures more or less independently of the remainder of the database, that is, with clearly circumscribed effects on what the system 'knows' " (Barr & Feigenbaum, 1989, p. 149). While a strong argument can be made that it is easier to understand modular and decomposable systems than systems that do not share these properties (e.g., Simon, 1969), and that the value of these properties has been demonstrated in fields such as software engineering, it is an empirical question whether human knowledge is modular or not. A rich source of data about this question has been gained from research into expert behaviour, to which we now turn our attention.

Chess Experts' Knowledge

In his seminal study, De Groot (1946/1965) subjected chess players to a number of problem-solving and memory experiments. The surprising result was that, in a choice-of-a-move task, there was no large skill difference in variables such as depth of search, number of moves considered, or search heuristics employed. However, a clear difference was found in a memory task where a chess position was presented for a few seconds. Masters could recall the entire position almost perfectly,

while weaker players could recall only a handful of pieces. De Groot concluded that expertise does not reside in any superior abilities but in knowledge.

Continuing de Groot's research, Chase and Simon (1973) carried out a study destined to have a huge impact in cognitive science. They used two tasks. In the *recall task,* based on de Groot's (1965) method, a chess position was presented for five seconds, and players had to reconstruct as many pieces as possible. In the *copy task,* the stimulus board remained in view, and the goal was to reconstruct it onto a second, empty board. As the stimulus and the reconstruction boards could not be fixated simultaneously, Chase and Simon used the glances between the boards to detect memory chunks. Comparing the latencies between successive pieces in the copy and recall tasks, they inferred that pieces replaced with less than 2 seconds' interval belonged to the same chunk, and that pieces placed with an interval of more than 2 seconds belonged to different chunks. Finally, they showed that the chunk definition based upon the latencies between two successive pieces was consistent with a definition based upon the pattern of semantic relations (attack, defence, proximity, colour, and type of piece) shared by these two pieces. This converging evidence was used to infer the chunks used to mediate superior performance, and to explore how they allowed masters to find good moves despite their highly selective search. A number of other experimental tasks (reviewed in Gobet & Simon, 1998) have brought converging evidence for the psychological reality of chunks, as defined either by latency in placement or by number of relations between pieces.

Simon and Gilmartin (1973) developed a computer program (MAPP; Memory-Aided Pattern Perceiver) implementing some of Chase and Simon's ideas. MAPP is based upon EPAM (Elementary Perceiver and Memorizer; Feigenbaum & Simon, 1984), a theory developed to account for empirical phenomena where chunking (i.e., acquisition of perceptual units of increasing size) is seen as essential. The basic idea in MAPP was that long-term memory (LTM) is accessed through a discrimination net, and that, once elicited, LTM chunks are stored in short-term memory (STM) through a pointer. MAPP's relatively low recall performance—slightly better than a good amateur, but inferior to an expert—was attributed to the small number of nodes, about two thousand, stored in its LTM. MAPP simulated several results successfully: increase in performance as a function of the number of chunks in LTM; kind of pieces replaced; and contents of chunks. However, in addition to its failure in simulating expert behaviour, the program had several limitations (De Groot & Gobet, 1996). In particular, the chunks were chosen by the programmers and not autonomously learnt, and the program made incorrect predictions for a number of experiments that were later carried out. These limitations were removed in the CHREST program discussed below.

CHREST

CHREST (Chunk Hierarchy and REtrieval STructures; De Groot & Gobet, 1996; Gobet & Simon, 2000) is a cognitive architecture similar to MAPP. CHREST originally addressed high-level perception, learning and memory, but various problem-solving mechanisms have been implemented recently. It is composed of processes for acquiring low-level perceptual information, an STM, attentional mechanisms, a discrimination net for indexing items in LTM, and mechanisms for making associations in LTM such as production rules or schemas. STM mediates the flow of information processing between the model's components. The central processing of CHREST revolves around the acquisition of a discrimination net based on high-level perceptual features picked up by attentional mechanisms and on the creation of links connecting nodes of this net together.

After the simulated eye has fixated on an object, features are extracted and processed in the discrimination net, and then, based upon the output of the discrimination, a further eye fixation is made, and so on. STM operates as a queue; that is, the first elements to enter are also the first to leave. STM has a limited capacity, which consists of four chunks (Cowan, 2001; Gobet & Simon, 2000). Processing is constrained by a number of restrictions, including time parameters such as the time to fixate a chunk in LTM (8 s) and capacity parameters such as the four-chunk limit of STM.

The discrimination net consists of *nodes*, which contain *images* (i.e., the internal representation of the external objects; images correspond to Chase and Simon's *chunks*); the nodes are interconnected by *links*, which contain *tests* allowing items to be sorted through the net. Learning happens as follows: once an item has been sorted through the net, it is compared to the image in the node reached. If the item and image agree but there is more information in the item than the image, then *familiarisation* occurs, in which further information from the item is added to the image. If the item and image disagree in some feature, then *discrimination* occurs, in which a new node and a new link are added to the net. Based on empirical data, it has been estimated that discrimination requires about 8 s and familiarisation about 2 s.

In addition to these learning mechanisms, CHREST has mechanisms for augmenting semantic memory by the creation of schemas (known as *templates*) and of *lateral* links connecting nodes together (Gobet, 1996); for example, these links can be created when nodes are sufficiently similar ('similarity links'), or when one node can act as the condition of another node ('condition links'). The creation of these links is consistent with the emphasis on processing limits present in both EPAM and CHREST, in that all nodes used for creating new links must be in STM.

Note: * means p<.01, ** means p<.001 (both two-tailed). The statistical significance levels are based on the *z*-values that were computed using the following formula (assuming the normal approximation to the binomial distribution):

$$z = \frac{p_o - p_e}{\text{s. e.}}, \qquad \text{where s. e.} = \sqrt{\frac{p_e\,(1 - p_e)}{\text{sample size}}},$$

and where p_o is the observed probability and p_e the *a priori* (expected) probability.

CHREST can reproduce a number of features of the behaviour of skilled and unskilled chess players in memory experiments, such as their eye movements, the size and number of chunks, the number and type of errors, and the differential recall of game and random positions (De Groot & Gobet, 1996; Gobet & Simon, 2000). As a psychological theory, CHREST has several strengths. It is parsimonious, with few free parameters. It provides absolute quantitative predictions, for example about the number of errors committed or the time taken by a subject to carry out a task. Together with EPAM, it simulates in detail a number of empirical phenomena from various domains, such as verbal learning, context effects in letter perception, concept formation, expert behaviour, acquisition of first language by children, and use of multiple representations in physics (see Gobet et al., in press, for a review).

A Replication of Chase and Simon (1973)

As noted above, Chase and Simon (1973) operationalised the concept of chunk using both the latencies between successive piece placements and the semantic relations between them. Their experiment has recently been replicated and extended by Gobet and Simon (1998). The main difference between the two studies is that Gobet and Simon used a computer display to present the tasks instead of physical chessboards. In spite of this difference, there is an important overlap between the results of the two studies.

Gobet and Simon analysed 26 players (Chase and Simon had only 3) ranging from good amateurs to professional grandmasters, who were divided into three skill levels (Masters, Experts and Class A players). The results were in line with previous experiments, showing a massive skill effect with game position, and a small but reliable skill effect even with meaningless positions. Here, we focus upon the operationalisation of chunks, relying both upon Gobet and Simon's published data and upon additional analyses.

Latencies Predict Chunk Boundaries

Gobet and Simon essentially followed Chase and Simon's approach. They first estimated a time threshold (2 s) as a means to decide whether two pieces placed in succession belonged to the same chunk, and then

validated this threshold by showing that it led, on average, to similar chunks as those obtained by using semantic relations. If they are modular, chunks should be characterised by a high density of relations between the elements that constitute it, and by a low density of relations with elements from other chunks (Chase & Simon, 1973; Cowan, 2001). That is, there should be many more relations between successive pieces within the same chunk than between successive pieces on opposite sides of a chunk boundary. Thus, the relations between successively replaced pieces should be different depending on whether they are separated by short or long latencies. In addition, assuming that the same cognitive mechanisms mediate the latencies in the copy and recall experiments, the two experiments should show the same pattern of interaction between latencies and number of relations. In other words, the relations for the within-glance placements in the copy task should correlate with those for rapid placements (≤ 2 s) in the recall task and the relations for between-glance placements in the former should correlate with those for slow placements (> 2 s), in the latter.

These predictions are met in both the copy and the recall tasks, whose results correlate highly. Within chunks, small latencies correlate with a large number of relations, while large latencies occur when there are few relations between successive pieces. No such relationship is observed for successive pieces belonging to different chunks. The shortest latencies are found with four relations (Defence, Proximity, Colour, and Kind), which mainly occur with pawn formations.

Relations Predict Chunk Boundaries

The next step consists in showing that the pattern of relation probabilities for within-chunk, but not for between-chunk placements, differs from what could be expected by chance. Table 1 gives the probabilities of the presence of different combinations of relations in the various experimental conditions, with the three skill levels pooled. The last two columns give the *a priori* probabilities (for game and random positions, respectively) that were calculated by recording, for each position, all relations that exist between all possible pairs of pieces; the *a priori* probability for a relation is obtained by dividing the total number of occurrences of a relation by the total number of possible pairs. These *a priori* probabilities were based on 100 positions and 26,801 pairs. Finally, the *z*-values indicate whether the observed probabilities reliably differ from the *a priori* probabilities.

In the copy task, with game positions but not with random positions,[1] the between-glance probabilities are much closer to chance than the within-glance probabilities. This pattern holds also in the recall of both random and game positions when slow placements (> 2 s) are compared with fast placements (≤ 2 s). The probabilities for pieces with three and four relations are high in the within-glance and fast (≤ 2 s) conditions compared with the between-glance and slow (> 2 s) conditions; the opposite is true for pieces with one relation or none. Note also that the probabilities for combinations of relations that include an attack (A) are conspicuously low, compared with chance, for game positions but not for random positions.

One way to make sense of Table 1 is to analyse the correspondence between the number of chess relations and the deviations from *a priori* probabilities, computed by subtracting the *a priori* probabilities from the observed frequencies of a given condition. Based on the notion of modularity, it should be expected that the within-chunk deviations from *a priori* probabilities would be highly correlated with the number of relations, while this would not be the case for the between-chunk deviations. This is exactly what was found. The correlations with number of relations are high for the within-chunk conditions (copy game within-glance: 0.81; copy random within-glance: 0.68; recall game short latencies: 0.86; recall random short latencies: 0.79; all the correlations are statistically significant at $p = .005$). The correlations are smaller with the between-chunk conditions (copy game between-glance: 0.61; copy random between-glance: 0.56; recall game long latencies: 0.58; recall random long latencies: -0.15; none of the correlations are significant at the .01 level). These results are illustrated graphically in Figure 1, which shows the results for game and random positions as a function of whether the placements were within-chunk or between-chunk. From the Figure, it is clear that, for within-chunk conditions, the placements having few relations are below chance, while the placements having several relations are above chance. There is no such clear relation for the between-chunks placements.

Computer Simulations

We now show that CHREST captures the composition of chunks and the pattern of relations of within- and between-chunk placements. Simulations of similar phenomena, carried out by Simon and Gilmartin (1973) using MAPP, were limited to a single subject and matched the data only approximately.

Methods

In the *learning phase*, the program scanned a large database of master-game positions, fixating squares with simulated eye movements, and learning chunks using discrimination and familiarisation. Three nets were created, estimated to correspond roughly to the recall percentages of Class A players, experts, and masters with a five-second presentation time. These nets had respectively 1,000 nodes, 10,000 nodes, and 100,000 nodes.

For the simulations of the *performance phase*, the program was tested with 100 game positions and 100

[1] That this pattern does not hold with the copy of random positions may be due to the strategy used by subjects to replace these positions. Several subjects copied the positions line by line or column by column.

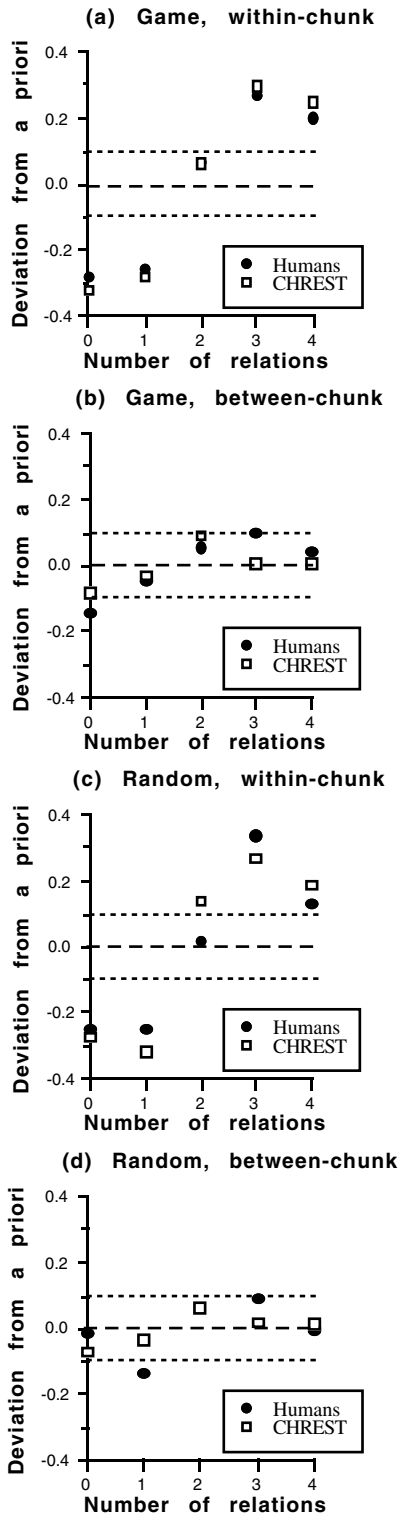

Figure 1: Relation between chess relation probabilities and the number of relations shared by two pieces successively placed. The long-dash line indicates zero deviation, and the short-dash lines indicate deviations of 0.1 above or below zero.

random positions. Learning was turned off. During the five-second presentation of a position, CHREST moved its simulated eye around the board. Each eye fixation defined a visual field (all squares within two squares from the square fixated); the pieces within the visual field are treated as a single pattern and sorted through the discrimination net. Other patterns are defined by the pieces focused upon in two successive eye fixations. If a chunk is found in the discrimination net, a pointer to it is placed in STM.

During the reconstruction of a position, CHREST used the information stored in STM. When a piece belonged to several chunks, it was replaced only once. In case of conflicts (e.g., a square is proposed to contain several pieces), CHREST resolved them sequentially, based on the frequency with which each placement is proposed. Like humans, it sometimes made several different proposals about the location of a piece or about the contents of a square. Finally, some weak heuristics were used, such as the fact that only one white king can be replaced in a position. (See Gobet & Simon, 2000, for more detail.)

A chunk refers to the image of a node in the discrimination net. It is therefore straightforward to decide whether two pieces do or do not belong to the same chunk. The relations between pieces were extracted using the same program as that used with the human data.

Results

Table 2 gives the probabilities of observing a pattern of relations, as a function of the type of position and the kind of placement. Although the fit with the corresponding human data shown in Table 1 is reasonable

(the r^2 are: game within-chunk: .83; game between-chunk: .82; random within-chunk: .58; random between-chunk: .75), not too much weight should be given to them, because they are sensitive to a few large values, and because they may in part reflect the statistics of the chess environment (i.e., the *a priori* probabilities). As with the human data, we subtracted the *a priori* probabilities from the recall probabilities, and took the sum for each number of relations. Figure 1 shows the results for both the humans and CHREST. The model fits the human data quite well. In particular, the between-chunk placements show little deviation from the *a priori* probabilities, in contrast to the within-chunk placements, which are clearly below chance with zero and one relation, and above chance with three and four relations. All conditions pooled, CHREST accounts for 90% of the variance of the human data.

Conclusion

EPAM and CHREST's learning mechanisms, based upon the construction of a discrimination net of chunks, offer a crisp and computational definition of the concept of knowledge module. Using this definition, Chase and Simon (1973) have found, and Gobet and Simon (1998) have confirmed, that relations and latencies between pieces offer converging evidence for validating the psychological reality of chunks. This paper has shown that, with the same mechanisms used to account for a variety of chess data, CHREST acquires chunks that have the same relational properties as humans'.

The acquisition mechanisms consisting in learning pieces within the visual field and between two eye fixations largely explain the high number of relations within chunks. It is important to note that this phenomenon is not trivial to simulate, however. For example, learning mechanisms such as Saariluoma and Laine's (2001) frequency-based heuristic, where chunk construction is not constrained by spatial contiguity, would fail to account for the data, because they do not capture the relation of proximity which is essential in the chunks acquired by humans (cf. Table 1).

These results, as well as others, indicate that the modular structure of the type of discrimination net used by EPAM and CHREST captures essential aspects of human cognition. Chunks, whose elements share a number of relations, are built up gradually and recursively, with later chunks being built from smaller 'sub-chunks'. Some of these chunks evolve into schema-like structures, and some get later connected by lateral links, thereby constructing both a net of productions and a semantic network. It is not only the presence of a node storing a piece of knowledge which matters, but also the richness with which this node is perceptually indexed and the density with which this node is connected to other nodes. These two aspects give some computational meaning to "conceptual understanding": a richly-connected network of links connecting productions and schemas, that is accessible through perceptual chunks. In addition to expert behaviour, CHREST, which incorporates mechanisms for all these kinds of learning, including the acquisition of modular structures, accounts for empirical phenomena in a variety of domains.

Acknowledgements

I am grateful to Herb Simon for his involvement in many aspects of this research and to the members of the CHREST group for comments on this paper.

Strategies in Analogous Planning Cases

Andrew S. Gordon (asgordon@us.ibm.com)
IBM TJ Watson Research Center, 30 Saw Mill River Road
Hawthorne, NY 10532 USA

Abstract

Strategies are abstract patterns of planning behavior that are easily recognized, compared, and used by people in everyday planning situations. In an effort to better understand them as a type of mental knowledge structure, three hundred and seventy-two strategies were identified from ten different planning domains, and each was represented in a preformal manner intended to describe the common characteristics of their instances. In doing this large-scale representation work, two observations were made with significance to current theories of analogical reasoning. First, strategies are portions of the relational structure shared by analogous planning cases. Second, representations of strategies include propositions about the reasoning processes of the agent employing them. We propose that a theoretical understanding of analogical reasoning allows us to use strategies as an investigative lens to view the mental models that people have of others and of themselves.

Introduction: Strategy Representations

The term *strategy* periodically appears in cognitive science literature to refer to the abstract patterns that can be recognized in planning behavior. People appear to have a near-effortless ability to use and reason about strategies despite their complexities - as when considering the case of a corporation that underprices part of its product line to bankrupt their competitors, or a case where a parent bird pretends to be wounded to lure a predator away from a place where their nest would be discovered. From the cognitivist's perspective, strategies can be viewed as knowledge schemas, with the assumption that these schemas are mental representations that can be manipulated, compared, and used in intelligent planning and problem-solving behavior. In order to understand this view more deeply, we undertook a project to systematically analyze and represent strategies on a large scale.

We began this project by identifying three hundred and seventy-two strategies from ten diverse domains of planning and problem-solving. Three competitive planning domains were examined: business, warfare, and dictatorship. Three cooperative planning domains were examined: scientific research, education, and personal relationships. Two individual performance domains were included: artistic performance and object counting. Finally, two anthropomorphic domains, where non-people are viewed as planners, were studied: immunology and animal behavior. Strategies for each of these domains were collected using a variety of methods, which included formal interviews with subject-matter experts, introspection, and the analysis of texts such as Niccolo Machiavelli's *The Prince* and Sun Tzu's *The Art of War*, which are nearly encyclopedic of strategies in the domains of dictatorship and warfare, respectively.

For each of these strategies, we authored a definition in the form of a representation such that all situations that match the definition would be positive examples of the strategy, and all cases that do not match the definition would not be examples of the strategy. Recognizing that the same strategy could be applicable in a wide variety of situations - even those that cross domain boundaries - our efforts focused on strategy representations that were of the highest possible level of abstraction while still meeting these definition requirements.

While some descriptive and functional planning languages are beginning to emerge in the artificial intelligence planning community (Tate, 1998; Gil & Blythe, 2000; McDermott, 2000), we chose not to attempt to use them for this representation work, following the belief that these current efforts are not yet expressive enough to describe the subtle planning features found in strategies. Instead, we adopted a style that can be best viewed as *preformal*, somewhat similar to the strategy representations found in smaller-scale efforts (Collins, 1986; Jones, 1992), and where the content of these representations was loosely drawn from a wide range of content theories of planning, notably from Owens (1990). The motivation for using this preformal style was to enable the scaling-up of representation work by relaxing the syntactic formality of logic while preserving the unambiguity of representational terms.

Figure 1 gives three examples of the 372 preformal representations that were authored. Words and phrases in the representations meant to refer to planning concepts and abstractions were capitalized and italicized as they were authored, which allowed us to algorithmically extract them so that they could be analyzed outside of the context of specific

Education strategy: Pop quiz. Ensure that students do their homework with the threat of a unannounced quiz

Representation: The planner has the goal that an agent achieve a set of *Knowledge goals* and has a *Plan* with a *Plan duration* that includes the *Agency* of the agent to execute *Subplans* that are not *Observed executions* by the planner. The planner *Envisions a threat* to the plan in that the agent do not execute the *Subplan* with cause that it is not a *Subplan* of a goal of the agent, and the planner *Envisions the possibility* that the *Successful execution of the plan* would not achieve the goal. The planner *Modifies the plan* by *Scheduling* a set of *Subplans* at *Start times* that are *Randomly selected* from *Moments* in the *Duration*. In each subplan the planner *Requests the execution* of a plan by the agent such that the *Successful execution* of the plan *Requires* that the agent *Executed the subplan* in the goal that were *Subplans previously scheduled*, and where a *Failed execution* will cause a *Violation of a goal* of the agent. The planner adds a *Planning constraint* against plans that cause the agent to have *Knowledge* of the *Scheduled start time* of these subplans.

Animal behavior strategy: Mark your territory. Leave scent marking to avoid unneccessary defensive conflicts

Representation: The planner has a *Competitive relationship* with a set of agents, and has a *Competitive plan* that includes the *Monitoring of execution* of plans of the other agents for *Locations of execution* that are *Locations* in a *Region*, and *In this case* the execution of an *Attack* on the agent. A *Threat* exists that the execution of the *Attack* will be a *Failed execution* with a cause of a *Successfully executed counterplan*. The planner envisions that *If it were the case* that agents in the set had *Knowledge* of the *Competitive plan* of the planner, then a subset of the agents would add the *Planning preference* against plans that had a *Location of execution* in the *Region*. The planner executes a *Repetitive plan* to *Encode information* that is the *Competitive plan* of the planner and *Transfer locations* of the *Encoding of information* to a *Location* that is in the *Region*, where the *Location* is *Selected from the set* with a *Selection criteria* of *Random choice*.

Counting strategy: Transfer between spaces. Count objects as they are moved into an empty location

Representation: The planner has the *Knowledge goal* of the *Quantity* of *Physical objects* in a set. There exists a set of two *Disjoint regions*, where every object has a *Location* that is *Contained within a region* that is a member of the set. The planner has a *Subplan* to *Transfer the location* of a specific object that is *Contained within a region* of the set to a different *Location* that is *Contained within the other region*. The planner executes a plan to achieve the goal that all of the objects in the set have a *Location* that is *Contained within the region* that is the *Start location* in the *Transfer of location* subplan. The planner then *Repetitively executes* a subplan where the planner executes the *Transfer of location* subplan and *Imagines a number*. In the *First repetition*, the number is 1, and in *Subsequent repetitions* the number is the addition of 1 to the *Imagined number* in the *Previous iteration*. The *Termination of repetition condition* is that the planner has an *Execution failure* of the subplan with a cause of *Unfound object in start location*. The planner then *Achieves* the *Knowledge goal* that is the *Imagined number* in the *Last repetition*.

Figure 1. Three preformal representations of strategies from different planning domains

representations. In all, 8,844 italicized words and phrases were extracted from the representations, which was reduced to a set of 974 terms by removing duplicate instances, selecting a representative lexical form for sets of instances that differed only in their inflection, and combining the forms that we determined to be synonymous, i.e. referring to the same planning concept.

The driving motivation behind this large-scale representation work was twofold. First, we aimed to identify the broad representational requirements of strategic planning and outline the mental models that people have of intentional agents. The findings in reference to this first motivation are reported in a separate publication (Gordon, 2001). Our second motivation, which is the subject of this current report, was to further our understanding of the peculiar role that strategies play in the way that people reason about analogous planning cases.

During and after the completion of this large-scale representation work, we made several observations that contribute to our theoretical understanding of strategies. In particular, two points are presented here that are specifically targeted at the cognitive science research area of analogical reasoning. First, we argue that strategies are themselves portions of the relational structure that serves as the basis for analogical reasoning about planning cases. Second, mental representations of strategies include references to the reasoning processes of intentional agents, providing us with a means of describing the models that people have of their own reasoning processes and those of others. Both of these arguments are developed in the following two sections.

Strategies are Relational Structures Shared by Analogous Planning Cases

In June of 1941, Germany invaded Ukraine with three million troops, threatening to advance eastward into Russia. Soon after, Soviet leader Joseph Stalin announced a scorched-earth policy for Ukraine, ordering that retreating Ukrainians destroy everything that could be of value to the advancing German army, including grains, fuel, and engines that could not be transported east to Russia. In an analogous case, Iraq invaded their oil-rich neighbor Kuwait in August of 1990, leading to the Persian Gulf war. The following January, the United States launches an attack against Iraq, and Saddam Hussein responded by blowing up Kuwaiti oil wells and dumping millions of gallons of oil into the Persian Gulf.

Analogies of exactly this sort have been the subject of a number of experimental studies of analogical reasoning (especially Spellman & Holyoak, 1992), and competing theories have been proposed as cognitive models for this sort of mental processing. The two theories that have received the most attention are Structure-mapping theory (Gentner, 1983, 1989) and Multiconstraint theory (Holyoak & Thagard, 1989, 1995). Although they have their differences, the two theories agree that analogical reasoning is based on structural similarity, the similarity of the systems of relationships that exist between the represented entities in two different cases. Both agree on the constraint of *one-to-one correspondence* between represented entities in analogous cases, e.g. Kuwait could potentially correspond to Germany, Ukraine, or Russia, but not more than one of these in any given analogical mapping. Both also agree on the constraint of the *systematicity*, requiring that sets of relationship correspondences have consistent argument correspondences, e.g. because Iraq is an argument in both the relationships of invading and destroying, both of these relationships cannot be a part of the same system of analogical mappings to the WWII case, where Germany did the invading and the Ukraine did the destroying.

Given the constraints of one-to-one correspondence and systematicity, these theories predict that the strength of any given analogy is strongly dependent on the way that the cases are represented. If we assume representations that are too sparse, we risk predicting that the analogy between a Persian Gulf war case and a WWII case would be a relatively weak one. If Germany is mapped to Iraq, then we have correspondence between the relationship of invading (Germany/Ukraine and Iraq/Kuwait) and the relationship of contained-within (Ukraine/Grains and Kuwait/oil wells). If the Soviet Union is instead mapped to Iraq, then we have a correspondence between the relationship of destroying (Soviet Union/grains and Iraq/oil wells) and that of possession or ownership (Soviet Union/Grains and Iraq/oil wells).

However, this analogy is intuitively very strong and unambiguous. The obvious mapping is that Iraq is like the Soviet Union, as their decision to destroy the Kuwaiti oil wells was analogous to when Stalin ordered the destruction of resources in the Ukraine. These cases are two examples of the *exact same strategy* - instances of an abstract pattern of planning behavior that is so prevalent in our culture that we've given it a name, *scorched earth policy,* so that we could refer to it again and again in analogous cases, whether they appear in warfare or in completely different domains such as politics or business. To account for the comparative strength over this interpretation of the analogy over others, we must assume that the representations of these cases are much richer.

When we consider the abstract similarities that are found in the planning that is done in these two cases, the structural alignment becomes clear. The agent that is doing the planning in these cases (Stalin/Hussein) has some adversarial relationship with some other agent (Hitler/Bush). This planning agent imagines a likely future where the adversary acquires possession of some resources (grain/oil) that are currently possessed by the planner. They imagine that the adversary will make use of these resources to further the pursuit of their adversarial plan (march on to Russia/control the middle east). They decide that the best plan is to do something (destroy grain/blow up oil wells) that will cause these resources to be destroyed, or to make it impossible that the adversary could make use of them, and to do so before the adversary gains possession.

While the rich relational alignment between these two military examples is described using natural language in the preceding paragraph, a corresponding mental representation language would necessarily include structures to refer to the adversarial relationship, the imagination of a likely future, the acquisition of resources, the expenditure of resources in an adversarial plan, the goal of disabling a resource, and the execution deadline. It is this collection of relationships that constitutes the representation of the strategy, and which also makes a significant contribution to judgments of analogical similarity to *every other case* that describes an instance of this sort of strategic behavior.

To clarify, we would like to point out that not all of the relational structure shared between analogous planning cases can be thought of as part of a strategy. Certainly there are analogous planning cases that are so not because of any similarity in the strategies of the participating agents. For example, a case where a person marries someone just before the other person

wins the lottery may be analogous to a corporation that acquires another business just before it has an unexpected licensing windfall, but the commonalties in these cases have more to do with unforeseen benefits than strategic thinking. In contrast, if it turns out that the person and the parent corporation both had selected their candidate acquisitions based on a perception of how lucky the candidates were, we would say that they shared the same strategy - in reference to the portion of the shared relational structure that concerned the planning processes of these agents.

The research opportunity that is evident here concerns the apparent ease that people have in making casual references to large portions of shared relational structure, removing these portions from their context to be considered independently, and assigning to them names like *scorched earth policy* when they are particularly interesting for one reason or another. This ease with strategies enables researchers to collect whole catalogs of naturally occurring analogical mappings, and to argue about how they could be represented on a much larger scale than was possible in previous knowledge representation debates.

Strategy Representations Include the Reasoning Processes of Agents

The formal case representations that have appeared in computer models of analogical reason consist almost entirely of propositions about the external world (Falkenhainer *et al*., 1989; Forbus *et al*., 1994; Holyoak & Thagard, 1989; Holyoak *et al*., 1994). The most compelling examples that support their corresponding theories of analogical reasoning are often in the domain of physical systems, where existing representational theories support the way that these example cases were represented, notably Qualitative Process Theory (Forbus, 1984). Likewise, the case representations in the computer models of analogical reasoning that seem the most contrived are those that are more story-like in nature, involving the intentional behavior of intelligent agents.

A somewhat notorious example of this problem can be seen in the "Karla the hawk" stories that were used in support of the Structure-Mapping Engine (Falkenhainer *et al*., 1989). The main story concerned the actions of Karla, an old hawk, and her encounter with a hunter who had attempted to shoot Karla with an arrow, but had missed because the hunter's crude arrow lacked the feathers needed to fly straight. Karla knew that the hunter wanted her feathers so she offered some of hers to him, and he gratefully pledged never to shoot at a hawk again. In the dozen propositions that were authored to represent this story, emphasis was placed on describing the actions that where done (e.g. seeing, attacking, offering, obtaining, promising) with only a single, highly ambiguous predicate of *realizing* to refer to the reasoning processes that Karla undertook.

What is lacking from these representations is the richness of planning and reasoning that is ascribed to these characters when we read stories like this - the conceptual glue that allows us to make sense of the story in the first place. Much of this knowledge can be packaged into the form of a single strategy, the one that we guess that Karla had in mind when she offered the feathers. Figure 2 offers a preformal representation of this strategy, where the capitalized and italicized words and phrases come from the set used in our large-scale strategy representation project. Of course, it is possible to imagine that Karla wasn't thinking strategically at all - often characters in this genre of fable-like stories seem to stumble across some course of action by mere chance, without thinking things through. However, it is difficult to imagine that a reader could be as ignorant. Indeed, it is the planning lessons that can be learned from stories of this genre that make them compelling and valuable.

What should be noticed in Figure 2 is that the strategy

Karla's Strategy: Turn enemies into friends by improving their capabilities
The planner has an *Adversarial Relationship* with another agent that has had an *Execution failure* of an *Adversarial plan*, with a *Cause of failure* of *Instrument failure*. The planner *Envisions* that this agent will *Attempt the execution* of this *Adversarial plan* in *Future states* against the planner and *Envisions a possibility* that this plan will be *Successfully executed.* The planner has a *Partial plan* to *Reduce the probability* of *Instrument failure* in *Future executions* of the *Adversarial plan* by this other agent that includes *Modifying the instrument* and includes the *Instrumental use* of *Resources* of the planner. The planner executes a plan to *Make an offer* to the agent where the *Offered action* is that the planner *Transfers possession* of *Resources* that *Enable* the agent to execute the *Partial plan*. The planner then *Adds the expectation* that *If it is the case* that the agent *Accepts the offer*, that the agent will *Terminate their role* in the *Adversarial relationship*, which will cause them to *Abandon plans* that are *Adversarial plans* against the planner. The planner then *Adds a threat* that the *Expectation* is a *False expectation*, and that the agent will execute the *Partial plan* followed by the execution of the *Adversarial plan*.

Figure 2. The strategy of Karla the hawk as a preformal representation

contains a significant amount of references to mental states of both the planner and the adversary. There is the imagining of future states, of a partial plan not entirely worked out, an expectation of the consequences of an action, and an explicit threat of what might happen if this expectation is wrong. Each of these mental states is critical to the understanding of the story, and we argue that they should be included in the representation of this case to explain analogies to cases where only the strategy is shared.

Just as analogies in physical systems are based on mental models of processes in physical domains, analogies in intentional domains include assertions that only make sense with respect to a mental model of agents and intentional behavior. In arguing for the inclusion of these sorts of assertions in case representations in intentional domains, we are also making the argument that people have a rich model of agents and their reasoning processes.

A great deal of attention has been directed toward developing models of agents and intentional behavior among decision theorists and artificial intelligence logicians, often centered around the notion of Belief, Desire and Intention (BDI) agents. Formalizations of these models (e.g. Cohen and Levesque, 1990) typically strive to maximize the number of simplifying assumptions in order to retain the ability to prove related theorems, but to do so without sacrificing the expressiveness required to compute useful functions. The engineering value of this approach is demonstrated when theories lead to practical applications (see Rao & Georgeff, 1995), but we caution against this approach for the purpose of cognitive modeling. Certainly there are times where the mental representations that people have may appear to exhibit the qualities of elegance and simplicity, but our aim should be to describe the mental models of people as they are - without simplifying assumptions - if we are to understand and predict how they are manipulated by cognitive processes.

In our own investigation of mental representation through the lens of strategies, we have found that the models that people have of other agents and their reasoning processes is enormously complex in comparison to previous formalizations. From the most generalized perspective, the model appears to be comprised of many of the components that are commonly proposed. These components include representations of the current state, agents and their goals, the plans that are held by these agents, the envisionments that these agents construct of past and future states, of the plan construction process, the making of decisions, the scheduling of behaviors, the monitoring of events, and the process of executing an intended plan in the world. Given a closer look, we find that each of these model components is extremely complex. For example, the representations that people have of the process of executing an intended plan are rich enough to refer to the sensations that agents experience during an execution, and to remark on whether it had a natural quality to it or not - as in reference to a concert pianist that finds a particular passage in a piece cumbersome due to an awkward fingering that they selected. Indeed, a strategy that concert pianists employ is to reduce the risk of performance blunders by explicitly identify the sections of a musical piece that give rise to these sensations of awkwardness, and to rework their plan of execution for these sections so that they have a more natural quality.

Conclusions: Analogy as a Tool

"The association of solved problems with those unsolved may throw new light on our difficulties by suggesting new ideas. It is easy to find a superficial analogy which really expresses nothing. But to discover some essential common features, hidden beneath a surface of external differences, to form, on this basis, a new successful theory, is important creative work." (Einstein & Infeld, 1938)

Einstein and Infeld presented this idea to justify making an analogy between a violin string and the wavelike properties of elementary particles. The essential common features that Einstein and Infeld discovered were the concepts of a *standing wave* and a *moving wave*, and the new successful theory that they were forming was that of probability waves in quantum physics.

Einstein and Infeld's quote reveals something about the way that they approached scientific problem solving, but from a cognitive science perspective, we might also view it as a proposed methodology for forming theories of people's mental models. That is, by analyzing analogous cases, discovering the essential common features that are hidden beneath a surface of external differences, we can form theories of the mental models that people have that cause these cases to be analogous.

In this paper we have argued that planning strategies are particularly appropriate as the subject of analysis using the tools of analogy. Strategic analogies reveal features of our mental models of human planning, and in doing so, challenge our cognitive theories and models of intelligent planning and problem solving behavior. It is this hope that led us to author three hundred and seventy two representations of strategies in ten different planning domains, where each representation attempted to define the features of the planning situation that were common among all analogous instances of the strategy.

Einstein and Infeld made reference to two important activities in the quoted text. The first, to discover

essential common features of analogous cases, has been accomplished on a large scale for instances of strategies. Achieving the second, to form a new successful theory, will require a substantial amount of additional work. This paper has argued for the inclusion of two claims in the future successful theories that are developed. First, we argued that strategies are themselves portions of the relational structure that is the basis of similarity between analogous planning cases. Second, the representations of these strategies include propositions about the reasoning processes of the agents employing them, giving researchers a investigative lens to examine the rich mental models that people have of others and of themselves.

Abstract

It has long been observed that we sometime perceive complex scenes in blots, rocks, or clouds, but the phenomenon has attracted little scientific attention. We propose that a weak–or superstitious–match between a memory template and a sparse stimulus is responsible for such perceptions. We provide reverse-correlation evidence for this theory.

Introduction

> If you look at walls that are stained or made of different kinds of stones […] you can think you see in them certain picturesque views of mountains, rivers, rocks, trees, plains, broad valleys, and hills of different shapes […] battles and rapidly moving figures, strange faces and costumes, as well as an infinite number of things […]
>
> (Leonardo da Vinci, *Notebooks*)

We have all seen a human face or a landscape in a cloud floating by, in a pebble lying on a beach, or in blots on a wall. Notorious examples of this phenomenon include the Mars channels and the Man on the Moon; Hermann Rorschach has even made it the basis of a projective test. The earliest known reference to the phenomenon reaches back as far as classical antiquity, and thousands of others have been enumerated (Janson, 1973; Gombrich, 1960). Given this human fascination for the phenomenon, it is surprising how little–if any–scientific attention it has received. Here, we provide evidence that these perceptions result from a weak–or superstitious–match between a memory template and a sparse stimulus. Beyond the anecdotes, a rigorous study of superstitious perceptions could reveal important properties of internal object representations. It is one aim of our research to illustrate this point.

We instructed naïve observers to decide whether one particular target (the letter 'S' in Experiment 1 and a smiling face in Experiment 2) was present or not in stimuli. No signal was ever presented in the stimuli. Each stimulus comprised only two-dimensional static bit "white" noise. White noise has several desirable properties: It has equal energy across the entire spatial frequency spectrum and does not correlate across trials. In other words, white noise does not in itself represent coherent structures in the image plane and across trials.

These properties make white noise the perfect basis for reverse correlation (see Appendix), a statistical technique that uses noise to derive the information the observer *uses to respond* in a particular visual task (e.g., Ahumada & Lovell, 1971; Beard & Ahumada, 1998; Neri, Parker & Blakemore, 1999; Gold, Murray, Bennett & Sekuler, 2000). In Experiment 1, we used reverse correlation (supplemented with careful debriefing) to assess the properties of the letter 'S' that the observers superstitiously perceived (remember that they only saw white noise). Experiment 2 replicated the findings in the more realistic case of faces.

Experiment 1: 'S' as in Superstitious

In this experiment, we asked a first subject to detect in white noise the presence of a black 'S' on a white background filling the image. As just explained, only bit noise was presented.

Method

Subject

One 24-year old female student from the University of Glasgow with normal vision was paid £50 to participate in this study. She was an experienced psychophysical observer, but had no knowledge about the goals of the experiment.

Procedure

The experiment ran on a Power PC Macintosh using a program written with the Psychophysics Toolbox for Matlab (Brainard, 1997; Pelli, 1997). It comprised 20,000 trials equally divided into 40 blocks. The subject took two weeks to complete the experiment. A trial consisted in the presentation of one 50 x 50 pixels (2 x 2 deg of visual angle) static bit noise image with a black-pixel density of 50%. No signal was ever presented. The subject was told, however, that she was participating in a detection experiment. She was instructed to say whether or not a black letter 'S' on a white background filling the image was present. No more detail was provided about the 'S'. We told her that 50% of the trials were positive. The subject was under no time pressure to respond.

When the 20,000 trials were completed, we debriefed the subject. We asked her the following questions: How often did she see the letter? When she

saw it, how noisy was it? What strategy did she use to respond?

Results and discussion

On 22.7% of the trials the subject pressed on the 'yes' key, indicating that an 'S' was present. During debriefing, she said that she saw an 'S' each time she responded positively, and she estimated the quantity of noise in the letter 'S' to vary between 30% and 50%. She summarized her strategy as follows: "I simply waited to see if the S "jumped out at me"."

All the static bit noise images leading to a 'yes' response were added together and so were those leading to a 'no' response. The two resulting images, the 'yes' and the 'no' images, were normalized. A raw classification image was then computed by subtracting the normalized 'no' image from the normalized 'yes' image. This classification image is the linear template that best explains the behavior of the subject in the least square sense of the term (see Appendix).

There is an objective method to understand the information that drove the illusory perceptions of the 'S' in the experiment. As explained earlier, white noise is completely unbiased. If the observer responded randomly (i.e., without having the illusion of the presence of an 'S'), the classification image would itself be unbiased. From this reasoning, any bias appearing in the spectral analysis of the observer's classification image should indicate the structures underlying the illusory perceptions. The spectral analysis reveal a bias for information concentrated between 1 and 3 cycles per image, with a peak at 2 cycles per image (see arrow in Figure 1a). This is consistent with Solomon and Pelli's (1994) finding that letter identification is most efficient around 3 cycles per letter.

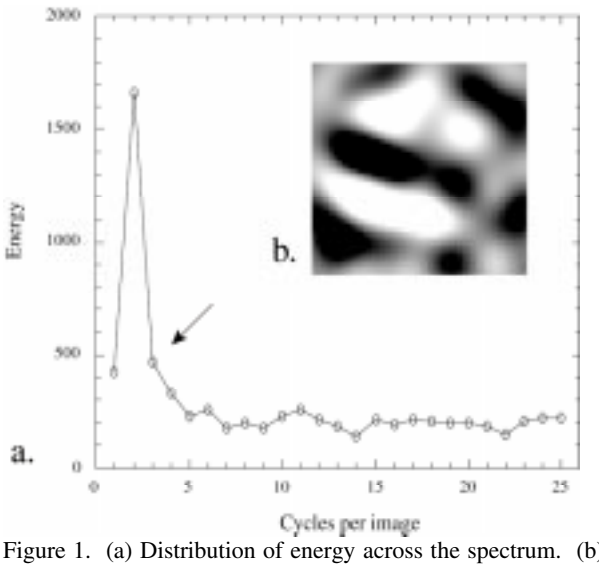

Figure 1. (a) Distribution of energy across the spectrum. (b) Classification image low-passed at 3 cycles per image.

We can visualize the information that drove the illusory detection by filtering the raw classification image with a low-pass Butterworth filter with a cutoff at 3 cycles per image. To provide a better depiction, we further remove all the outlier pixel intensities (two standard deviations away from the mean). The resulting image is a black 'S' on a white background.

To summarize, we have induced illusory perceptions of an 'S' by asking one subject to detect this letter in noise. Unknown to her, the stimuli did not comprise the letter, but only white noise. If the subject had been performing only according to the stimulus (i.e., in a bottom-up manner), her classification image should have had the same properties as noise—i.e., having identical energy across all spatial frequencies. However, there was a marked peak of energy between 1 and 3 cycles per degree that could only arise from top-down influences on the interpretation of white noise. Further analyses revealed the precise shape of the letter that the subject thought she saw. Specifically, it is worth pointing out that the best depiction of the information used

Experiment 2: Simile smile

In Experiment 2, we generalized the technique to a more complicated stimulus, using another subject. The task was to discriminate between a smiling and non-smiling face. However, the face presented in noise had no mouth whatsoever.

Method

Subject

One 26-year old female student at the University of Glasgow with normal vision was paid £50 to take part in this study. She was naïve with respect to the goals of the experiment, but was an experienced psychophysics observer.

Procedure

The experiment ran on a Macintosh G4 using a program written with the Psychophysics Toolbox for Matlab (Brainard, 1997; Pelli, 1997). It consisted in 20,000 trials equally divided in 40 blocks. The subject took three weeks to complete the experiment. In each trial, one sparse image spanning 256 x 256 pixels (5.72 x 5.72 deg of visual angle) was presented. This image comprised 27.5% of the black pixels of the contours of a mouthless face (see the white marker in Figure 2b) randomly sampled and, for the remainder, of bit noise with the same density of black pixels. No signal was therefore presented in the mouth area.

The subject was instructed to decide whether the face was smiling or not–no detail was provided regarding the alternative expressions. This ensured that the subject focused on seeking information for "smile". We also told her that the face would be smiling in 50%

of the trials. The subject was under no time pressure to respond. Following the 20,000 trials, we debriefed the subject as in Experiment 1.

Results and discussion

On 7.07% of the trials the subject pressed on the 'yes' key, indicating that the "noisy" face was smiling. During debriefing, she explained that she had been very conservative and that she had only responded 'yes' when she was absolutely certain that the face was indeed smiling. The subject looked for teeth and used the eyes and the nose to localize the mouth.

All the static bit noise images leading to a 'yes' response were added to form a 'yes' image, and all those leading to a 'no' were added to form a 'no' image. A raw classification image was then computed by subtracting the normalized 'no' image from the normalized 'yes' image.

The distribution of energy in the spectrum for the raw classification image is represented in Figure 2a. The energy is concentrated in the bandwidth ranging from 1 to 20 cycles per image (from 0.35 to 12.29 cycles per face–see arrow in Figure 2a). This roughly corresponds to the most efficient bandwidth found by Bayer, Schwartz and Pelli (1998) in an expression identification task (i.e., maximum efficiency centered at 8 cycles per face).

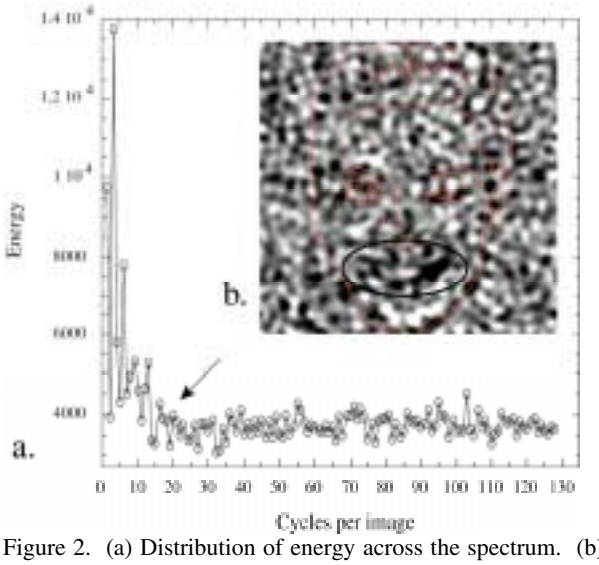

Figure 2. (a) Distribution of energy across the spectrum. (b) Classification image low-passed at 20 cycles per image.

Figure 2b is the raw classification image low-passed at 20 cycles per image with a Butterworth filter–with outlier pixel values removed, followed by a normalization. A white mouthless face marker has been superimposed on filtered classification image. A smile revealing teeth is clearly visible (see circled area in Figure 2b).

Conclusion

The evidence we have gathered in two experiments corroborates the idea that superstitious perceptions result from a weak match between a memory template and a sparse stimulus. We have shown that we could induce superstitious perceptions of a letter ('S', Experiment 1) and part of a face (a mouth expressing a smile, Experiment 2) in bit noise. Reverse correlation demonstrated that observers in these experiments used information from memory ressembling an 'S' and a smile, respectively. It is important to stress that this information did not originate from the signal, by from their memory. It is only because these memory representations are partially correlated with white noise that the superstitious perceptions occur. But then, because white noise is weakly correlated with every visual stimulus, this technique could in principle extend to depicting a wide range of visual representations. In our experiments, these representations had properties expected from what is know in the recognition literature. So, the superstitious perceptions were not random hallucinations, but instead well-constrained perceptions derived from specific knowledge.

Superstitious perceptions could therefore be used to explore the properties of representations in the absence of any bottom-up information.

Appendix

We suppose that the observer matches two vectors at each trial of the experiment: a stimulus vector of dimensionality k and a template vector $\mathbf{ß}$ of the same dimensionality representing the memorized pattern to match against the input (e.g., the letter 'S' or a smiling face).

Suppose further that we arrange the n stimuli of the experiment in the $n * k$ matrix $\mathbf{X}$. The behavior of the observer for the whole experiment is described by

$$\mathbf{y} = \mathbf{ß}\mathbf{X}+\varepsilon,$$

where $\mathbf{y}$ is an n-dimensional vector of decision responses, and ε is an n-dimensional vector of "error" random variables with $E(\varepsilon) = \mathbf{0}$ and $V(\varepsilon) = \sigma^2\mathbf{I}$.

For simplicity, the "target present" and "target absent" responses in $\mathbf{y}$ as well as the white and black pixels in $\mathbf{X}$ are encoded with values of 1 and –1, respectively.

Given that we know $\mathbf{X}$ and can observe $\mathbf{y}$, we can resolve the linear system of equations by finding $\mathbf{ß}$. The *least square* solution requires that we minimize the scalar sum of squares

$$\mathbf{S} = (\mathbf{y}-\mathbf{X}\mathbf{ß})'(\mathbf{y}-\mathbf{X}\mathbf{ß})$$

for variations in $\mathbf{ß}$. Differentiating, we have

$$2\mathbf{X}'(\mathbf{y}-\mathbf{X}\mathbf{ß}) = \mathbf{0},$$

which gives, for our least square estimator, the vector

$$\mathbf{ß} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}.$$

This is the logic of standard multiple regression (e.g., Sprent, 1969). Because our stimulus vectors are uncorrelated, we have

$$(\mathbf{X}'\mathbf{X})^{-1} = (k\mathbf{I})^{-1} = k^{-1}\mathbf{I},$$

Therefore,

$$\mathbf{ß} = k^{-1}\mathbf{X}'\mathbf{y}.$$

Leaving the constant k aside, this equation reduces to summing all stimuli that led to a 'yes' response and subtracting from it the sum of all the stimuli that led to a 'no' responses. This is the essence of reverse correlation.

Words and Shape Similarity Guide 13-month-olds' Inferences about Nonobvious Object Properties

Abstract

We examined the influence of shape similarity and object labels on 13-month-old infants' inductive inferences. In two experiments, infants were presented with novel target objects with or without a nonobvious property, followed by test objects that varied in shape similarity to the target. When objects were not labeled, infants generalized the nonobvious property to test objects that were highly similar in shape (Expt. 1). When objects were labeled with novel nouns, infants generalized the nonobvious property to both high shape similarity and low shape similarity test objects (Expt. 2). These findings indicate that infants as young as 13 months of age expect those objects which share the same shape or the same label to possess the same nonobvious property.

Introduction

Inductive reasoning involves invoking the premise that things that are true for one member of a category (e.g., the blue ball bounces) will hold true for other members of the same category (e.g., therefore all balls bounce; Moore & Parker, 1989). The ability to reason inductively is an invaluable cognitive skill, allowing an individual to generalize knowledge to new instances and new situations. In recent years, a great deal of empirical attention has been devoted to examining preschoolers' inductive reasoning abilities, with particular focus on the nature of the categories that guide their inferences. In a typical inductive generalization task, preschoolers are taught a fact about a target object and then are asked whether that fact can be generalized to other test objects. Using this methodology, studies have demonstrated that by 2-1/2-years of age, children can reason inductively about object properties in remarkably sophisticated ways (e.g., Gelman, 1988; Gelman & Markman, 1986, 1987; Kalish & Gelman, 1992). For example, Gelman and Coley (1990) found that 2-1/2-year-olds will overlook perceptual similarity and generalize properties on the basis of shared underlying kind when the target and test objects are given the same count noun label.

In recent years, researchers have begun to examine the development of inductive capabilities during the infancy period using the generalized imitation paradigm. In a typical task, an experimenter will first model a specific action on a target object. He or she will then hand infants test objects and observe whether or not they imitate the target action on the various objects. Studies using this paradigm indicate that infants as young as 9 months of age will draw inferences about nonobvious object properties based on knowledge gained during the experimental session (Baldwin, Markman, & Melartin, 1993). Furthermore, research suggests that both perceptual similarity and conceptual knowledge may play a role in guiding infants' inferences (Baldwin et al., 1993; Mandler & McDonough, 1996, 1998). In a recent series of studies (Welder & Graham, in press), we found that 18-month-old infants will rely on shared shape similarity to guide their inductive inferences about novel objects' nonobvious sound properties when no other information about category membership is available. More importantly, however, when infants were provided with information about conceptual category membership in the form of shared object labels, shape similarity was either attenuated in significance (in the case of novel labels) or disregarded (in the case of familiar labels). These findings indicate that 18-month-old infants can make inductive inferences about object properties based on a conceptual notion of object kind. Furthermore, these findings suggest that infants as young as 18 months of age recognize the conceptual information conveyed by object labels. That is, they recognize that noun labels supply information about underlying object kind and that members of the same kind share nonobvious properties.

In the present studies, we pursued the investigation of infants' inductive abilities, with specific focus on the reasoning abilities of infants who are just beginning to acquire productive language. First, we examined whether 13-month-olds, like 18-month-olds, will rely on shared shape similarity to generalize nonobvious object properties, in the absence of other information about

object kind (Experiment1). Second, we examined whether 13-month-olds will rely on shared object labels to direct their inductive inferences (Experiment 2). In particular, we examined whether infants will extend a nonobvious property on the basis of a shared object label, even if the objects differ in shape.

In both experiments, we employed a generalized imitation paradigm to examine infants' inductive abilities (see also Baldwin et al., 1993; Mandler & McDonough, 1996, 1998). We presented infants with novel target objects that possessed nonobvious properties (e.g., a cloth-covered object that squeaked when squeezed). The experimenter demonstrated the nonobvious property using a specific target action and then presented infants with test objects which varied in their degree of perceptual similarity to the target. We reasoned that if infants considered test objects to be members of the same category as the target, they would expect the test objects to share the same nonobvious property as the target. That is, infants' imitation of a target action on test objects would provide evidence of inductive reasoning.

Experiment 1

The goal of Experiment 1 was to examine the role of shape similarity in guiding infants' generalization of nonobvious object properties when they are presented with novel object categories. Infants were presented with object sets consisting of a target object followed by a high similarity match, a low similarity match, and a dissimilar object in three within-subjects conditions. The high and low similarity matches within each set varied in shape and color but shared similar textures. The dissimilar objects in each set, however, differed from the target object in texture, shape, and color. The dissimilar objects were included to ensure that infants' inductive generalizations were specific to objects that they perceived as belonging to the same category and to ensure that infants were not merely imitating the experimenter's actions on any object, regardless of whether an expectation was generated.

We presented infants with target and test objects in three within-subjects expectation conditions. In the surprised condition, the target object possessed an interesting sound property (e.g., squeaked when squeezed), but the test objects were disabled so that they could not exhibit the property (e.g., could not squeak when squeezed). This condition was of particular interest, as infants' performance would indicate whether they expected test objects to possess the same nonobvious property as the target. In the baseline condition, neither the target nor the test objects possessed the interesting property (e.g., neither produced a squeak sound). This condition provided a baseline measure of infants' exploratory actions. A comparison of infants' performance in the baseline condition to the surprised condition would indicate whether the target property of the target object was, in fact, nonobvious upon visual inspection. In the predicted condition, both the target and test object possessed the property (e.g., both could squeak). This condition was included to preclude the development of the expectation that all test objects were disabled (as all test objects in both the surprised and baseline conditions were), leading infants to become bored or frustrated with the stimuli.

We expected that infants would use shape similarity to guide their generalizations of the nonobvious property as object shape is easily perceived and is often an excellent index of object kind (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). More specifically, we predicted that the greater the degree of shape similarity between a test object and a target object, the higher the frequency of target actions performed on that test object.

Method

Participants Participants were 20 infants ranging in age from 12.07 months to 13.92 months (M = 12.73; SD = .53). Ten infants were male and 10 were female.

Stimuli Four objects were used for the warm-up trials: a garlic press, a roller ball, a clicking clock, and a clothesline pulley. Three object sets (a "squeaking" set, a "ringing" set, and a "rattling" set) were created for use in the imitation task. There were four objects in each set: a target object, and three test objects (a high similarity object, a low similarity object, and a dissimilar object). The high similarity test objects possessed the same shape and texture as the target object but differed in color. The low similarity objects shared the same texture as the target object but differed in shape and color. The dissimilar object shared no properties in common with the target object. The dissimilar objects included a plastic orange file (squeaking set), a small white strainer (ringing set), and a plastic green hose splitter (rattling set). There were two versions of each target and test object in each set: a functional version that could produce the target sound and a nonfunctional version that was disabled and thus unable to produce the target sound. In the functional squeaking object set, objects could produce a squeaking noise when squeezed. In the functional ringing set, objects could produce a ringing noise when tapped. In the functional rattling set, objects could produce a rattling noise when shaken.

To establish whether test objects could reliably be categorized as high or low in shape similarity relative to the target object, 15 adults rated the similarity of each test object to its target. The adult ratings followed the expected pattern. That is, the high and low similarity test objects in each object set were perceived as significantly different in shape from one another (all t-tests: $p < .05$), in the direction intended.

Design For each infant, one of the three object sets was presented in the surprised condition, one set was presented in the baseline condition, and one set was presented in the predicted condition. The specific object set assigned to the surprised, baseline, and predicted conditions was counterbalanced across infants.

The imitation task was comprised of three blocks of three trials each: one trial in the surprised condition, one trial in the predicted condition, and one trial in the baseline condition. Each object set was presented once within each block. That is, one of the test objects (e.g., a high similarity object) from a given set was presented in the first block, another (e.g., a low similarity object) was presented in the second block, and a third (e.g., a dissimilar object) was presented in the third block. The order of presentation of test objects was randomized within each block and order of presentation of expectation condition within each trial block was counterbalanced across infants.

Procedure Infants were seated in their parent's lap at a table in a testing room with the experimenter seated across from them. Before testing began, the experimenter instructed parents to interact with their infant as little as possible and not to direct their infant's attention to the objects. Parents were also instructed to silently place objects back on the table within the infant's reach if objects were dropped on the floor near the parent or if the infant handed objects to the parent. All sessions were videotaped for coding purposes.

During the warm-up phase, the experimenter demonstrated a target property of each of the warm-up objects to the infant and asked the parent to do the same. After demonstrating the target property, parents silently handed the object to their child for him/her to imitate the actions observed.

During the test phase, the experimenter began each trial by presenting infants with one of the target objects from a given object set. She introduced the object (e.g., "Look at this one!") and demonstrated the nonobvious property of the target object five times (e.g., shaking the rattle). Only the properties of target objects in the surprised and predicted conditions were demonstrated (as the target objects in the baseline condition did not possess the property). The experimenter handed the object to the infant's parent who demonstrated the property of the target object twice. The parent then passed the object to the infant. After a period of 10 seconds, the experimenter retrieved the object and placed it within the infant's view, but out of reach. The experimenter then presented the infant with a test object and infants were allowed to explore the test object for 20 seconds. This same procedure was repeated for each of the other 8 trials. The target object from each object set was reintroduced to infants on each trial; however, parents only demonstrated the property the first time a target object was introduced. The experimenter continued to demonstrate the target object's property on each trial. If an object was dropped off the table or passed/thrown out of the infants' reach during the session, the experimenter quickly placed the object back within their reach. Time lost due to these actions was not compensated for, as they were considered to be intentional actions of frustration or disinterest (see Oakes, Madole, & Cohen, 1991).

Coding Coders, blind to the hypotheses of the experiment, recorded the frequency of actions performed by the infants on the target and test objects. Only the experimenter's back was visible on the videotapes and all sessions were coded with no volume. Thus, the coders could not detect whether the experimenter had demonstrated a target action on an object and could not hear whether objects actually made sounds when actions were performed by either the experimenter or the infants. Thus, we were confident that the coders could not distinguish the surprised, baseline, and predicted conditions from one another.

A detailed coding scheme for each target action was developed for each object set. The target action for the squeaking set was defined by a squeezing motion, that is, the infant gripped and then compressed his/her fingers together on the object (not tapping the object, hitting the object on the table, shaking the object, or gripping it to look at it or passing/throwing it to the experimenter or parent). The target action for the ringing set was defined by a tapping, hitting, or patting motion (not squeezing the object, hitting it on the table, shaking it, or gripping it to look at it or pass/throw it to the experimenter or parent). Finally, the target action for the rattling set was defined by a shaking motion with the wrist and/or whole arm in a back/forth or up/down motion (not tapping the object, squeezing it, hitting the table or a body part with it, or gripping it to look at it or pass/throw it to the experimenter or parent). If the infant performed a fluid shaking movement, then only one target action was counted.

Results

The mean frequency of target actions performed on the different test objects in the surprised and baseline conditions are presented in Table 1[1]. We first examined whether the target properties of the object stimuli were indeed nonobvious to infants by comparing the number of target actions infants performed on test objects after having first seen a functional target object (in the surprised condition) versus a nonfunctional target object (in the baseline condition). We used one-tailed dependent t-tests to compare the frequency of target actions in the surprised condition to those in the baseline condition at each level of shape similarity. (Note that we used one-tailed tests as our predictions were directional). As

[1] In all analyses, we chose not to include the data from the predicted condition as it was difficult to interpret why infants continued to perform target actions on test objects in this condition. That is, it was impossible to distinguish those target actions performed as a result of an expectation about an object's nonobvious property from those performed as a result of the reinforcing nature of the sound property of the test objects themselves (see Baldwin et al., 1993 for a discussion of this issue).

Table 1:Frequency of Target Actions Performed on Test Objects at Each Level of Shape Similarity within each Expectation Condition (Expt. 1).

	Shape Similarity to Target		
Condition	High	Low	Dissimilar
Surprised	2.1 (2.9)	0.6 (1.3)	0.2 (0.9)
Baseline	0.4 (0.7)	0.6 (1.2)	0.0 (0.0)

expected, infants performed significantly more target actions on the high similarity objects in the surprised condition than in the baseline condition, t (19) = 2.39, p < .03. In contrast, infants did not differ significantly in their performance of target actions on the low similarity objects or on the dissimilar objects in the surprised condition versus the baseline condition, (t (19) = .00, p > .99; no statistic was computed for the dissimilar object comparison as no target actions were performed in the baseline condition). These analyses indicated that the appearances of the high similarity objects did not suggest that the objects possessed the nonobvious properties. Instead, infants performed target actions on test objects only after they had been exposed to the properties of particular functional target objects during the testing session.

We next examined the influence of shape similarity on infants' generalization of nonobvious properties within the surprised condition only. As predicted, infants performed significantly more target actions on the high similarity objects than on the low similarity objects (t (19) = 2.55, p < .02), or the dissimilar objects (t (19) = 2.55, p < .02). Furthermore, infants did not differ significantly in their performance of target actions on the low similarity objects and dissimilar objects, t (19) = 1.16, p > .25. The results of these analyses indicate that infants expected objects that shared a high degree of shape similarity to share nonobvious properties, consistent with our hypotheses.

Discussion

As expected, infants performed significantly more target actions on the high similarity test objects in the surprised condition than in the baseline condition. This finding indicates that the appearance of the objects did not suggest the nonobvious properties. Furthermore, in the surprised condition, infants generalized the nonobvious properties to the high similarity test objects but not to the low similarity objects (which still shared textural similarity with the target object), nor to the dissimilar test objects (which differed from the target object in texture, shape, and color). Infants' lack of performance of the target actions on the low similarity objects and on the dissimilar objects indicates that they were not simply imitating any action that the experimenter did--they only imitated the target action when they viewed the test object as a member of the same category as the target object.

The results of this experiment thus indicate that 13-month-old infants will form specific expectations about the nonobvious properties of objects from knowledge gained during the testing session. Furthermore, these findings indicate that infants were relying solely on shared shape similarity to index category membership, an issue discussed further in the General Discussion.

Experiment 2

In Experiment 2, we examined whether 13-month-old infants would treat labels for novel objects as a conceptual marker of object kind and expect those objects that shared the same label to possess the same nonobvious property. The design of Experiment 2 was similar to that of Experiment 1 with one exception: The experimenter labeled the target and test objects with novel count nouns when she introduced them. We predicted that infants would generalize the nonobvious property to objects that shared the same label, even if they shared little shape similarity with the target object.

Method

Participants Participants were 20 infants ranging in age from 12.20 months to 13.85 months (M = 13.02; SD = .54). Ten infants were male and 10 were female.

Stimuli Same as Experiment 1.

Design Same as Experiment 1.

Procedure The procedure was similar to that of Experiment 1, with one exception: The experimenter introduced the target and test objects using novel count nouns (e.g., "Look at this blint!"). Note that the same count noun was used to label the target object and the test objects in a given set (i.e., the target and the test object from the rattling set were all labeled as blints).

Coding Identical to Experiment 1.

Results

The mean frequency of target actions performed on the different test objects in the surprised and baseline conditions are presented in Table 2. As in Experiment 1, we first examined whether the target properties of the object stimuli were nonobvious to infants by comparing the number of target actions infants performed on test objects after having first seen a functional target object (the surprised condition) versus a nonfunctional target object (the baseline condition). (Note we again used one-tailed t-tests as our predictions were directional). As expected, infants performed significantly more target actions on the high similarity objects in the surprised condition than in the baseline condition, t (19) = 2.76, p < .005. Similarly, infants performed more target actions on the low similarity objects in the surprised condition than in the baseline condition, t (19) = 1.86, p < .05. In contrast, infants did not differ significantly in their

Table 2:Frequency of Target Actions Performed on Test Objects at Each Level of Shape Similarity within each Expectation Condition (Expt. 2).

	Shape Similarity to Target		
Condition	High	Low	Dissimilar
Surprised	2.7 (3.9)	2.2 (3.1)	0.5 (1.4)
Baseline	0.3 (0.7)	0.7 (2.3)	0.0 (0.0)

performance of target actions on the dissimilar object in the surprised condition versus the baseline condition (no statistic was computed as no target actions were performed on this object in the baseline condition). These analyses indicated that the appearances of the high and low similarity objects did not suggest that the objects possessed the nonobvious properties.

We next examined the influence of labels on infants' generalization of nonobvious properties within the surprised condition only. In contrast to Experiment 1, infants did not perform more target actions on the high similarity objects than on the low similarity objects (t (19) = 0.51, $p > .60$). However, infants performed significantly more target actions on both the high similarity objects and on the low similarity objects than on dissimilar objects, t (19) = 2.31, $p < .03$ and t (19) = 3.31, $p < .01$, respectively. The results of these analyses indicate that infants expected objects that shared the same label to share nonobvious properties, regardless of shape similarity.

Discussion

In this experiment, infants performed as many target actions on the low similarity objects as on the high similarity objects. This finding indicates that infants relied on shared labels, rather than shape similarity, to guide their inferences about nonobvious object properties, an issue discussed further in the General Discussion. It is important to note, however, that the presence of labels, however, did not lead infants to completely disregard perceptual information. That is, labeling the dissimilar object with the same count noun as the target object did not lead infants to generalize nonobvious object properties to that object. Recall that the dissimilar object shared no perceptual properties in common with the target object. Thus, it appears that some minimal perceptual overlap is necessary for infants to generalize the nonobvious properties.

General Discussion

The present studies were designed to examine the role of object shape similarity and object labels in guiding 13-month-old infants' inferences about nonobvious object properties. The results of our studies yielded three major insights into the nature of infants' inductive reasoning. First, the results of both experiments provide evidence that infants between 12 and 13 months of age will form expectations about shared properties of novel objects after only a ten second experience with a functional target object. Furthermore, infants will extend a specific nonobvious property from a target exemplar to other objects perceived as members of the same category, consistent with the results of previous studies (e.g., Baldwin et al., 1993; Mandler & McDonough, 1996, 1998; Welder & Graham, in press). Thus, our finding that infants could rapidly and efficiently form expectations about the nonobvious properties of novel objects provides important evidence that infants possess well-developed inductive reasoning abilities by the end of the first year of life.

Second, our findings indicate that infants will rely on shape similarity to generalize nonobvious object properties, in the absence of other information about object kind. In Experiment 1, infants were more likely to generalize a nonobvious object property to objects that were highly similar in shape than to objects that were less similar in shape. These findings provide clear evidence that infants expect that objects that share a high degree of shape similarity will also share other "deeper" characteristics. Furthermore, this result suggests that infants appreciate that shared shape similarity is predictive of category membership. That is, infants attend to shape information because it serves as a perceptually-available cue to the underlying structure of a category (see Bloom, 2000; Gelman & Diesendruck, 1999 for a discussion).

Finally, our findings demonstrate that when a novel object is labeled with a novel count noun, infants will overlook shape information and rely on the label to generalize the nonobvious property. In Experiment 2, infants performed as many target actions on low similarity objects as on high similarity objects, when objects were labeled with the same count noun. As discussed earlier, labeling the objects did not lead infants to completely disregard perceptual information as they did not generalize the nonobvious object properties to the dissimilar object (which shared no perceptual features with the target object). Thus, when infants are provided with information about category membership in the form of shared object labels, perceptual information is attenuated. This finding provides clear evidence that young infants can form novel categories and make inductive inferences about nonobvious properties based on a conceptual notion of object kind (see also Mandler & McDonough, 1996, 1998; Welder & Graham, in press). Moreover, our findings indicate that infants as young as 13 months of age recognize the conceptual information conveyed by object labels. That is, infants, like preschoolers, appear to recognize that count noun labels supply information about underlying object kind and furthermore, that members of the same kind share nonobvious properties. This finding is particularly compelling given that the infants in our studies are only just beginning to acquire productive language. Finally, these findings add to a growing body of literature

indicating that naming can foster infants' formation of object categories (e.g., Balaban & Waxman, 1997; Graham, Baker, & Poulin-Dubois, 1998; Waxman, 1999; Waxman & Hall, 1993; Waxman & Markow, 1995) and moreover, these findings provide evidence that labels enhance the inductive potential of categories for young infants.

In summary, the results of these experiments have advanced our understanding of infants' inductive abilities, indicating that 13-month-old infants will use shape similarity and count noun label information for making inferences about nonobvious object properties. These results also suggest a number of important directions for future research. For example, it remains to be seen whether infants who have not yet acquired productive vocabulary (i.e., infants younger than 12 months of age) can rely on object labels to guide their inferences about object properties, and whether count noun labels (versus words from other form classes or versus nonlinguistic stimuli) are privileged in guiding infants' inferences. Research into these issues is currently underway in our lab and we expect that the results of these studies, in conjunction with other recent empirical work, will lead to a coherent account of the developmental processes underlying inductive reasoning during infancy.

Abstract

This paper presents a computational model of semantic memory, trained with behaviourally inspired vectors. The results are consistent with the *conceptual structure account* (Tyler, Moss, Durrant-Peatfield & Levy, 2000), which claims that concepts can be understood, and the effects of random damage predicted, based on (i) the number of correlations its features make, and (ii) the distinctiveness of those correlated features; the former indicating category membership, the latter distinguishing between concepts. The model shows a changing direction of domain-specific deficits as damage accumulates (animals concepts lost first, then objects upon severe lesioning). Also, the pattern of error differs between domains; animals tend to be confused for other members of the same category, whilst object errors disperse more widely across categories and domain. Recent neuropsychological evidence demonstrates a similar pattern for semantically impaired patients. For both patients and the model, this can be attributed to the timing of featural loss: distinctive features are lost earlier than shared features. The model demonstrates that the relative timing of feature loss differs between domains, resulting in the emergence of domain-specific effects.

Introduction

The neuropsychological literature on semantic memory shows patients can develop an impairment in one domain of knowledge, whilst the other is relatively spared. Most commonly, semantically impaired patients show a deficit for living things (e.g. Warrington & Shallice, 1984), with the reverse pattern being rarer (e.g. Hillis and Caramazza, 1991).

There are three main types of explanation for the double dissociation. One postulates physically separate and functionally independent stores in the brain for dissociable categories of knowledge (e.g. Goodglass, Klein, Carey and Jones, 1966; Carramazza & Shelton, 1998). Another suggestion is that concepts may vary by domain according to the type of semantic information upon which they depend, with living things depending more on sensory information and artefacts depending more on functional properties (Warrington & Shallice, 1984; Warrington & McCarthy, 1983; 1987). Selective brain damage to one type of semantic information will lead to a category-specific deficit. This account assumes neuro-anatomical specialisation for type of property rather than category per se, to permit their independent disruption by brain damage. Finally, and most recently, attempts to account for category-specific deficits suggest that they can emerge from the *internal structure of concepts* alone without any type of neural or functional specialisation. Computational models have shown that random damage to a unitary, distributed system can produce category-specific deficits (e.g. Devlin, Gonnerman, Anderson and Seidenberg, 1998; Tyler et al, 2000). These models draw on structural aspects such as property correlation and distinctiveness.

Conceptual Structure Account

Common to all distributed accounts of semantic memory (see McRae, de Sa, Seidenberg, 1997; Devlin et al, 1998; Tyler et al, 2000) is the observation that similar concepts tend to have overlapping sets of semantic features. Properties that frequently co-occur in concepts will serve to predict each others presence, a fact that a distributed connectionist network will exploit during training, leading to mutual activation of those properties. A consequence of mutual activation is resilience to damage of those properties, and hence their continued 'availability' to a stricken network when identifying concepts. A second important factor, is the distinctiveness[1] of features (cf. Devlin et al, 1998). A feature that is present in only one concept can be used

[1] Distinctiveness is calculated as 1/number of concepts for which the property is given.

to discriminate that concept from all others. As a feature occurs in an increasing number of concepts it becomes a progressively poorer marker for each of those concepts.

The *conceptual structure account* of semantic memory (Durrant-Peatfield, Tyler, Moss, & Levy, 1997; Tyler et al 2000) recognises that these factors – correlation and distinctiveness – will interact to determine which features will survive random damage, and the usefulness of the remaining features in preventing concept loss. By their very nature correlation and distinctiveness tend to be inversely related with each other. Highly correlated properties are often present in many concepts, and hence are not very distinctive. Thus, they will be robust to damage, but their preservation will be more useful for identifying the category to which an item belongs rather than distinguishing it from other category members. However, those distinctive properties that do correlate with other properties (especially other distinctive properties) will protect the concept in which they are found. Distinctive properties that fail to make strong correlations with other properties will be very vulnerable to damage. Domain differences and dissociations arise because concepts in different domains differ in these respects. We theorize that living things concepts have many intercorrelated properties, compared to artefacts, but these tend to be less distinctive. As a consequence, artefact concepts are more robust at all but severe levels of damage when only highly correlated properties remain intact.

Computational Model

Previous work instantiating the conceptual structure account of semantic memory (Tyler et al, 2000) used 16 vectors that incorporated the theoretical assumptions of the account. In the current model the vectors are designed to broadly reflect the observed differences between living and non-living domains, as found in a large-scale property generation study (Moss, Tyler & Devlin, In Press). The simplified vectors, homogenous within domain and of equal number between domains, ensure the model's results are readily interpretable. In addition, the model was scaled up, and trained on 96 vectors. Consequently, the training set is as sparse as the property norm data which it resembles. One might expect a distributed model to perform differently as the training set becomes more sparse, as a sensible error-reduction strategy would be to turn all units off. This model sought to confirm that a distributed model would still build internal representations reflecting correlational structure in spite of extreme sparsity.

Property norm data

Tables 1 and 2 report the global and distributional statistics of the property norm concepts. Data is also given for the model vectors, designed to resemble the property norm concepts as far as practicable.

Table 1: Global properties of the property norm set and the model vectors

	Property norms	**Model vectors**
Number of concepts	93	96
Features that are highly distinctive[2]	78%	78%
Sparsity[3]	3.7%	4.6%

Table 2: Characteristics of property norm concepts across domains (figures for model vectors in brackets)

	Living things	**Artefacts**
Mean no. properties/concept	17.7 (20)	11.3 (14)
Mean distinctiveness of properties	0.64 (0.22)	0.73 (0.32)
No. of shared properties/concept[4]	13.7 (15)	7.5 (6)

Following McRae et al (1997) the Pearson product moment correlation was computed for all pairs of semantic features. For the property norms, of the 78,210 possible correlations, only 2332 scored $|r|>0.3$. Living things had more correlated property pairs (CPPs) than artefacts (4070 vs. 1612), but artefacts had proportionally more CPPs occurring between distinctive features (20.0% artefacts vs. 11.7% living things).

Representations

The training set consisted of 96 vectors, divided into 2 domains (Animals and Objects) and 4 categories (labelled somewhat arbitrarily as Land animals, Birds, Tools and Furniture). The vectors embodied the facts outlined below:

- There were 48 Animal vectors (24 Land animals and 24 Birds).
- Each Animal vector turned on 20/368 features.
- Every Animal vector turned on 10 'Animal shared' features.

[2] The proportion of features in the set shared by just 1 or 2 concepts.

[3] Sparsity refers to the average proportion of features turned on for each vector.

[4] A shared property being defined as one held by three or more concepts, otherwise the property is distinctive.

- Land animals were distinguishable from Birds by which group of 5 shared features was turned on – 'Land shared' or 'Bird shared'.
- All animals could be distinguished from each other by which three 'Animal distinctive features' were on.
- There were 48 cross-domain features, each concept turning on two. Each concept, whether animal or object turned on a unique combination of cross-domain features (say 1 and 4; or 2 and 5 etc) such that each unit was turned on by 4 different concepts (2 animal, 2 objects). This means that having a cross-domain feature on does not predict at all which domain's concept is on, but limits the concept to one of four possibilities.
- There were 48 object concepts (24 tools and 24 furniture).
- Every Object vector turned on 14/368 features.
- Tools and Furniture were distinguishable by which group of 6 shared features they turned on.
- Object concepts were identifiable by which 2 'object distinctive triplets' were on. They are termed triplets because, within a triplet, if one feature is on then the other two must also be on (likewise when off). However, each "object distinctive triplet" is turned on both by 1 tool concept and 1 furniture concept, so having a triplet on does not perfectly predict which object is on (in contrast to "animal distinctive features").

The resultant vectors resemble the concepts analysed in the property generation study (see tables 1 and 2). The resemblance extends to the vectors' correlational structure. For the model vectors, of the 67,528 possible correlations, 1864 scored $|r|>0.3$. Animals had more correlated property pairs (CPPs) than objects (5472 vs. 2016), but objects had proportionally more CPPs occurring between distinctive features (35.7% objects vs. 2.6% animals). This reproduces the pattern of the domain effects in the property norms, but exaggerates the size of the difference.

Architecture and training

The network consisted of three layers, a semantic input layer, a hidden layer and a semantic output layer, as shown in Figure 1. During training, with the back-propagation learning algorithm (Rumelhart, Hinton & McClelland, 1986), the network was required to reproduce the input on the output layer. 10 networks were trained with different initial random weights (±0.005), with a learning rate of 0.25 and momentum 0.5. Training was stopped when the squared error for each feature in every vector was below 0.01, occurring after a mean of 193 presentations of the complete target set.

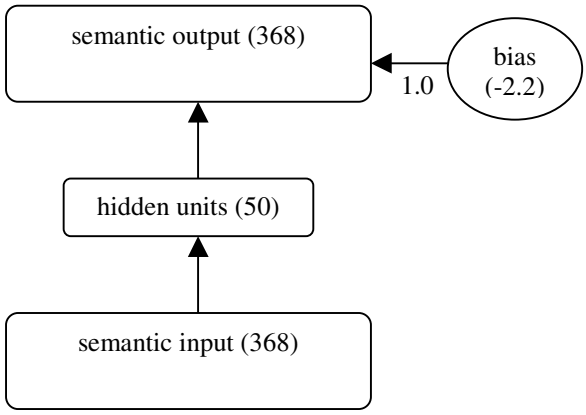

Figure 1: Model architecture: the numbers in each box indicate the number of units in that layer, while arrows indicate full connectivity between layers[5]

Lesioning

Brain damage is simulated in this model by random deletion of semantic connections (by setting weights to 0). Initially 10% of weights were cut, then the model's performance analyzed. The proportion of damaged connections was increased by increments of 10% until all inter-layer connections were set to 0. This lesioning process was carried out 5 times on each of the 10 trained networks to produce a total of 50 networks.

Testing

Network performance was analyzed both at the level of features and concepts. The training set was presented to the network's input layer and the pattern of activations on the output layer examined. We predict that highly shared features will be more resilient to damage than distinctive features (i.e. will still activate when they should). In the model vectors this will correspond to the greatest advantage being for 'animal shared features', then 'land', 'bird', 'tool' and 'furniture' shared features behaving similarly, with 'animal distinctive' features being least preserved. A different pattern is predicted at the conceptual level where discrimination is dependent primarily upon distinctive features. Object distinctive features cluster into 'triplets', this additional inter-correlation is predicted to enhance their robustness to damage relative to Animal distinctive features, leading to an advantage in concept identification. Only at severe levels of damage, when all distinctive features are lost to the network, will the advantage for animal shared features translate to an advantage in concept naming.

[5] Bias ensures the 100% damaged model outputs 0s (approximately); in its absence the semi-linear logistic activation function makes every semantic output unit 0.5. Bias connections were not lesioned.

Featural analysis

For each vector, the activation of the semantic output layer was binarised – unit values <0.5 were scored 0 while values ≥0.5 were scored 1. Each unit value was compared to that of the input vector and declared correct or error. Attention focused on the subset of units that were supposed to be on for each vector, and the number of errors summed for each domain. Because each output unit represents a local feature it is possible to compare the errors across the different feature types (i.e. 'animal shared', 'object distinctive triplet' etc).

Overall analysis

The pattern of activity over the output units was compared to all 96 vectors; both had been normalised to remove effects of concept size[6]. The closest match, by Euclidean distance, was considered the model's response. Upon network lesioning, errors occur of three types: within-category error, cross-category error, or a cross-domain error.

Results

Figure 2 presents the results of the featural analysis averaged over 50 simulations. The general pattern is for a greater impairment of unique relative to shared features at all levels of lesioning between 20 and 80%.

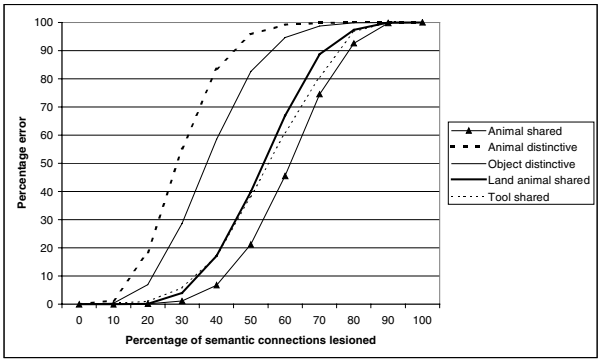

Figure 2:Featural error (failure to activate) as a function of network damage.

The effects of damage upon concept identification are shown in Figure 3, which shows an advantage for objects over animals up until 80% of connections had been lesioned. A two-way ANOVA (domain*damage) showed a main effect of domain (i.e. animals vs. objects, (F[1,539]=317, p<.0001), and a significant domain by damage interaction (F[10,539]= 5406, p<.0001).

A repeated measures t-test on the 90% damaged data-points showed that the advantage for animals, although small, was significant (t= -6.249, p<.0001).

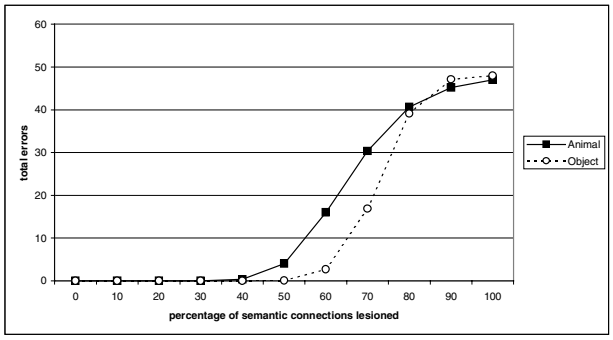

Figure 3: Identity mapping as a function of damage.

Figure 4 shows the difference in the distribution of error types when concepts were mis-identified. It attributes the early animal deficit to within-category error, with all errors involving members of the same category. Conversely, object errors are more widely dispersed between the two domains.

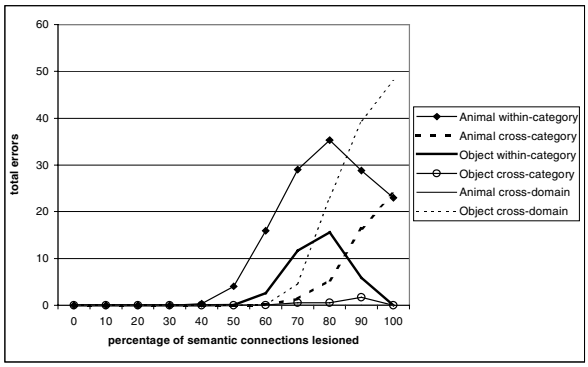

Figure 4: Error types as a function of damage.

Discussion

This research demonstrates how category and domain-specific deficits can arise following damage to a single distributed semantic system without explicit category structure. Further, it accounts for the patterns of impairment observed in patients as resulting from a complex interaction of correlations between features and the extent to which features are shared or distinctive. In general, the behaviour of the model is very similar to the behaviour of some brain-damaged patients with category/domain specific deficits.

The preservation of individual features was dependent on the number of correlations each feature entered into, with more highly shared, correlated features being more robust. This pattern is similar to that observed in semantically-impaired patients who show better preserved knowledge of shared, category-

[6] Concept size refers to the number of features turned on.

defining information compared to distinctive, concept-identifying information (Moss, Tyler, Durrant-Peatfield, & Bunn, 1998; Moss et al, In Press).

The preservation of individual concepts showed a different pattern. Global damage, where connections between layers were randomly lesioned, produced an initial impairment for animals, followed at severe lesioning, by impairment for objects. Successfully identifying a concept relies most heavily on activating its distinctive features. With damage, object distinctive properties were more robust than animals, which can be attributed to their tendency to correlate with other distinctive properties. Crucially, this same pattern of correlations occurred in the empirically derived property norms (Moss et al, In Press). This shows that the same factor that accounts for an early animal deficit in the computational model could also account for the initial living-things deficit found in at least some semantic dementia patients (Moss & Tyler, 2000; Moss et al, In Press). Beyond 70% lesioning all distinctive features failed to activate, whether animal or object. Consequently, the model had to 'make a guess', though the odds of guessing correctly would have differed for the two domains. The animal shared features are both more numerous and more correlated, hence will remain more likely to be available to the network. Therefore the model would have been guessing from a smaller subset of possible concepts than would have been the case for objects, which could lead to a mild object deficit. This unequal distribution of shared features between domains is also characteristic of the property norm data.

The lesioning data shows that the magnitude of the early disadvantage for naming animals exceeds that of the late disadvantage for naming objects. This too seems to be reflected in semantic dementia patients where living-thing deficits tend to be both greater in size and more numerous than corresponding artefact deficits (Moss & Tyler, 2000).

The conceptual structure account, realised in the computational model, also predicts the type of error likely to be made when concepts are mis-identified. Due both to the robustness of animal shared features, and the vulnerability to damage of their distinctive features, animals will most commonly be confused with other members of the same category. Cross-domain errors should hardly ever occur. Whilst the same should be true of objects, this tendency will be less marked, and errors will be dispersed more widely between the types of error possible: within-category; cross-category; and cross-domain. There is some evidence for this pattern in longitudinal studies of picture naming. Hodges, Graham & Patterson (1995) report a semantic dementia patient, JL. For living things, he made progressively more within-category and superordinate errors, but never produced a cross-category or cross-domain error. Similarly for the progressive aphasic patient AA (Moss et al, 1999), tested on four occasions over two years, but failing to produce a living things cross-category mistake until the final testing session. For artefacts, in contrast, she occasionally made cross-category and cross-domain errors throughout the testing period.

Epilogue: The problem of determining error

In common with other models of semantic memory, the network's output was compared to every vector in the training set, and the vector with which the normalised Euclidean distance was smallest, regarded as the network response. As a result the network was forced to make a response, irrespective of the meaningfulness or otherwise of the output. A potential limitation of this procedure is that the network could not respond "don't know", a response commonly produced by semantically impaired patients in semantic tasks. As a first step to simulating a "don't know" response a threshold for normalised Euclidean distance was introduced; if the error between the output and every vector exceeded this threshold then the output was scored incorrect. The problem then was to decide how strict the threshold ought to be. The result of some early explorations is shown in figure 5.

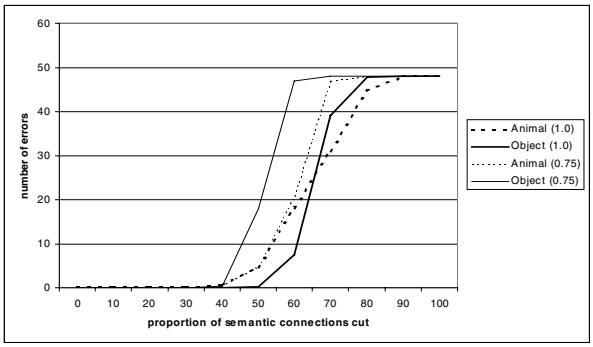

Figure 5: The variability of domain effects with different thresholds for normalised Euclidean distance.

A threshold value of 1.0 produced a strong cross-over, an early animal deficit progressing to an object deficit with damage. Reducing the threshold value to 0.75 had a catastrophic effect upon object identification, but animal identification was less impaired. As a result, the graph showed a consistent deficit in identifying objects. A threshold figure of 1.5 produced a graph identical to that when no threshold was applied (i.e. the same as figure 3). The sensitivity of object identification to varying threshold values probably reflects the smaller number of inter-correlations between object features. The representation of an object concept in semantic space will be sparser, so when the representation is damaged, and a strict threshold is applied, it will be unlikely to fall into a neighbouring concept's space.

Instead the output will be scored "don't know", an outcome which is much less likely in the denser animal semantic space.

The problem here is how we determine where the error threshold should lie? One approach might be to record the number of "don't know" responses the model makes, and relate this to patient data. This is complicated by the difficulty of relating the degree of brain damage to particular levels of network lesioning. Also, patient performance on tests of semantic knowledge varies with the demands of the task. For example, "Don't know" is a more common response for picture naming than word-picture matching.

Speculatively, the normalised Euclidean threshold could reflect a compromise position in a speed/accuracy trade off. Tasks that demand a rapid response would have a more relaxed threshold than those where time is given for a considered response.

Conclusion

This model suggests that the data inherent in conceptual structure is sufficient to account for the domain-specific effects observed in semantically impaired patients. Categories and domains emerge when concepts are represented in a single, distributed system. Some recent neuro-imaging studies fail to show regional differences in activation for different conceptual domains (e.g. Devlin, Russell, Davis, Price, Moss, Matthews, & Tyler, 2000), consistent with the neural substrate of concepts being organised in a distributed fashion.

Beliefs Versus Knowledge: A Necessary Distinction for Explaining, Predicting, and Assessing Conceptual Change

Abstract

Empirical research and theoretical treatments of conceptual change have paid little attention to the distinction between knowledge and belief. The distinction implies that conceptual change involves both knowledge acquisition and belief revision, and highlights the need to consider the reasons that beliefs are held. We argue that the effects of prior beliefs on conceptual learning depends upon whether a given belief is held for its coherence with a network of supporting knowledge, or held for the affective goals that it serves. We also contend that the nature of prior beliefs will determine the relationship between the knowledge acquisition and the belief revision stages of the conceptual change process. Preliminary data suggests that prior beliefs vary in whether they are held for knowledge or affect-based reasons, and that this variability may predict whether a change in knowledge will result in belief revision.

Introduction

Theorists and researchers tend to agree that prior concepts often impede people's ability to learn conflicting information (e.g., Chi, 1992; Dole & Sinatra, 1998; Thagard, 1992). The paradox of knowledge acquisition is that new information can only be understood in terms of existing ideas, yet existing ideas act as a filter, often distorting new information to make it more consistent with prior concepts. This raises the question of how we ever learn anything fundamentally new.

At least two widely cited models agree about crucial steps in the conceptual change process (Chi, 1992; Thagard, 1992): (1) recognizing that the new information conflicts with (or is fundamentally different from) existing concepts; (2) constructing a new knowledge structure to support the new information; (3) replacing the old concepts with the new, more coherent concepts. In short, conceptual change involves learning new concepts and then substituting them for the old. Though these models (i.e., Chi, 1992; Thagard, 1992) diverge in some of the details about the process, they seem to agree that conceptual coherence largely determines conceptual replacement.

In addition, Ohlsson and Lehtinen (1997) have suggested that the use of abstract schemas may be needed to explain how new knowledge representations can be created that will not be distorted by the conflicting prior concepts. They suggest that activation of conflicting prior concepts activates related abstract concepts that are not in direct conflict with the new information, and that can be utilized in constructing an accurate representation of the new information. These aspects of the conceptual change process become more important when we consider how beliefs differ from knowledge.

Belief Versus Knowledge

The present paper defines knowledge as the comprehension or awareness of an idea or proposition ("I *understand* the claim that humans evolved from early primates"). After a proposition is known, one can accept it as true ("I *believe* the claim that..."), reject it as false ("I *disbelieve* the claim that..."), or withhold judgment about its truth-value ("I have *no opinion* about the claim that...").

The present knowledge/belief distinction is intended to be psychological. Thus, knowledge and belief refer to qualitatively different aspects of the mental representation: knowledge refers to the representation of a proposition, and belief refers to the representation of a truth-value associated with a proposition. These definitions are consistent with Quine, and Ullian's (1970) argument that people can have knowledge of an idea or proposition, but either not believe it to be true, or hold a belief that the concept is false.

A proper distinction between comprehension versus acceptance or rejection of an idea allows us to consider the multiple influences on belief formation, and to speak more clearly (and realistically) about the relationship between knowledge and belief change.

A Change in Knowledge, Beliefs, or Both?

It is striking that discussions of conceptual change use the terms 'knowledge', 'beliefs', and 'prior conceptions' interchangeably. Recently, diSessa (2000) highlighted the unexamined lack of agreement among conceptual change researchers regarding basic issues such as whether the conceptual change refers to a change in concepts, beliefs, nodes, or links.

In the models previously mentioned (Chi, 1992; Thagard, 1992) conceptual change involves both the creation of new knowledge (step 2), and a process of abandoning the old ideas in favor of the new ones (step 3). Step 2 amounts to acquiring new knowledge or conceptual understanding, while step 3 amounts to belief revision. Thus, belief revision is characterized as rationally disavowing a prior belief whenever the computed conceptual coherence of a new knowledge structure is higher. This account presupposes that knowledge is the only foundation for belief.

The present argument favors a distinction between knowledge and belief, but acknowledges that knowledge of a concept must precede any judgment of its truth or falsehood. The issue being raised here is that acceptance or rejection of a concept may not be solely contingent upon the coherence of its relations to supporting knowledge in the form of evidence, argument, and logical implications. Belief in a concept may serve affective and social functions. Thus, people might accept a certain idea independent of its coherence with relevant knowledge, and perhaps change a belief even though it will reduce conceptual coherence. Beliefs may vary qualitatively in the degree to which they are part of a specified and coherent network of relevant knowledge.

This claim about the varying bases of belief is similar to one made regarding the affective versus cognitive bases of attitudes (e.g., Eagly & Chaiken, 1993). However, while attitudes refer to subjective evaluations of objects as 'positive' or 'negative', beliefs refer to the acceptance or rejection of propositions. Knowing that a person believes in a proposition, such as "humans evolved form primates", tells us nothing about whether that person feels positively or negatively about this state of affairs. Furthermore, attitude-change theories predict greater change in attitudes that are grounded more in affect than cognitions: precisely the opposite prediction being made here for affect-based beliefs.

A number of implications arise when considering the variability in the bases of beliefs. This variability could influence how belief-conflicting information is processed and understood. Even if a new conceptual scheme is understood, the role of affective motivations in belief acceptance calls into question the notion that belief revision results every time a new conceptual scheme increases coherence.

Belief Bases and Conceptual Learning

Part of the importance in making a knowledge/belief distinction lies in the potential influence that a belief's underlying knowledge structure (or lack thereof) might have on the comprehension of belief-conflicting information. The greater conceptual coherence of knowledge-based beliefs should aid in conceptual learning by making conflict recognition more likely and providing a context that facilitates the construction of a new conceptual representation.

Knowledge-based beliefs are defined by greater coherence with related conceptual networks than beliefs held for affective goals. Therefore, a person should more easily recognize when the evidence, argument, or logical implications of a new conceptual scheme are in conflict with a knowledge-based belief than with an affect-based belief. As already stated, conflict recognition is the first step in the conceptual change process and a necessary step in avoiding distortion via assimilation (Chi, 1992; Thagard, 1992). Thus, when people encounter information that conflicts with knowledge-based versus affect-based beliefs, they should be less likely to assimilate and distort and more likely to begin the process of constructing an accurate representation of the information.

Following conflict recognition, the richer and more detailed conceptual context of knowledge-based beliefs should help compare and contrast the belief with the new information, thus facilitating the process of constructing a representation of the new information. By definition, a prior belief that conflicts with new information is relevant to that new information. The concepts of ‘black’ and ‘white’ contain components that oppose one another, yet our understanding of ‘black’ seems to rely heavily on its contrast with the concept of ‘white’. Conceptual contrast could help highlight the boundaries that separate and therefore define the concepts.

In addition, contrasting old and new concepts might lead to the generation of useful abstractions that capture the principles underlying the contrast. In fact, the conceptual network underlying knowledge-based beliefs may provide direct links to abstract concepts that already exist. Given the theorized role of abstract concepts in constructing new representations (i.e., Ohlsson & Lehtinen, 1997), the conceptual framework provided by knowledge-based beliefs could prove quite beneficial in the comprehension of conflicting concepts.

The hypothesis that conflicting beliefs can assist learning via conceptual contrast has received indirect support from classroom studies of pedagogical techniques (for a review, see Guzzetti, Snyder, Glass, Gamas, 1993). A meta-analysis of 70 reading and science education studies revealed that techniques that contrasted new concepts with common misconceptions resulted in better comprehension of the new concepts compared to a number of alternative techniques. The problematic conclusion drawn from was that prior concepts impede learning, so they must be refuted. However, refutational techniques did not directly refute the students' *own* prior concepts, but rather informed students of *common* misconceptions, then presented new concepts as a contrast to these misconceptions.

It is possible that merely highlighting contrasting concepts facilitated comprehension. This interpretation is consistent with the fact that students who did not already possess the prior concepts appeared to benefited equally from refutation compared to students who did have the misconceptions. Contrary to a common assumption, these results could be evidence that conflicting prior beliefs can aid in conceptual learning, so long as the prior concepts are made salient and explicitly contrasted with the new information.

In sum, there are sound theoretical reasons to expect that knowledge-based beliefs should lead to greater conceptual understanding of conflicting information than affect-based beliefs. In fact, if the initial problem of recognizing conceptual conflict is overcome, then the conceptual framework of knowledge-based beliefs may result in greater comprehension than when there are no prior beliefs at all. However, the final stage of conceptual change (i.e., belief revision) remains.

Belief Bases and Belief Revision

There are some obvious reasons to expect that the third and final stage of conceptual change will also be influenced by the underlying source of prior beliefs.

Updating beliefs with new knowledge should be heavily influenced by motivation and epistemological values. Those who are affectively motivated to form beliefs independent of conceptual coherence will have little motivation to revise those beliefs in light of new ideas that could increase coherence. These people may be specifically motivated to 'isolate' new information and actively avoid evaluative comparisons of conceptual coherence. Recent work has shown that different kinds of beliefs are associated with different epistemological values, and these values predict how different beliefs are affected by anomalous information (Chinn & Brewer, 2000). Conceptual replacement or belief revision may follow the competitive rules of conceptual coherence, but only when the initial belief is based upon its coherence with other knowledge.

Beyond motivational influences on belief revision, the conceptual structure of prior beliefs is likely to have direct cognitive effects on coherence comparisons. Making meaningful comparisons between affect-based beliefs and new conceptual knowledge will prove difficult given the different levels of conceptual specification. Also, if coherence comparisons are made, the lack of conceptual specificity inherent in affect-based beliefs will make any revision short of complete abandonment cognitively difficult. Thus, affective beliefs seem to face an 'all or nothing' dilemma, where the most probable outcome is a lack of belief revision. Issues of motivation and conceptual structure make it unlikely that affect-based beliefs will be revised following the comprehension of a coherent conceptual framework.

In short, the present paper advances the following arguments: (1) beliefs differ from knowledge; (2) beliefs vary in whether they are held for coherence with supporting knowledge versus affective motives; (3) conceptual change involves both knowledge acquisition and belief revision; (4) the variability in prior belief bases may influence both of these components of the conceptual change process. The first step in the empirical validation of these claims is to demonstrate that people believe in different concepts for affective as well as knowledge-based reasons and that this difference is related to their willingness to change those beliefs.

Method

The following study was a preliminary investigation of the variability in the underlying bases for beliefs. Any attempt to assess whether beliefs are the result of knowledge coherence or affective goals will have weaknesses that can only be overcome with the use of multiple converging methodologies. Our modest goal in this study was to examine whether people would self-report that their beliefs were held for largely affective reasons and not due to support from relevant knowledge. We hoped to demonstrate variability across beliefs regarding their bases in knowledge versus affect. We also expected that people's underlying reasons for holding their beliefs would be related to their self-reported willingness to revise those beliefs in the face of strong conflicting evidence.

Participants

Participants were 120 undergraduates at the University of Illinois at Chicago.

Belief Assessment Materials and Procedures

Participants reported their prior beliefs on five different topics: creationism, evolution, extra sensory perception, the 'opposites attract' theory of romantic attraction, and the existence of an afterlife. The topics were chosen for their potential relationships to relevant knowledge and affect. For each topic participants were told "for the purpose of this study [topic] is defined as...", followed by a one sentence description of the topic. The descriptions were worded as simply as possible and participants were told to ask for clarification if needed.[1]

Following each description was the question "To what extent do you believe in [topic]?" Participants indicated their level of belief on a scale ranging from 1 (completely disbelieve) to 9 (completely believe).

[1] No participants asked for clarification. Also, failures in definition comprehension would be consistent with the present theory, and would not alter the interpretation of the present results.

Participants were then asked to list their top 3 reasons for their belief on the topic. This self-generation task was designed to examine participants' most accessible reasons that they had previously associated with their belief on the topic.

After participants reported their degree of belief and listed their reasons for all five topics, they were presented with a list of potential reasons why a person might hold any given belief. They were told "for each potential reason below indicate whether that reason is why you personally, hold your belief about the idea." Participants responded on a likert-scale ranging from 1(not at all my reason) to 9(completely my reason). Five reasons were presented, two knowledge based reasons and three affective reasons (see Table 1).

Table 1. Knowledge and Affective Reasons for Belief.

Affective Reasons*:
My belief about [topic] makes me feel good or is comforting.
When it comes to issues like [topic], I trust my 'heart', not my 'head' to tell me the truth.
I don't need proof, I have faith that my belief about [topic] is correct.
Knowledge Reasons*:
My belief about [topic] is a result of examining all of the evidence I'm aware of and choosing the most convincing explanation.
My belief about [topic] is supported by current scientific knowledge.

*Reasons were not labeled 'affective' or 'knowledge'.

After rating their reasons for each belief, participants were asked: "Imagine that you were presented with strong evidence that contradicted your belief. How likely would you be to change your belief?" Participants indicated their willingness to change each belief on a scale from 1(not at all) to 9(completely).

Results

For each of the five topics, participants were classified into one of three groups: 1 to 3 rating = 'disbeliever'; 4 to 6 rating = 'no opinion'; 7 to 9 rating = 'believer'. Believers on one topic could be believers, disbelievers, or have no opinion on the other topics. The results that follow compare the knowledge versus affective reasons given by believers and disbelievers across the five topics. Those with no opinion are not included here.

Self-Generated Reasons

A qualitative examination of participants' self-generated reasons for belief revealed that participants gave both affective and knowledge-based reasons for their beliefs. The types of reasons varied systematically across topics and between believers and non-believers (see Table 2, for prototypical reasons given by 'believers'). The reasons given for belief in creationism, an afterlife, and disbelief in evolution were rarely knowledge-based and often referred to affect. Some participants simply mentioned that the belief was part of their religion or just how they were brought up. In contrast, belief in evolution, and disbelief in creationism and an afterlife were never supported with affective reasons and participants often referred to evidence. Belief and disbelief in ESP and opposites attract was most often supported by personal experience or reference to media portrayals, but affective reasons were also provided.

Table 2. Prototypical reasons for belief*.

Creationism
"I rely on faith"; "the bible says so"; "I couldn't live if I didn't think there was a God"
Afterlife
"I hope there is one"; "It relieves my fear"; "life would be meaningless otherwise"
Evolution
"biological evidence"; "You can observe similarities between species"
ESP
"I have this ability"; "t.v. documentaries"; "It sounds cool"
Opposites attract
"personal experience"; "media"; "I have seen it"

*Reasons for disbelief are not included in this table

Ratings of Knowledge Versus Affective Reasons

The mean scores were calculated for the three affect reasons and the two knowledge reasons. Figures 1 and 2 report the mean levels of knowledge and affect scores, and self-reported willingness to change a belief or disbelief in the face of conflicting evidence. As mentioned previously, each participants belief or disbelief varied as a function of topic. This presents a problem for any straightforward statistical test of the Belief X Topic interaction. Thus, a qualitative comparison of the means was followed-up by a formal test using correlational methods.

As expected, both the mean levels of affect and knowledge associated with a belief varied across the different topics (see Figure 1). Belief in evolution was associated with higher knowledge than affect scores, and with lower affect scores than belief in the other four topics. In contrast, belief in creationism and an afterlife were associated with higher affect than knowledge scores, and with higher affect than belief in the other three topics.

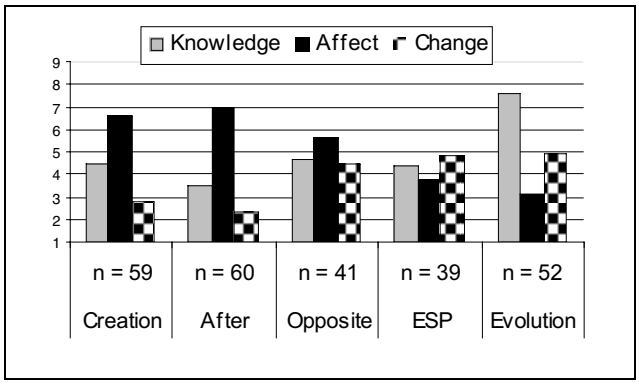

Figure 1: Reasons and Will to Change for Believers.

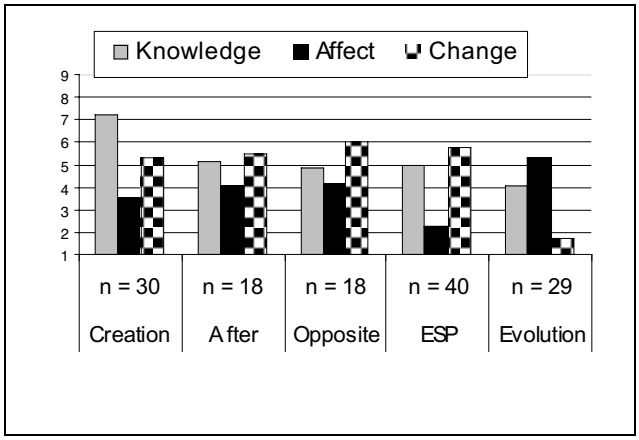

Figure 2: Reasons and Will to Change for Disbelievers.

The opposite pattern of results was found for disbelief across topics (see Figure 2). Specifically, disbelief in creationism was associated with higher knowledge than affect scores, and higher knowledge scores than disbelief in the other four topics. In contrast, disbelief in evolution was associated with higher affect than knowledge scores, and higher affect than the other topics. Overall, the differences in knowledge and affective scores for belief and disbelief across the five topics were consistent with the kinds of reasons participants provided in the self-generation task.

To get around the problem of the membership overlap between believers and disbelievers across topics, belief was treated as a continuous variable. Also, a single score of endorsed reasons was calculated for participants on each topic, by subtracting their affect score from their knowledge score on each topic. Each of the five difference scores was correlated with the continuous measure of belief for the corresponding topic. The results are the five coefficients in Table 3.

For all topics, the knowledge-affect difference score was significantly correlated with the tendency to believe or disbelieve. Negative correlations suggest that as belief in the issue was greater, knowledge reasons decreased compared to affect reasons. This was the case for belief on all issues except for evolution. As belief in evolution increased the endorsement of knowledge reasons increased greatly compared to affect reasons. These findings are consistent with the descriptive examination of the mean scores for believers and disbelievers.

Reasons for belief were also related to self-reported willingness to change. As seen in Figures 1 and 2, mean change scores were lowest when beliefs were associated with higher affect than knowledge scores, as was the case for belief in creationism, an afterlife, and a disbelief in evolution. This relationship was tested by correlating participants' knowledge-affect difference scores with their willingness to change their beliefs on the five topics. All five bi-variate correlations were significant at $p < .05$, and the coefficients ranged between .30 and .40. Thus, the more a participant's belief was based in knowledge relative to affect, the more willing they were to change that belief in the face of conflicting evidence.

In sum, many participants reported that their beliefs were based more on affect than on any relation to existing knowledge. Also, there was significant variation among beliefs in terms of their knowledge versus affective bases. Lastly, participants claimed they would be less willing to change affect-based beliefs than knowledge-based beliefs if presented with sound belief conflicting evidence.

Table 3. Correlations between knowledge-affect difference scores and belief, on all five topics.

Creationism	Afterlife	ESP	Opposites	Evolution
-.68*	-.38*	-.42*	-.35*	.73*

*$p < .05$.

Discussion

These preliminary results support our hypothesis that beliefs and knowledge are related but distinct constructs. People will not only report that some of their beliefs are held on affective grounds, they will even specifically reject knowledge based reasons as the bases for some of their beliefs. In addition, these self-reported reasons for belief predicted participants willingness to change those beliefs.

These data are only a first attempt to examine this issue. It is a difficult task to assess the true bases for individual beliefs. If belief formation and maintenance are relatively deliberate mental enterprises then it is reasonable to assume that people would be able to accurately report the relationships between their beliefs and relevant knowledge and affective goals. The validity of these self-reports is aided by the fact that

participants' self-generated reasons matched their endorsement of the knowledge and affective reasons that we provided.

It should be noted that self-reported willingness to change a belief was not intended to be an actual measure of belief revision. This point is made obvious by the fact that no belief conflicting information was ever provided to participants. However, we argue that belief revision is highly subject to motivational influence and that epistemological values are integral to people's motivation to update beliefs with any newly acquired knowledge. Self-reported willingness to change a belief reflects belief-specific epistemological values that should affect the motivations relevant to belief revision. Thus, it is noteworthy that participants reported being rather unwilling to change their affect-based beliefs, even if presented with sound conflicting evidence, but relatively willing to change knowledge-based beliefs.

Implications and Future Research

The obvious next step is to see whether these reported differences in belief bases predict how well people comprehend new information in conflict with their beliefs. The distinction between knowledge and beliefs requires that outcome measures be tailored to assess change in one or the other. If conceptual understanding (knowledge change) is being assessed, then participants must be clear that their task is to demonstrate their understanding of the new concepts, and not to report their current point of view.

A similar concern arises when the outcome of interest is belief revision or conceptual replacement. Dependent measures must show that people are spontaneously employing new concepts in their thinking, not merely adapting their thinking to the expectations of experimental or educational settings. Being explicit in our discussions and methodologies about beliefs versus knowledge may reveal where the real disagreements are in the area of conceptual change and perhaps reveal that there is less disagreement than it seems.

Previous accounts of conceptual change have assumed a uniformly negative influence of prior beliefs on conceptual change. We argue that the knowledge versus affective basis of prior beliefs may be an important determinant of whether conflicting concepts are accurately understood. We also contend that the coherence competition accounts of belief revision are too simplistic, given the existence of affect-based beliefs. A conceptual-coherence theory of belief revision only makes sense for the sub-set of beliefs that are initially based on their coherence with current knowledge.

Previous theories claim that conceptual change is in the direction of greater coherence. Thus, incoherent prior beliefs should be more likely to change than coherent beliefs. The present theory suggests several reasons to expect just the opposite in some circumstances. Affect-based beliefs by virtue of their lack of coherence with the conceptual framework might be immune to threats posed by conflicting information. Any new information is likely to be distorted, and if it is accurately comprehended, it will have little influence on an affect-based belief.

The present theory predicts that emotional beliefs not derived from relevant knowledge are the least likely to change in the face of conflicting information. This prediction should make intuitive sense to anyone who has ever had a dinner-time discussion about politics or religion. Scientific ideas may change slowly, but the informal observation that they seem to change quicker than non-scientific ideas may be an indication that the scientific enterprise generally does adhere to the principles of forming ideas based on knowledge and coherent argument.

Abstract

We argue that the apparent inconsistency between people's intuitions about chance and the normative predictions of probability theory, as expressed in judgments about randomness and coincidences, can be resolved by focussing on the evidence observations provide about the processes that generated them rather than their likelihood. This argument is supported by probabilistic modeling of sequence and number production, together with two experiments that examine judgments about coincidences.

People are notoriously inaccurate in their judgments about randomness, such as whether a sequence of heads and tails like HHTHTTTH is more random than the sequence HHHHHHHH. Intuitively, the former sequence seems more random, but both sequences are equally likely to be produced by a random generating process that chooses H or T with equal probability, such as a fair coin. This kind of question is often used to illustrate how our intuitions about chance deviate from the normative standards set by probability theory. Our intuitions about coincidental events, which seem to be defined by their improbability, have faced similar criticism from statisticians (eg. Diaconis & Mosteller, 1989).

The apparent inconsistency between our intuitions about chance and the formal structure of probability theory has provoked attention from philosophers and mathematicians, as well as psychologists. As a result, a number of definitions of randomness exist in both the mathematical (eg. Chaitin, 2001; Kac, 1983; Li & Vitanyi, 1997) and the psychological (eg. Falk, 1981; Lopes, 1982) literature. These definitions vary in how well they satisfy our intuitions, and can be hard to reconcile with probability theory. In this paper, we will argue that there is a natural relationship between people's intuitions about chance and the normative standards of probability theory. Traditional criticism of people's intuitions about chance has focused on the fact that people are poor estimators of the likelihood of events being produced by a particular generating process. The models we present turn this question around, asking how much more likely a set of events makes a particular generating process. This question may be far more useful in natural inference situations, where it is often more important to reason diagnostically than predictively, attempting to infer the structure of our world from the data we observe.

Randomness

Reichenbach (1934/1949) is credited with having first suggested that mathematical novices will be unable to produce random sequences, instead showing a tendency to overestimate the frequency with which outcomes alternate. Subsequent research has provided support for this claim (reviewed in Bar-Hillel & Wagenaar, 1991; Tune, 1964; Wagenaar, 1972), with both sequences of numbers (eg. Budescu, 1987; Rabinowitz, Dunlap, Grant, & Campione, 1989) and two-dimensional black and white grids (Falk, 1981). In producing binary sequences, people alternate with a probability of approximately 0.6, rather than the 0.5 that is seen in sequences produced by a random generating process. This preference for alternation results in subjectively random sequences containing less runs – such as an interrupted series of heads in a set of coin flips – than might be expected by chance (Lopes, 1982).

Theories of subjective randomness

A number of theories have been proposed to account for the accuracy of Reichenbach's conjecture. These theories have included postulating that people develop a concept of randomness that differs from the true definition of the term (eg. Budescu, 1987; Falk, 1981; Skinner, 1942), and that limited short-term memory might contribute to people's responses (Baddeley, 1966; Kareev, 1992; 1995; Wiegersma, 1982). Most recently, Falk and Konold (1997) suggested that the concept of randomness can be connected to the subjective complexity of a sequence, characterized by the difficulty of specifying a rule by which a sequence can be generated. This idea is related to a notion of complexity based on description length (Li & Vitanyi, 1997), and has been considered elsewhere in psychology (Chater, 1996).

The account of randomness that has had the strongest influence upon the wider literature of cognitive psychology is Kahneman and Tversky's (1972) suggestion that people may be attempting to produce sequences that are "representative" of the output of a random generating process. For sequences, this means that the number of elements of each type appearing in the sequence should correspond to the overall probability with which these elements occur. Random sequences should also maintain local representativeness, such that subsequences demonstrate the appropriate probabilities.

Formalizing representativeness

A major challenge for a theory of randomness based upon representativeness is to express exactly what it means for an outcome to be representative of a random generating process. One interpretation of this statement is that the outcome provides evidence for having been produced by a random generating process. This interpretation has the advantage of submitting easily to formalization in the language of probability theory.

If we are considering two candidate processes by which an outcome could be generated – one random, and one containing systematic regularities – the total evidence in favor of the random generating process can be assessed by the logarithm of the ratio of the probabilities of these processes

$$\log \frac{P(\text{random}|x)}{P(\text{regular}|x)}, \tag{1}$$

where $P(\text{random}|x)$ and $P(\text{regular}|x)$ are the probabilities of a random and a regular generating process respectively, given the outcome x.

This quantity can be computed using the odds form of Bayes' rule

$$\frac{P(\text{random}|x)}{P(\text{regular}|x)} = \frac{P(x|\text{random})}{P(x|\text{regular})} \frac{P(\text{random})}{P(\text{regular})}, \tag{2}$$

in which the term on the left-hand side of the equation is called the posterior odds, and the first and second terms on the right-hand side are called the likelihood ratio and prior odds, respectively. Of the latter two terms, the specific outcome x influences only the likelihood ratio. Thus the contribution of x to the evidence in favour of a random generating process can be measured by the logarithm of the likelihood ratio,

$$\text{random}(x) = \log \frac{P(x|\text{random})}{P(x|\text{regular})}. \tag{3}$$

This method of assessing the weight of evidence for a particular hypothesis provided by an observation is often used in Bayesian statistics, and the log likelihood-ratio given above is called a Bayes factor (Kass & Raftery, 1995). The Bayes factor for a set of independent observations will be the sum of their individual Bayes factors, and the expression has a clear information theoretic interpretation (Good, 1979). The above expression is also closely connected to the notion of minimum description length, connecting this approach to randomness with the ideas of Falk and Konold (1997) and Chater (1996).

Defining regularity

Evaluating the evidence that a particular outcome provides for a random generating process requires computing two probabilities: $P(x|\text{random})$ and $P(x|\text{regular})$. The first of these probabilities follows from the definition of the random generating process. For example, $P(\texttt{HHTHTTTH}|\text{random})$ is $(\frac{1}{2})^8$, as it would be for any sequence of the same length. However, computing $P(x|\text{regular})$ requires specifying the probability of the observed outcome resulting from a generating process that involves regularities. While this probability is hard to define, it is in general easy to compute $P(x|h_i)$, where h_i might be some hypothesised regularity. In the case of sequences of heads and tails, for instance, h_i might correspond to a particular probability of observing heads, $P(\texttt{H}) = p$. In this case $P(\texttt{HHTHTTTH}|h_i)$ is $p^4(1-p)^4$. Using the calculus of probability, we can obtain $P(x|\text{regular})$ by summing over a set of hypothesized regularities, $\mathcal{H}$,

$$P(x|\text{regular}) \quad = \quad \sum_{h_i \in H} P(x|h_i)P(h_i|\text{regular}) \tag{4}$$

where $P(h_i|\text{regular})$ is a prior probability on h_i. In all applications discussed in this paper, we make the simplifying assumption that $P(h_i|\text{regular})$ is uniform over all $h_i \in \mathcal{H}$. However, we stress that this assumption is not necessary for the models we create, and the prior may in fact differ from uniformity in some realistic judgment contexts.

Random sequences

For the case of binary sequences, such as those that might be produced by flipping a coin, possible regularities can be divided into two classes. One class assumes that flips are independent, and the regularities it contains are assertions about the value of $P(\texttt{H})$. The second class includes regularities that make reference to properties of subsequences containing more than a single element, such as alternation, runs, and symmetries. Since this second class is less well defined, it is instructive to examine the account that can be obtained just by using the first class of regularities.

Taking $\mathcal{H}$ to be all values of $p = P(\texttt{H}) \in [0,1]$, we have $P(H,T|\text{random}) = (\frac{1}{2})^{H+T}$ and $P(H,T|\text{regular}) = \int_0^1 p^H(1-p)^T dp$, where H,T are the sufficient statistics of a particular sequence containing H heads and T tails. Completing the integral, it follows from (3) that

$$\text{random}(H,T) = \log(\tbinom{H+T}{H}) + f(H+T), \tag{5}$$

where $f(H+T)$ is $-\log 2^{H+T} - \log(H+T+1)$, a fixed function of the total number of flips in the sequence. This result has a number of appealing properties. Firstly, it is maximized when $H = T$, which is consistent with Kahneman and Tversky's (1972) original description of the representativeness of random sequences. Secondly, the ratio involved essentially measures the size of the set of sequences sharing the same number of heads and tails. A sequence like HHHHHHHH is unique in its composition, whereas HHTHTTTH has a composition much more commonly obtained by flipping a coin eight times.

The Zenith radio data

Having defined a framework for analyzing the subjective randomness of sequences, we have the opportunity to develop a specific model. One classic data set concerning

the production of random sequences is the Zenith radio data. These data were obtained as a result of an attempt by the Zenith corporation to test the hypothesis that people are sensitive to psychic transmissions. On several occasions in 1937, a radio program took place during which a group of psychics would transmit a randomly generated binary sequence to the receptive minds of their listeners. The listeners were asked to write down the sequence that they received, one element at a time. The binary choices included heads and tails, light and dark, black and white, and several symbols commonly used in tests of psychic abilities, and all sequences contained a total of five symbols. Listeners then mailed in their responses, which were analyzed. These responses demonstrated strong preferences for particular sequences, but there was no systematic effect of the actual sequence that was transmitted (Goodfellow, 1938). The data are thus a rich source of information about response preferences for random sequences. The relative frequencies of the different sequences, collapsed over choice of first symbol, are shown in the upper panel of Figure 1.

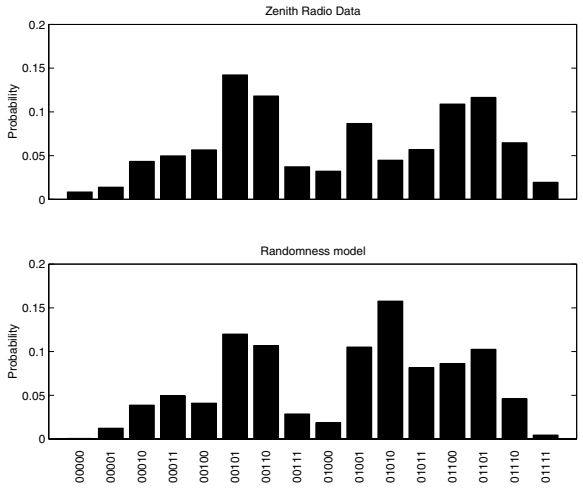

Figure 1: The upper panel shows the original Zenith radio data, representing the responses of 20,099 participants, from Goodfellow (1938). The lower panel shows the predictions of the randomness model. Sequences are collapsed over the initial choice, represented by 0.

Modeling random sequence production

One of the most important characteristics of the Zenith radio data is that people's responses were produced sequentially. In producing each element of the sequence, people had knowledge of the previous elements. Kahneman and Tversky (1972) suggested that in producing such sequences, people pay attention to the local representativeness of their choices – the representativeness of each subsequence.

To capture this idea, we define L_k to be the local representativeness of choosing `H` as the kth response – the extent to which `H` results in a more random outcome than `T`, assessed over the subsequences starting one step back, two steps back, and so forth,

$$L_k = \sum_{i=1}^{k-1} \text{random}(H_i + 1, T_i) - \text{random}(H_i, T_i + 1), \quad (6)$$

where the H_i, T_i are the tallies of heads and tails counting back i steps in the sequence. We can then convert this quantity into a probability using a logistic function, to give a probability distribution for the kth response, R_k:

$$\begin{aligned} P(R_k = \texttt{H}) &= \frac{1}{1 + e^{-\lambda L_k}} \\ &= \frac{1}{1 + \prod_{i=1}^{k-1} \left(\frac{T_i+1}{H_i+1}\right)^{-\lambda}} \quad (7) \\ &= \frac{\prod_{i=1}^{k-1} (T_i+1)^{\lambda}}{\prod_{i=1}^{k-1} (T_i+1)^{\lambda} + \prod_{i=1}^{k-1} (H_i+1)^{\lambda}}. \quad (8) \end{aligned}$$

The λ parameter scales the effect that L_k has on the resulting probability. The probability of the sequence as a whole is then the product of the probabilities of the R_k, and the result defines a probability distribution over the set of binary sequences of length k. This distribution is shown in the lower panel of Figure 1 for $k = 5$.

This simple model provides a remarkably good account of the response preferences people demonstrated in the Zenith radio experiment. There is one clear discrepancy: the model predicts that the sequence `01010`, equivalent to `HTHTH` or `THTHT`, should occur far more often than in the data. We can explain people's avoidance of this sequence by the fact that alternation itself forms a regularity, which could easily be introduced into the hypothesis space. More striking is the account the model gives of the different frequencies of sequences with less apparent regularities, such as `00001` and `00010`. Excluding the discrepant data point, the model gives a parameter-free ordinal correlation $r_s = 0.97$, and with $\lambda = 0.6$ has a linear correlation $r = 0.95$. Interestingly, the model predicts alternation, for sequences that are otherwise equally representative, with a probability of $\frac{1}{1+2^{-\lambda}}$. With the value of λ used in fitting the Zenith radio data, the resulting predicted probability of alternation is 0.6, consistent with previous findings (eg. Falk, 1981).

Pick a number

Research on subjective randomness has focused almost exclusively on sequences, but sequences are not the only stimuli that excite our intuitions about chance. In particular, random numbers loom larger in life than in the literature, although there have been a few studies that have investigated response preferences for numbers between 0 and 9. Kubovy and Psotka (1976) reported the frequency with which people produce numbers between 0 and 9 when asked to pick a number, aggregated across several studies. These results are shown in the upper panel of Figure 2. People showed a clear preference for

the number 7, which Kubovy and Psotka (1976, p. 294) explained with reference to the properties of the numbers involved – for example, 6 is even, and a multiple of 3, but it is harder to find properties of 7. This explanation is suggestive of the kinds of regular generating processes that could be involved in producing numbers. Shepard and Arabie (1979) found that similarity judgments about numbers could be captured by properties like those described by Kubovy and Psotka (1976), such as being even numbers, powers of 2, or occupying special positions such as endpoints.

Taking the arithmetic properties of numbers to constitute hypothetical regularities, we can specify the quantities necessary to compute random(x). Our h_i are sets of numbers that share some property, such as the set of even numbers between 0 and 9. For any h_i, we define $P(x|h_i) = \frac{1}{|h_i|}$ for $x \in h_i$ and 0 otherwise, where $|h_i|$ is the size of the set. This means that observations generated from a regularity are uniformly sampled from that regularity. Setting $P(h_i|\text{regular})$ to give equal weight to all h_i, we can compute $P(x|\text{regular})$.

This model can be applied to the data of Kubovy and Psotka (1976). Since there are ten possible responses, we have $P(x|\text{random}) = \frac{1}{10}$. Taking hypothetical regularities of multiples of 2 ($\{0,2,4,6,8\}$), multiples of 3 ($\{3,6,9\}$), multiples of 5 ($\{0,5\}$), powers of 2 ($\{2,4,8\}$), and endpoints ($\{0\},\{1\},\{9\}$), we obtain the values of random(x) shown in the lower panel of Figure 2. Randomness also needs to be included in $\mathcal{H}$ so that random(x) is defined when x is not in any other regularity. Its inclusion is analogous to the incorporation of a noise process, and is in fact formally identical in this case. The order of the model predictions is a parameter free result, and gives the ordinal correlation $r_s = 0.99$. Applying a single parameter power transformation to the predictions, $y' = (y - \min(y))^{0.98}$, gives $r = 0.95$.

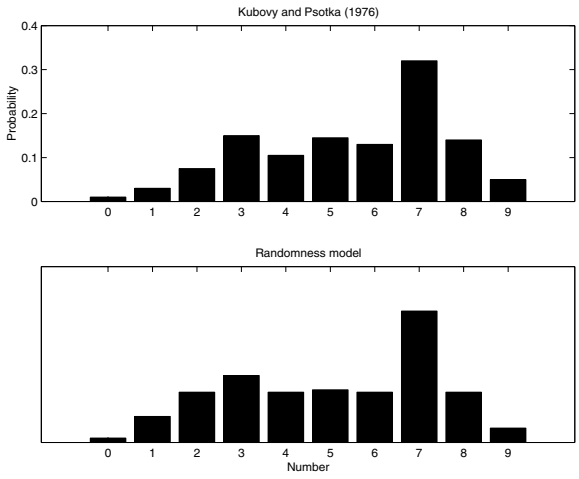

Figure 2: The upper panel shows number production data from Kubovy and Psotka (1976), taken from 1,770 participants choosing numbers between 0 and 9. The lower panel shows the transformed predictions of the randomness model.

Coincidences

The surprising frequency with which unlikely events tend to occur has drawn attention from a number of psychologists and statisticians. Diaconis and Mosteller (1989), in their analysis of such phenomena, define a coincidence as '...a surprising concurrence of events, perceived as meaningfully related, with no apparent causal connection' (p. 853). They go on to suggest that the "surprising" frequency of these events is due to the flexibility that we allow in identifying meaningful relationships. Together with the fact that everyday life provides a vast number of opportunities for coincidences to occur, our willingness to tolerate near misses and to consider each of a number of possible concurrences meaningful contributes to explaining the frequency with which coincidences occur. Diaconis and Mosteller suggested that the surprise that people show at the solution to the Birthday Problem – the fact that only 23 people are required to give a 50% chance of two people sharing the same birthday – suggests that similar neglect of combinatorial growth contributes to the underestimation of the likelihood of coincidences. Psychological research addressing coincidences seems consistent with this view, suggesting that selective memory (Hintzman, Asher, & Stern, 1978) and preferential weighting of first-hand experiences (Falk & MacGregor, 1983) might facilitate the under-estimation of the probability of events.

Not just likelihood...

The above analyses reflect the same bias that made it difficult to construct a probabilistic account of randomness: the notion that people's judgments reflect the likelihood of particular outcomes. Subjectively, coincidences are events that seem unlikely, and are hence surprising when they occur. However, just as with random sequences, sets of events that are equally likely to be produced by a random generating process differ in the degree to which they seem to be coincidences. Following Diaconis and Mosteller's suggestion that the Birthday Problem provides a domain for the investigation of coincidences, consider the kinds of coincidences formed by sets of birthdays. If we meet four people and find out that their birthdays are October 4, October 4, October 4, and October 4, this is a much bigger coincidence than if the same people have birthdays May 14, July 8, August 21, and December 25, despite the fact that these sets of birthdays are equally likely to be observed by chance. The way that these sets of birthdays differ is that one of them contains an obvious regularity: all four birthdays occur on the same day.

Modeling coincidences

Just as sequences differ in the amount of evidence they provide for having been produced by a random generating process, sets of birthdays differ in how much evi-

dence they provide for having been produced by a process that contains regularities. We argue that the amount of evidence that an event provides for a regular generating process will correspond to how big a coincidence it seems, and that this can be computed in the same way as for randomness,

$$\text{coincidence}(x) = \log \frac{P(x|\text{regular})}{P(x|\text{random})}. \qquad (9)$$

To apply this model we have to define the regularities $\mathcal{H}$. For birthdays, these regularities should correspond to relationships that can exist among dates. Our model of coincidences used a set of regularities that reflected proximity in date (from 1 to 30 days), belonging to the same calendar month, and having the same calendar date (eg. January 17, March 17, September 17, December 17). We also assumed that each year consists of 12 months of 30 days each. Thus, for a set of n birthdays, $X = \{x_1, \ldots, x_n\}$, we have $P(X|\text{random}) = (\frac{1}{360})^n$. In defining $P(X|\text{regular})$, we want to respect the fact that regularities among birthdays are still striking even when they are embedded in noise – for instance, February 2, March 26, April 3, June 12, June 12, June 12, June 12, November 22 still provides strong evidence for a regularity in the generating process. To allow the model to tolerate noisy regularities, we can introduce a noise term α into $P(X|h_i)$. The probability calculus lets us integrate out unwanted parameters, so the introduction of a noise process need not result in adding a numerical free parameter to the model. In particular, $P(X|h_i) = \int_0^1 P(X|\alpha, h_i)P(\alpha|h_i)d\alpha$. Assuming that the dates we observe are independent, we have $P(X|\alpha, h_i) = \prod_{x_j \in X} P(x_j|\alpha, h_i)$, and, taking a uniform prior on α, $P(X|h_i)$ is simply $\int_0^1 \prod_{x_j \in X} P(x_j|\alpha, h_i)d\alpha$, where

$$P(x_j|\alpha, h_i) = \begin{cases} \frac{\alpha}{360} + (1-\alpha)\frac{1}{|h_i|} & x_j \in h_i \\ \frac{\alpha}{360} & x_j \notin h_i \end{cases}. \qquad (10)$$

This corresponds to dates being sampled uniformly from the entire year with probability α, and uniformly from the regularity with probability $(1-\alpha)$. The resulting $P(X|h_i)$ can then be substituted into (4), and taking a uniform distribution for $P(h_i|\text{regular})$ gives $P(X|\text{regular})$.

How big a coincidence?

The model outlined above makes strong predictions about the degree to which different sets of birthdays should be judged to constitute coincidences. We conducted a simple experiment to examine these predictions. The participants were 93 undergraduates from Stanford University, participating for partial course credit. Fourteen potential relationships between birthdays were examined, using two sets of dates. Each participant saw one set of dates, in a random order. The dates reflected: 2, 4, 6, and 8 apparently unrelated birthdays, 2 birthdays on the same day, 2 birthdays in 2 days across a month boundary, 4 birthdays on the same day, 4 birthdays in one week across a month boundary, 4 birthdays in the same calendar month, 4 birthdays with the same calendar dates, and 2 same day, 4 same day, and 4 same date with an additional 4 unrelated birthdays, as well as 4 same week with an additional 2 unrelated birthdays. These dates were delivered in a questionnaire. Each participant was instructed to rate how big a coincidence each set of dates was, using a scale in which 1 denoted no coincidence and 10 denoted a very big coincidence.

The results of the experiment and the model predictions are shown in the top and middle panels of Figure 3 respectively . Again, the ordinal predictions of the model are parameter free, with $r_s = 0.94$. Applying the transformation $y' = (y - \min(y))^{0.48}$, gives $r = 0.95$. The main discrepancies between the model and the data are the four birthdays that occur in the same calendar month, and the ordering of the random dates. The former could be addressed by increasing the prior probability given to the regularity of being in the same calendar month – clearly this was given greater weight by the participants than by the model. Explaining the increase in the judged coincidence with larger sets of unrelated dates is more difficult, but may be a result of opportunistic coincidences: as more dates are provided, participants have more opportunities to identify complex regularities or find dates of personal relevance. This process can be incorporated into the model, at the cost of greater complexity.

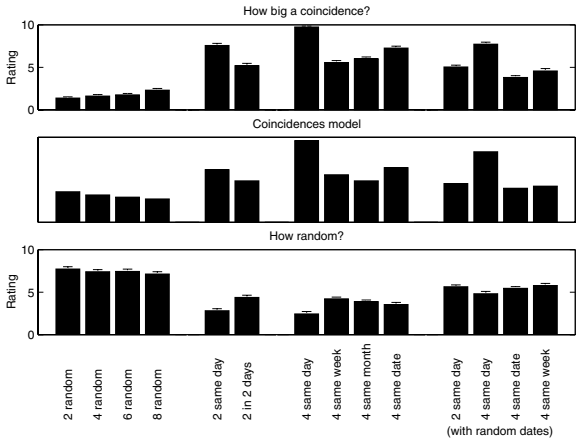

Figure 3: The top panel shows the judged extent of coincidence for each set of dates. The middle panel is the predictions of the coincidences model, subjected to a transformation described in the text. The bottom panel shows randomness judgments for the same stimuli.

Relating randomness and coincidences

Judgments of randomness and coincidences both reflect the evidence that a set of observations provides for having been produced by a particular generating process. Events that provide good evidence for a random generating process are viewed as random, while events that provide evidence for a generating process incorporating some regularity seem like coincidences. By examining

(3) and (9), we see that these phenomena are formally identified as inversely related: coincidences are events that deviate from our notions of randomness.

We conducted a further experiment to see if this relationship was borne out in people's judgments. Participants were 120 undergraduates from Stanford University, participating for partial course credit. The dates were the same as those used previously, and delivered in similar format. Each participant was instructed to rate how random each set of dates was, using a scale in which 1 denoted not at all random and 10 denoted very random.

The results of this experiment are shown in the bottom panel of Figure 3. The correlation between the randomness judgments and the coincidence judgments is $r = -0.94$, consistent with the hypothesis that randomness and coincidences are inversely linearly related. The main discrepancy between the two data sets is that the addition of unrelated dates seems to affect randomness judgments more than coincidence judgments.

Conclusion

The models we have discussed in this paper provide a connection between people's intuitions about chance, expressed in judgments about randomness and coincidences, and the formal structure of probability theory. This connection depends upon changing the way we model questions about probability. Rather than considering the likelihood of events being produced by a particular generating process, our models address the question of how much more likely a set of events makes a particular generating process. This is a structural inference, drawing conclusions about the world from observed data. Framed in this way, people's judgments are revealed to accurately approximate the statistical evidence that observations provide for having been produced by a particular generating process. The apparent inaccuracy of our intuitions may thus be a result of considering normative theories based upon the likelihood of events rather than the evidence they provide for a structural inference.

Abstract

The hypothesis that category descriptions are interpreted narrowly, in terms of representative instances, is examined by comparing probability judgments for packed descriptions of events to judgments for coextensional unpacked descriptions. The representativeness of the unpacked instance was varied along with the type of unpacking (direct vs. priming). In contrast to the prediction of Support Theory (Tversky & Koehler, 1994), we found no evidence that unpacking has a nonnegative effect on probability judgments (subadditivity). Instead, we found a negative effect with low representative direct unpackings (superadditivity). Our data suggest that probability judgments are proportional to the typicality of instances in the description.

Introduction

People frequently assess the probability of uncertain events such as the chance of rain or the success rate of a medical treatment. Such probability assessments are important because they determine not only whether to plan a barbecue, but also whether or not to have surgery. Judgments concerning rain or effectiveness of a treatment are categorical in the sense that the event being judged could be instantiated in many ways. We consider whether the typicality of the instances used in a categorical description affects the judged probability of corresponding events.

Normative models of probability judgment assume *description invariance*: the probability of an event does not depend on how the event is described. This assumption is descriptively invalid (Tversky & Kahneman, 1986). People give lower probability ratings for the packed hypothesis "Death from homicide, rather than accidental death" than for the coextensional unpacked hypothesis "Death from homicide by an acquaintance or by a stranger, rather than accidental death" (Rottenstreich & Tversky, 1997).

Support for Support Theory?

To accommodate this fact, Tversky and Koehler (1994) proposed a descriptive theory of probability judgment, Support Theory, that suggests that subjective probabilities are assigned not to events, but to descriptions of events or *hypotheses*. Probability judgments are hypothesized to be mediated by evaluations of evidence for and against a hypothesis. Specifically, the judged probability of a hypothesis H rather than an alternative hypothesis A is given by:

$$(1) \quad \text{Judged } P(H, A) = s(H) / [s(H) + s(A)]$$

where s(X) is a global measure of support for hypothesis X. It is a sum of the (weighted) support of all representative instances of X that are available to the judge at the time of evaluation.

A key assumption of Support Theory is that exhaustively unpacking a hypothesis H into mutually exclusive and exhaustive sub-hypotheses ($H_1 \vee \ldots \vee H_n$) can increase the support for H:

$$(2) \quad s(H) \leq s(H_1 \vee \ldots \vee H_n)$$

This assumption is motivated on the grounds that unpacking may bring additional instances to mind, or increase the salience of the unpacked instances. Either or both of these effects would increase the perceived support for a hypothesis.

Taken together, Support Theory's assumptions predict implicit subadditivity: The judged probability of an implicit (or packed) hypothesis H is no greater than the judged probability of a coextensional unpacked hypothesis. Implicit subadditivity has been observed several times (see Rottenstreich & Tversky, 1997).

However, not all the data are so supportive. Hadjichristidis et al. (1999) showed that selectively unpacking hypotheses into components that enjoy low levels of support results in the opposite phenomenon, implicit superadditivity. To illustrate, students gave higher probability estimates for the packed hypothesis "death from a natural cause" than for its coextensional unpacked counterpart "death from asthma, the flu, or some other natural cause." In a series of follow-up studies we have consistently found implicit superadditivity with novel categories unpacked with atypical instances. We have consistently failed to find implicit subadditivity, even when events were unpacked using representative instances, instances that enjoy high levels of support. In sum, contrary to support theory's predictions, these data suggest that unpacking does not always increase subjective probability judgments.

The Supported Theory

A parsimonious interpretation of our data is based on Support Theory's own assumption that people interpret category-based hypotheses narrowly, in terms of representative instances. Unpacking unrepresentative instances induces superadditivity by making instances of very low support part of what is judged. Unpacking representative instances leaves probability judgments unaffected because packed categories are interpreted in terms of representative instances.

Unlike Support Theory, we suggest that unpacking can decrease support. According to the present proposal, people assess the likelihood of a category-based hypothesis by thinking about instances in which the event is expected to occur (i.e., by bringing to mind representative instances, instances enjoying high levels of support). This dovetails with Kahneman and Miller's (1986) proposal that norms—contrast events for judgments of surprise, blame, etc.—are constructed according to the availability and representativeness of exemplars. Our proposal is that the determinants of exemplar retrieval control not only how contrast events are conceived, but how focal ones are too. Moreover, the mere availability in memory of an instance is not sufficient to change judgments of likelihood, the instance must be one of the objects of judgment.

Study

The current study tests our hypothesis by crossing representativeness (high- vs. low-representative instances) with type of unpacking (direct vs. priming) in a between-participants design. A separate group of participants was asked to provide estimates for corresponding packed hypotheses. The dependent measure was subjective probability judgment. Table 1 gives one illustration from each of the five experimental conditions.

Table 1: An example stimulus from each of the five conditions. The sentence in bold-faced letters is a description that preceded evaluations in all conditions.

	Sarah is a very energetic and happy eight year old who loves playing with her stuffed animals.
Packed	How likely is it that Sarah hates some types of pets (as opposed to loving all pets)? _____
Direct High Rep	How likely is it that Sarah hates tarantulas or some other types of pets (as opposed to loving all pets)? _____
Direct Low Rep	How likely is it that Sarah hates horses or some other types of pets (as opposed to loving all pets)? _____
Priming High Rep	Same as packed but prior to making the judgment primed with a list of words including "tarantulas"
Priming Low Rep	Same as packed but prior to making the judgment primed with a list of words including "horses"

Direct unpacking refers to a conventional unpacking manipulation. Participants in the direct unpacking conditions were asked to judge categories from which one of their instances had been unpacked. Based on previous findings, we expected to find a negative effect of unpacking unrepresentative instances (i.e., implicit superadditivity), and no effect of unpacking representative instances.

Participants in the priming unpacked conditions were asked to judge packed hypotheses after being primed with either representative or unrepresentative instances. Priming consisted of asking participants to study the instances for 1 min. for a later memory test. We reasoned that priming would make the critical instances highly available in memory at the time of judgment without specifically making them the objects of judgment. If merely making an instance available in memory increases the likelihood that it will be considered during judgment of a category that is superordinate to it, then superadditivity should be observed in the Priming Low Representativeness condition (i.e., probability judgments should be higher in the Packed condition than the Priming Low Representativeness condition) and additivity should be observed in the Priming High Representativeness Condition. However, if the availability of an instance is not sufficient, if a narrow interpretation of categories is so ingrained that making atypical instances available in memory does not influence how people conceive of the category being judged, then the priming unpacking conditions should produce additive judgments. That is, we should see no effect of the priming manipulation.

The availability hypothesis predicts a main effect of representativeness and no effect of type of unpacking.

The narrow interpretation hypothesis predicts a Representativeness by Unpacking interaction due to a negative effect of low representativeness in the direct unpacking condition and no other differences.

Method

162 first-year students participated in the experiment, 76 sampled at the University of Durham (UK), and 86 at the University of North Carolina at Greensboro (US). Participants were presented with booklets containing eight examples from one of the 5 experimental conditions, followed by 16 items asking for judgments of representativeness. The judgments of representativeness were obtained as a validation check on the assignment of examples in the high- and low-representativeness conditions.

Results

Representativeness judgments

Table 2 presents mean representativeness estimates for both populations for High Rep and Low Rep conditions. As expected, ratings for "High Representativeness" items were much higher than those for "Low Representativeness" items.

Table 2: Mean Population by Representativeness subjective representativeness estimates.

	High Rep	Low Rep
Greensboro	65.7	34.3
Durham	61.4	30.0

To make sure our UK and US population samples were comparable, we conducted a 2 (Population) by 2 (Representativeness) repeated-measures ANOVA across items. The main effect of representativeness was highly significant ($F(1,14)=23.33$, $p<.001$). There was also a main effect of population, US probability judgments were about 4 percentage points higher than UK judgments ($F(1,14)=4.55$, $p<.06$). Most importantly, no interaction was observed ($F<1$). The results justify the assignment of items to High- or Low-representativeness conditions.

An examination of the judgments for each item showed that the direction of representativeness judgments for one were opposite to our expectations. This item was excluded from subsequent analyses.

Probability Judgments

Population To test whether population influenced probability judgments, we performed a 2 Population by 5 Experimental condition ANOVA across participants. Only Experimental condition reached significance ($F(4,151)=5.18$, $p<.001$). The data for the two populations were combined for subsequent analyses.

Unpacking by Representativeness Table 3 presents mean subjective probability judgments for each Unpacking (direct vs. priming) and Representativeness (high vs. low) condition. The mean of the direct low-representativeness cell is the lowest; means of the other cells are about equal.

Table 3: Mean probability judgments by Type of unpacking and Representativeness.

	High Rep	Low Rep
Direct	57.3	44.6
Priming	55.1	55.0
Packed	56.2	

The data were analyzed by two 2 Unpacking by 2 Representativeness analyses of variance, one by participants (F_1) and one by items (F_2). Unpacking had a significant main effect by participants but not by items ($F_1(1,124)=3.96$, $p<.05$; $F_2(1,6)=1.87$, $p>.22$). Representativeness had a significant main effect by participants ($F_1(1,124)=9.71$, $p<.005$) but only a marginal effect by items ($F_2(1,6)=3.03$, $p<.14$). The interaction was significant by participants ($F_1(1,124)=9.37$, $p<.005$) but only marginally by items ($F_2(1,6)=3.08$, $p<.14$).

Two-tailed t-tests compared each Unpacking by Representativeness condition to the rest. The only tests reaching significance were those comparing the direct low-representativeness condition to each of the others.

Superadditivity Mean probability ratings for each of the four Unpacking by Representativeness conditions were compared to the mean rating for the packed condition (M=56.2) to detect deviations from additivity. The only condition that deviated substantially from additivity was the direct low-representativeness condition that demonstrated superadditivity: $t(61) = 3.27$, $p < .005$ (participants); $t(6) = 2.51$, $p < .05$ (items). The item analysis for the direct high-representativeness condition suggested a small amount of subaddivity: $t(6) = 2.43$, $p < .06$; but $t < 1$ (participants).

Discussion

The present study investigated the hypothesis that people interpret category descriptions narrowly, in terms of representative instances, when making subjective probability judgments by crossing representativeness with type of unpacking. We found a representativeness by unpacking interaction due to a negative effect of low representativeness in the direct unpacked condition. Only the direct low-representativeness ratings substantially deviated from

additivity: they were superadditive. Predictions were confirmed with both British and US samples.

The present data replicated Hadjichristidis et al.'s (1999) finding that directly unpacking unrepresentative instances induces implicit superadditivity. One account of these findings is that unpacked instances are treated as a pragmatic cue for determining what the experimenter means by the category label. When asked about "tarantulas or some other type of pet," people might infer that the experimenter has a different category in mind than when asked only about "pets." This account is indeed consistent with our data, but only if construed in a way equivalent to our hypothesis. The data suggest that people interpret categories narrowly and the explicit inclusion of atypical instances broadens the normal interpretation. But our methodology rules out the interpretation that we are merely asking people to a judge different category in the Low Representativeness condition. In every case, categories were described in the current study by clearly stating the alternative hypothesis (e.g., in Table 1, the judged event is always stated along with "as opposed to loving all pets"). Therefore, although we believe our effect depends on how categories are interpreted, it does not represent a mere task demand induced by pragmatic biases. Rather, it represents a central and generalizable aspect of probability judgment of categorical events.

Support theory Our finding that direct unpacking of low representative instances induces superadditivity disconfirms support theory's prediction that unpacking cannot have a negative effect on probability judgments. Our conclusion is independently supported by Macchi, Osherson, and Krantz (1999) who found that unpacking low-support instances resulted in explicit superadditivity for binary partitions.

Implicit subadditivity is not a robust phenomenon. Rottenstreich and Tversky (1997) themselves predicted it three times, but only observed it twice. Implicit subadditivity obtained in the Trial problem, which pitted the hypothesis "the trial will not result in a guilty verdict" against the disjunction "the trial will result in a not guilty verdict or a hung jury". It also obtained in the Homicide problem, which pitted "death from homicide" against "death from homicide by an acquaintance or a stranger". In both cases, they explained subadditivity in terms of enhanced availability. In the first problem, participants might not have considered the hung jury possibility in the packed condition. In the second, the unpacked hypotheses may have brought a host of possible causes of death to mind (e.g., crimes of passion) that would not have been available in the packed condition. In sum, support theorists have themselves identified a key factor that limits the generality of implicit subadditivity.

We believe that minor modifications would allow Support Theory to capture superadditive probability judgments. Here are some possible changes:

1. Allow for negative support.
2. Stick to nonnegative support, but modify the global support function (make it average rather than summed support).
3. Allow that unpacked instances replace instances that would otherwise have been available at the time of judgment.

Dynamic global support functions? A further possibility is that implicit subadditivity and superadditivity reflect different functional relations between the support attached to packed categories and the support attached to their unpacked instances (global support functions). Subadditivity may involve summing of support across instances, whereas superadditivity may involve averaging of support. In Rottenstreich and Tversky's (1997) examples, support is based on subjective impressions of frequencies or reasons, whereas in our "natural fuzzy category" examples (e.g. pets, restaurants), support is based on similarity. The support for the unpacked hypothesis of the Trial problem, for instance, seems to involve estimating the relative frequency of a "not guilty verdict" and a "hung jury" and adding them up. In contrast, the support for the unpacked hypotheses in our examples seems to involve estimating the similarity of the category instances to the description and averaging them out. Corroborating evidence that the similarity-based global support function may average support comes from Rottenstreich, Brenner, and Sood (1999) who showed that similarity-based likelihood judgment gives rise to nonmonotonicities: the support of a disjunction is less than that of one of its components. They presented participants with a description of Linda: an outspoken, socially conscious, and single woman. "Linda is a journalist" enjoyed higher support than the disjunctive hypothesis "Linda is a journalist or a realtor". Nonmonotonicities cannot be explained by a global support function that adds support, but could by one that averages support.

In sum, the global support function may change dynamically depending on the particular base of support –e.g. objective frequencies, similarity, and reasons. Similarity-based likelihood judgment may involve averaging; frequency-based likelihood judgment may involve summing. Supporting this hypothesis, Rottenstreich et al. (1999) showed that case judgments (e.g., the Linda example) that presumably involve similarity-based reasoning give rise to nonmonotonicities, whereas class judgments (e.g., the probability that a randomly selected American is a

journalist) that presumably promote frequency-based reasoning, do not. These suggestions all stay close to the spirit of Support Theory because we find its assumption that probability judgments are mediated by judgments of evidence to be appealing and worth maintaining in the next generation of descriptive theory (see also Fischhoff, Slovic, & Lichtenstein, 1979).

Decision-making Much everyday decision-making depends on subjective assessments of probability. For instance, the premium one is willing to pay for health insurance depends on a subjective assessment of the likelihood of getting hospitalized for the cases that the health insurance covers (see Johnson et al., 1993). The events for which an insurance provides coverage can be described in many ways. The results we report here can presumably be extended to the domain of decision-making.

Abstract

We propose that when evaluating conditionals, people construct an imaginary world that contains the antecedent, and then evaluate the plausibility of the consequent being true in the same world. Thus, when asked for an estimate of the probability of the conditional, people should produce the conditional probability of its consequent given its antecedent. We contrast this view with a view based on the theory of mental models, in which the judged probability of a conditional is derived from the proportion of models in which the premises are true. Study 1 examined this hypothesis by comparing probability estimates for (i) category-based conditional arguments (e.g. *If robins have ulnar arteries then sparrows have ulnar arteries*), (ii) corresponding conditional probabilities in the form of suppositions (e.g. *Suppose you knew that robins have ulnar arteries. How likely would you think it was that sparrows have ulnar arteries?*) and (iii) the argument strength of corresponding inductive arguments (e.g. *Fact: Robins have ulnar arteries. Therefore: Sparrows have ulnar arteries. How convincing do you find this argument?*) All three estimates were highly correlated, a finding that supports our hypothesis. The similarity between the two categories (e.g. robins and sparrows) was also manipulated. Similarity affected all three estimates equally, similar items being given higher estimates than dissimilar items. This finding indicates that similarity is one basis for the plausibility judgements. Study 2 tested our hypothesis using conditional statements with known probabilities. The results favoured our hypothesis. We discuss these results in terms of philosophical and psychological views of conditionals, and suggest that they bring together kinds of reasoning that are traditionally studied separately, such as conditional reasoning, induction, and judgements of probability.

Introduction

Psychological research on inductive and deductive reasoning has traditionally examined reasoning based on premises classified as true. Such research ignores most everyday reasoning, which is based on uncertain premises. Premise uncertainty, in turn, rightly influences the degree of certainty in the conclusion of an inference (e.g. Stevenson & Over, 1995). Understanding everyday reasoning, therefore, involves understanding subjective premise uncertainty, and the way in which such uncertainty gets translated into uncertainty about the conclusion of an inference. The present article investigates subjective uncertainty about conditional premises of the form *If p then q*.

The article focuses on the way in which people evaluate conditional arguments and how they arrive at judgements of the probability of a conditional. We propose that people evaluate conditionals with reference to imaginary situations that they mentally

construct; in particular, people evaluate the plausibility of the consequent in an imaginary situation in which the antecedent is true. For example, on encountering the conditional *If you study hard then you will pass the exam,* we propose that reasoners mentally construct an imaginary situation in which they study hard and then pass the exam. This imagined situation may be judged more plausible than one in which they study hard and do not pass the exam. Such a judgement might be mediated by causal schemas, e.g. one's intuitive theories about studying and success or failure (Collins & Michalski, 1989). In other situations, similarity (Osherson et al, 1991) or a judgmental heuristic, such as representativeness or availability (Kahneman et al, 1982) might be used. If people do indeed evaluate conditionals in the above manner, then when asked to estimate the probability of the conditional, they should state the probability of the consequent given that the antecedent is true; that is, they should give the conditional probability.

The view presented above is similar to Ramsey's (1931) notion of how a conditional is evaluated, and also has some similarities to proposals made by Adams (1975) and Edgington (1995). Ramsey's idea was that when we evaluate a conditional, we add the antecedent to our stock of beliefs, leaving everything else as undisturbed as possible, and then examine whether our new stock of beliefs contains the consequent. Our proposal that people construct an imaginary world that contains the antecedent is comparable to updating one's knowledge base by adding the antecedent and making the minimal changes resulting from the presence of the antecedent. People then assess the likelihood that the consequent also holds, using either heuristics or sometimes beliefs about relative frequencies. The psychological validity of this "imaginary worlds" view of conditionals has not yet been tested, although conditionals have been linked to conditional probabilities in other psychological work (Stevenson & Over, 1995; Oaksford, Chater, & Larkin, 2000). The present experiments test this view.

The mental models theory provides a contrasting view of how individuals untrained in logic evaluate the probability of conditional statements. Johnson-Laird et al. (1999) propose that such individuals infer the probability of events by reasoning extensionally. They construct mental models representing true possibilities (the *principle of truth*) and estimate the sum of the probabilities of the models in which the event occurs. *If p then q* conditionals are understood by representing up to the following three explicit mental models (¬ stands for the negation of a premise):

p q
¬ p q
¬ p ¬ q

"p ¬q" is not represented because it is a false possibility, though it can be inferred as the complement of the fully explicit models, although this rarely happens (see Barres & Johnson-Laird, 1997). However, consideration of the false possibility is critical for the conditional probability interpretation of conditional statements; the conditional probability of q/p depends on the relative ratio of *pq* to *p¬q* possibilities, i.e. Pr(q/p) = Pr(pq)/ [Pr(pq)+Pr(p¬q)]. Therefore, evidence for a conditional probability interpretation of conditional statements would challenge the mental models theory.

Study 1: Subjective probabilities

In Study 1 we compare the imaginary world hypothesis with the mental models hypothesis by obtaining judgements of (1) the probabilities of conditional arguments, (2) conditional probabilities, and (3) judgments of the convincingness of inductive arguments, that is, judgements of argument strength. Examples of the materials are shown in Table 1.

We propose that when asked to estimate the probability of the conditional shown on the top panel of Table 1, participants will evaluate the conditional in the same way as they evaluate the conclusion of the conditional probability statement shown in the middle panel of Table 1. That is, the reasoning in both cases will be based on the same representation, an imaginary world in which horses have stenozoidal cells and in which the plausibility of cows having stenozoidal cells is assessed.

We also propose that participants evaluate inductive arguments, like the one in the last panel of Table 1, in a similar way. Inductive argument tasks ask participants to assume that p is a fact. Our hypothesis, that when judging the probability of conditional, people imagine a world in which p is true and make judgements about that world, predicts that they should give the same judgement as they give when explicitly told that p is in fact true (i.e., when making argument strength judgements).

Because an imaginary world in which both horses and cows share a property is more representative of the real situation than a world in which horses have the property but cows don't, we expect all three types of judgments to be relatively high. Furthermore, we expect the probability of the conditional to be highly correlated with the conditional probability judgements on the one hand and judgements of argument strength on the other, since we argue that they all measure the same process. Note that an association between argument strength and conditional probability judgements has been presupposed in psychological research (e.g. by Sloman, 1998). By contrast, the mental models view of conditionals does not consider the case in which horses

have the relevant property but cows do not. Consequently it would not predict that judgements of the probability of the conditional would be highly related to either conditional probability judgements or argument strength judgements.

Table 1. Study 1: An example of materials used in Study 1. [Note: The example is from the similar condition. Half of the materials were in the dissimilar condition.]

Probability of conditional condition
Peter said the following: If horses have stenozoidal cells, then cows will have stenozoidal cells. How likely do you think it is that what Peter said is true?
0 1 2 3 4 5 6 7 8 9 10
not at all likely very likely
Conditional probability condition
Suppose you knew that horses have stenozoidal cells. How likely would you think it was that cows have stenozoidal cells?
0 1 2 3 4 5 6 7 8 9 10
not at all likely very likely
Inductive argument condition
Fact: Horses have stenozoidal cells

Conclusion: Cows have stenozoidal cells
0 1 2 3 4 5 6 7 8 9 10
not at all convincing very convincing

Study 1 also examined the hypothesis that the similarity between the two categories mediates the judgments in all three conditions. The more similar the categories, the more structure (features and dependencies) their representations share. Thus people are likely to infer that the more known structure two categories share, the more novel structure they are likely to share. We expect, for instance, an imaginary situation, in which similar categories (e.g. cows and horses) share a novel property, will be judged more plausible than an imaginary situation, in which dissimilar categories (e.g. cows and mice) share a novel property. (See Osherson et al, 1991, for a model of how conditional probabilities can be derived from similarity judgements.) Consistent with our view, research on category-based inductive arguments (like the one in the last panel of Table 1) has shown a robust effect of similarity (see e.g. Rips, 1975; Sloman, 1993). Moreover, to the extent that such similarity-based reasoning is non-extensional (see Johnson-Laird et al., 1999), it falls outside the scope of mental models theory, which only considers extensional reasoning.

Method

Participants. Forty-one first-year psychology students volunteered to participate in this study.

Design. Type of Measure (probability of conditional vs. conditional probability vs. argument strength) was crossed with Similarity (similar vs. dissimilar category pairs) in a mixed design with repeated measures on the last factor.

Procedure. Participants were presented with booklets containing 18 examples in one Type of Measure condition. Half of the examples in each condition contained similar and half dissimilar mammal pairs. The assignment of category pairs to similarity conditions was controlled by an independent group of twelve participants who were asked to rate the biological similarity of the 16 mammal pairs in a 0-10 scale, were 0 was labeled as "highly dissimilar" and 10 as "highly similar." The mean ratings for the similar and dissimilar items were, respectively, 7.39 (min=5.92, max=8.92) and 1.74 (min=.92, max=2.33). The results therefore justify the assignment of items to the similar or dissimilar conditions.

Participants in the probability of the conditional condition (N=16) were told that they would be presented with statements uttered by a person. Their task was to say how likely they thought it was that what the person said was true on a 0-10 scale, where 0 was labeled as "not at all likely" and 10 as "very likely." We used this task to obtain judgements of the probability of the conditional to ensure that our instructions did not encourage participants to give conditional probability judgements for superficial reasons[1]. If participants were simply asked "How likely do you think it is that *If p then q?*" they might interpret the question as asking the question "If p, what is the probability that q?" That is, as a direct request for the conditional probability of the consequent given the antecedent. This problem arises because a conditional consists of a main (the consequent) and a subordinate (the antecedent) clause, and it has been shown that, when processing sentences containing main and subordinate clauses, people often assume that the subordinate clause is true (Baker & Wagner, 1987). Our instructions were designed, therefore, to avoid responses based on this kind of linguistic paraphrase and to ensure instead that they were based on a conceptual understanding of the conditional.

Participants in the conditional probability condition (N=10) were told that they would be presented with examples asking them to suppose that a statement is

[1] We thank Phil Johnson-Laird and Vittorio Girotto for suggesting these instructions for the framing of the conditional probability condition.

true. Based upon this supposition, they had to judge the likelihood that a second statement is true. The same scale was used as for the Probability of the conditional participants. Participants in the argument strength condition (N=15) were told that they would be presented with a series of arguments, each containing a fact (which should be taken as true) separated from a conclusion by a line. Their task was to describe how convincing they found each argument on a 0-10 scale, where 0 was labeled as "not at all convincing" and 10 as "very convincing." Participants in all conditions worked through examples similar to the test items before starting the experiment.

Results and Discussion

Correlation statistics Table 2 presents the mean correlation coefficients relating the three types of measures across items. As predicted by the imaginary worlds view, the three measures were significantly correlated (beyond the .001 level).

Table 2. Mean correlation coefficients by items for each of the three conditions. CP=conditional probability. PC=probability of conditional. AS=argument strength.

	PC	*CP*	*AS*
PC	*1.0*	*.99*	*.94*
CP		*1.0*	*.96*
AS			*1.0*

Similarity Table 3 presents mean Type of measure by Similarity estimates. In each Type of measure condition, ratings for similar items were higher than ratings for dissimilar items.

Table 3. Mean Type of Measure by Similarity estimates CP=conditional probability. PC=probability of conditional. AS=argument strength.

	Similar Items	Dissimilar Items
PC	5.78	2.76
CP	6.66	2.83
AS	5.40	2.30

The data from each measure were analyzed by pairwise t-tests for participants, and independent t-tests for items. Pairwise tests were used in preference to a single ANOVA because we cannot assume that the three measures are comparable. For each type of measure, both across participants and items, similarity had a significant effect (beyond the .005 level). These results suggest that the plausibility judgements underlying the imaginary worlds view can be influenced by similarity. The mental models view, however, cannot account for either the correlational results or the effect of similarity.

Study 2: Objective probabilities

Study 2 also investigated how people evaluate conditional statements but with conditionals of known conditional probabilities. The use of known probabilities provides a direct test of our two competing hypotheses, because it allows judgements about the probability of the conditional to be directly compared with the objective conditional probability.

Participants were given three different versions of a text describing a probability problem. For example, a third of the participants read the following text and were then asked to estimate the probability that what Peter said was true:

> In an effort to boost its image, Waterstones bookstore organised lotteries in several Primary schools in Durham. In each school, only the 10 best students participated in the lottery. The name of each participant was written on a piece of paper and was put in a hat. A blindfolded teacher drew a piece of paper from the hat. The student whose name was written on that paper won an autographed storybook. In Durham Gilesgate Primary School the participants were 8 boys and 2 girls. A piece of paper was drawn from the hat. Peter, the father of one of the participants, cannot see the winner's name but says: "If a boy has won the lottery, then my son won it."

According to the imaginary world hypothesis, participants should construct an imaginary situation in which a boy wins the lottery and then consider how likely it is that the boy is Peter's son. Since there are 8 boys all together, this conditional probability is 1/8.

According to the theory of mental models, the correct answer depends upon considering the fully explicit models of the proposition and finding the proportion of models in which the proposition is true. These explicit models, which represent the true possibilities, are shown below, with tags indicating their relative frequencies. (*Boy* stands for the antecedent; *Son* stands for the consequent).

Boy	Son	1/10
¬Boy	Son	0[2]
¬Boy	¬Son	2/10

The proportion of models, therefore, in which the proposition is true is 3/10. We call this the material implication (MI) evaluation of the conditional.

[2] No doubt participants will rule out the possibility of ¬*Boy and Son* on pragmatic grounds. However, for the above problem, this does not affect the predicted probability judgement.

The probability estimates that agreed with one or other of these two evaluations (the conditional probability or material implication) were coded as supportive of either the imaginary world view or the mental models view respectively.

Method

Participants Forty-eight first-year undergraduate volunteers participated in Study 2. The sample included the same forty-one students that participated in Study 1.

Procedure Each participant was presented with a booklet containing one version of the problem given above. In one version the sample of children consisted of 2 boys and 8 girls (the 2b-8g version), in a second of 5 boys and 5 girls (the 5b-5g version), and in a third of 8 boys and 2 girls (the 8b-2g version). Table 4 lists the predictions for the imaginary world and the mental models view for each of the three versions of the problem.

Table 4. Conditional probability and material implication predictions for each of the 3 versions of the problem.

	Imaginary world view (Conditional probability)	Mental models view (Material implication)
2b-8g version	1/2	9/10
5b-5g version	1/5	6/10
8b-2g version	1/8	3/10

Results

Table 5 presents the number of participants in each version of the problem whose response agrees with one of the two evaluation modes for each version. Out of the 48 participants, 44 gave numerical answers.

Table 5. Number of participants in each version whose response falls in one of the two evaluation modes. N=number of participants who gave a numerical response for each version.

	N	Imaginary world View	Mental models view
2b-8g version	13	9	0
5b-5g version	14	5	0
8b-2g version	17	9	1
Total	*44*	*23*	*1*

Out of those 44, 24 gave a response that could be classified in one of the two response modes. The results reported in Table 5, therefore, account for 55% of those responses. The results of all except one of these 24 participants agreed with the conditional probability evaluation (X^2 = 20.17). These data clearly favor the imaginary worlds view of conditionals over the mental models view.

The main numeric responses made by the remaining 20 participants were "1/10" or its arithmetic equivalent (N=6), "1/2" or its arithmetic equivalent (N=7), "2/10" or arithmetic equivalent (N=5)[3]. The "1/10" responses are consistent with the mental models view that participants represent an explicit model of the premise and ignore other possibilities. The remaining two responses may reflect failures to understand the conditional.

General Discussion

These results with both subjective and objective probabilities support the imaginary worlds view. Judgements of the probability of a conditional correlated highly with conditional probability judgements and argument strength judgements in Study 1, and they matched the objective conditional probabilities in Study 2. Mental models theory cannot explain these results because it only considers true possibilities. Even if we grant that mental models theory allows that the false possibility may be inferred, the theory still cannot explain our results because it has no mechanism for calculating conditional probabilities when presented with a conditional (see Johnson-Laird et al, 1999).

Furthermore, mental models theory fails to explain the similarity effect found in Study 1. By contrast, this effect follows from the imaginary worlds view, which claims that reasoners evaluate conditionals by representing the antecedent and consequent in an imaginary world and then evaluating the plausibility of this world. Since similarity is a key component of plausible reasoning (Osherson et al, 1991), it follows that similarity should also be a key component in judgements of the plausibility of the consequent being true in a world in which the antecedent is true.

The results of Study 2 also suggest that explicitly presenting the negated antecedent is, in itself, insufficient to promote its inclusion in a mental representation. People might represent such possibilities when background knowledge makes them salient. For example, "If John is in Paris then he is in France" might make people represent the possibility "If John is not in Paris then he is not in France." But as far as the basic evaluation of a conditional is concerned, our results

[3] Some of the responses in the 2b-8g version that are classified as "conditional probability" responses may in fact be "fifty/fifty" responses. However, even if the 2b-8g version is omitted from the analysis, the results still clearly favor the conditional probability view.

suggest that people construct an imaginary world in which the antecedent holds and then consider the likelihood that the consequent holds in the same world.

Our notion of imaginary worlds could be seen as an example of mental models. However, our results suggest that mental models are represented and deployed in ways other than those proposed by Johnson-Laird (e.g. Johnson-Laird et al, 1999) when evaluating the probability of conditionals. For example, the principle of truth cannot apply to uncertain conditionals, since the "false possibility" (p ¬q), must be at least implicitly considered to arrive at the conditional probability. Furthermore, the role of similarity in evaluating an uncertain conditional needs to be included in such a theory.

Our proposal has something in common with possible worlds analyses of ordinary conditionals (Stalnaker, 1968; Lewis, 1973). However, if these conditionals are analyzed in this way in formal semantics, then there are technical reasons why the probability of a conditional cannot be absolutely identified with the corresponding conditional probability. (See Jackson, 1991, for the main technical papers on this issue.) But the technical issue not withstanding, there is reason to hold that the assertion and evaluation of most ordinary conditionals will make them closely related to the corresponding conditional probabilities (Stevenson & Over, 1995; Edgington, 1995). This is all we need for our psychological claims here. Our view is that the judged probability of an ordinary conditional will usually be estimated by assessing the plausibility of the consequent being present in a model that contains the antecedent. Finally, since our views derive from philosophical accounts of conditionals, the present studies also provide a bridge between philosophical and psychological accounts of If p the q conditionals. They also bring together components of reasoning that have been traditionally studied separately such as conditional reasoning, induction, and judgements of probability.

Abstract

Marcus (1998) and Phillips (2000) each have produced examples of human *generalizations* which, they argue, cannot be matched by the best known connectionist architectures and training algorithms. However, I argue that humans perform the crucial generalizations *without being trained* on the exemplars that Marcus and Phillips cite. So, in a sense, the issue whether networks can be trained to perform the crucial generalizations is a red herring. I argue further that humans achieve the dramatic generalizations in question as a side-effect of a variety of *pre-existing* skills, working in concert. Finally, it is shown that the "hard cases" displayed by Marcus and Phillips do in fact provide the basis for a serious challenge to *pure* (non-modular) connectionist architectures.

Introduction

In Marcus (1998, in press) and Phillips (2000), intriguing refinements on the (1988) Fodor-Pylyshyn "generalization challenge" are presented. Both Marcus and Phillips argue that linguistically competent humans exhibit important forms of *generalization* that backpropagation-trained networks (both recurrent and feedforward) cannot attain. Though neither author categorically asserts that their negative conclusions apply to every form of connectionist training, both authors argue that commonly recognized varieties of *eliminativist* architectures (i.e., those eschewing classical representations) are at stake.[1]

In this paper, I examine two instances which typify the "hardest challenges" produced by these authors. While I agree that they have each exposed some important training limitations of backpropagation networks, I shall argue that humans perform the crucial generalizations *without being trained* on the exemplars that Marcus and Phillips cite. So, in one sense, the issue whether networks can be *trained* to perform the crucial generalizations is a red herring. As I argue, humans possess the relevant generalization capacity because they have previously acquired separate skills which, working in concert, allow for nearly instantaneous pattern induction and reasoning. To be sure, the prior acquisition of these separate skills may involve "training up" various sub-networks in our brains, but this prior training may well *not* involve the "hard" kinds of generalization at issue.

Having said that, I would emphasize that my eventual, general conclusion supports both the positions of Marcus and Phillips. For, in the final section I consider whether connectionist architectures are capable (without implementing classically symbolic methods) of orchestrating the application of our "prior skills" in a fashion that permits very rapid pattern induction and reasoning. My conclusion favors the classicist position on this issue. Moreover, I propose a new challenge for eliminative connectionists which, in my view, formulates the deeper difficulty posed by the aforementioned "hard cases" of Marcus and Phillips.

The Hard Generalization Tasks

Generalizing Outside the Training Space

Marcus (1998) defines a network's training space as the N-dimensional vector space created by the non-zero training values of the N units comprising the network's input array. A datum presented during the network's (post-training) test phase lies "outside the training space" if and only if that datum does not fall within the vector space just mentioned. In effect, this entails that the datum is *novel* relative to the training corpus. For example, any datum would be novel in the relevant sense if it presented non-zero values to the input array in units that contained only zero values during training.

This "generalization hurdle" differs somewhat from the hierarchy of systematicity given in Hadley (1994a), but it appears equivalent to one of several levels of generalization formulated in Niklasson and van Gelder (1994). Interestingly, in the latter paper, the authors claim to satisfy this particular generalization challenge. Their claim is questioned in Hadley (1994b) and wholly disputed by Marcus (1998). Moreover, Marcus discusses a number of specific ways in which a network can fail to generalize outside its training space, and we now consider a particular "hard case" which Niklasson and van Gelder had not addressed.

Suppose a linguistically competent human is presented with the following series: "A rose is a rose", "A frog is a frog", "A pencil is a pencil". Humans will typically have no difficulty inducing the general pattern and complet-

[1] Here I am following Fodor and Pylyshyn's (1988) usage, according to which a composite (or complex) representation is classical in structure if one cannot activate (or token) that representation without, at the same time, tokening its syntactic constituents.

ing the following sentence: "A blicket is a ...". Humans will succeed here even though 'blicket' is a novel word which is outside their training space. In contrast, Marcus offers persuasive arguments, based upon the training-independence of output nodes, to show that backpropagation networks necessarily fail to match this success. These arguments are buttressed by several connectionist experiments conducted by Marcus.

On the basis of the above and related tasks, where a strong discrepancy exists between human performance and that of eliminative networks, Marcus concludes **C**: that human success in such cases is *not purely* due to any training of putative eliminative networks within our brains. This conclusion forms a keystone of Marcus' larger thesis – that the human ability to discover general patterns in cases such as these involves symbolic rule induction, and the application of such rules entails variable binding.

Now, while I agree with conclusion (**C**), I accept this conclusion for reasons other than any offered by Marcus. For one thing, I suspect that some Hebbian-competitive networks *can* generalize outside their training spaces on at least some tasks. This suspicion derives from recent experimentation with an architecture I have reported in (Hadley, et al, to appear). Another difficulty is that Marcus himself notes that when *distributed*, rather than local, representations are assigned to input tokens, backpropagation networks will, at first blush, provide the appearance of generalizing outside their training spaces. For example, in the "A blicket is a .....' test, a backpropagation network can successfully produce the distributed representation for 'blicket', *provided all the separate features* encoding blicket had, at some point, been employed in various nouns during the training phase. Admittedly, one could argue that this last proviso undermines any well founded claim to generalization outside the training space, but in doing so, one would undercut the entire force of the 'blicket' test case. For the word 'blicket' itself possesses only phonetic and graphemetic features that humans have often encountered prior to being presented with the 'a blicket is a ...' test phrase. That is, a plausible distributed representation for 'blicket' does not contain any features novel to English-speaking humans.

Marcus himself does not stress the objection I have assigned to some anonymous "one". Rather, he primarily objects (Marcus, in press, appendix 1) to the use of distributed representations on the grounds that they fail "... to unambiguously represent all and only the possible continuations to a given string ...". That is, when both nouns and verbs share several features in common (as indeed they would if we employ phonetic or graphemetic features), we run into the *superposition catastrophe* (crosstalk). (I would argue, however, that there is, *at most*, very little overlap between *semantic* features belonging to nouns and those belonging to verbs. For this reason, among others, the system described in Hadley et al, 2000, employs semantic features.) Be that as it may, it remains true that the phonetic and graphemetic features of 'blicket' are not novel. Moreover, *those* features are shared by both nouns and verbs, and, being a nonsense word, 'blicket' has no semantic features. So, if Marcus objects to the deployment of distributed representations in these network experiments, it seems incumbent upon him to demonstrate that humans are using only *local* representations when they successfully generalize from "A rose is a rose", etc. to "A blicket is a blicket". In the absence of such a demonstration, there seems no reason to grant that humans are in fact generalizing outside their training space in cases such as this.

For all the above reasons, I have serious reservations about Marcus' argument for conclusion **C**. Nevertheless, as mentioned, I believe there is a compelling reason to accept (**C**). And, if I am right about this latter reason, then the disputed capacity of eliminative networks to generalize outside their training spaces may be irrelevant *as the task is presently formulated*.

Here is the situation: humans clearly are able to perform very rapid pattern induction, not only in the various cases that Marcus cites, but in many other instances. In the above case, humans are able to induce a general pattern, and supply 'blicket' in response to the test phrase "A blicket is a ... ", within mere seconds after hearing "A rose is a rose", and the few remaining sample sentences. Given the very short time span involved, we may be quite certain that human success in this and similar cases does not stem from some extremely rapid training of "neural networks" (whether eliminative or not). As emphasized in Hadley (1993), in cases where humans make virtually instantaneous inferences, and when they acquire general rules in a matter of mere seconds, rapid synaptic weight change can be ruled out. Synapses simply do not grow fast enough to permit the acquisition of coherent functionality within the span of a few seconds. Functionally coherent synaptic changes occurs within spans of hours or days, not in a few seconds.

Now, it might be objected that in the case of the 'blicket' generalization, humans have in fact had entire days or even years to "train up" their networks, since, arguably, they have frequently heard phrases of the precise form, "an X is an X", in the past. However, this objection falters when we reflect that English-speaking adults have no difficulty inducing a *novel* pattern, and completing the final "sentence" in the following series: "Rose biffle biffle zarple zarple rose"; "Frog biffle biffle zarple zarple frog"; "Blicket biffle biffle — — —". In this case, the pattern being induced is clearly novel, since the pattern (template) itself not only includes the words 'biffle' and 'zarple', but involves a "syntax" that employs a double repetitive pattern not found in English. Yet, humans perform this induction in mere seconds. We must conclude, therefore, that the ability to perform rapid pattern inductions of this kind does not derive from some instantaneous training of a neural network, but must rely on at least some pre-existing skills. Certain of these prior skills involve the capacity to recognize phonemes or graphemes, which doubtless entails modification of synaptic "weights", which in turn (presumably) amounts

to the training of sub-networks within the brain.

Note, however, that this *prior* network training is not specifically directed to the generalization task just considered. The *novelty of the pattern* being induced ensures that very rapid, successful induction of this pattern must arise as a side-effect of prior skill acquisition. An appropriate challenge, therefore, for eliminative connectionism, is not whether a single network can be trained to generalize successfully from the few samples of data cited above, but *whether an essentially non-classical network can exercise its hitherto acquired skills* in a manner that yields, **as a side-effect**, the kind of rapid pattern induction considered above. Clearly, these are deep waters; I shall return to this issue in section 3.

Generalization in Rapid Inference

We turn now to consider an apparently "hard case", presented by Phillips (2000). This case is one of a series of generalization tasks considered by Phillips. Each task in the series possesses features which, at first blush, render it unlearnable by backpropagation methods in feed-forward and recurrent networks. However, Phillips engages in a dialectical process in each case, and *seems* to conclude that, provided overlapping distributed representations are assigned to functionally similar atomic constituents within the input data, then, with one exception, each task becomes learnable. The apparent exception is discussed below.

It is noteworthy, though, that even in the case of this seeming exception, Phillips describes a network capable of performing the task. He produces a carefully designed, fragile (and hand-crafted) network whose prescribed weight configuration suffices to display appropriate generalization behaviour. However, Phillips neither argues that the requisite weights could be acquired by learning, nor that the network possesses any cognitive plausibility. Given the precise and fragile nature of the requisite weight vectors, it seems unlikely that the particular network Phillips discusses could in fact be engendered through training.

Presently, I consider details of Phillips "recalcitrant case", but before doing so it will be helpful to consider a partially analogous example. Let us assume that Fiffle, Giffle, and Kiffle are names of propositions that have truth values. (I assume these three names, *qua* names, are novel for most readers.) Also suppose that the following three statements are true.

> If Fiffle is true, then Giffle is true.
>
> If Giffle is true, then Kiffle is true.
>
> If Kiffle is true, then Fiffle is true.

Finally suppose that Kiffle is true. What else can then be known to be true? Before reading further, I invite the reader to discover what can be inferred.

Doubtless, without effort, you have rapidly inferred the truth of the two remaining propositions, Fiffle and Giffle. Any number of literate humans, who have no training in formal logic, could similarly succeed at this task. Clearly, in the elapsed time between your having read the problem statement and your having derived the remaining propositions *no neural network was trained* within your brain to perform the relevant inferences. Rather, your success stems from a prior ability to engage in iterative processing and *modus ponens* inferences. Arguably, in the case of humans who lack formal logic training, the latter capacity derives from prior training in language use (with sentences of the form: if P then Q).

Of course, from a connectionist perspective, the capacity to apply inference patterns to novel data (Fiffle, Giffle, and Kiffle) is a significant achievement, and it is questionable whether any cognitively plausible ANN experiment has succeeded in this task.[2] However, just as in the case of 'blicket', 'Fiffle', 'Giffle', and 'Kiffle' possess only *non-novel* phonetic and graphemetic features. Given that Marcus was able to train a simple recurrent net to predict 'blicket' in the 'a Y is a Y' formula, there would seem no obstacle, in principle, to the *modus ponens* inference pattern being applied to nonsense words, provided the latter are represented by distributed representations of the right kind.

With this in mind, we now consider the problematic case that Phillips describes, viz., *transverse patterning*. Phillips defines transverse patterning as follows:

> Transverse patterning is an example of a stimulus-response task that depends on *between constituent* relations (my emphasis) . A task instance or problem set consists of three unique patterns (e.g., strings, shapes, etc.) *A, B* and **C**, such that: A predicts B; B predicts C; and C predicts A. Once the transverse patterning task structure has been learnt from the first few problem sets, subjects require only one of the three stimulus-response pairs to predict the remaining two, for any new transverse patterning problem set.

At first glance, there may appear to be an ambiguity in the last of the sentences just quoted. However, carefully read, the sentence tells us that human subjects can predict, when given a single *novel* stimulus-response pair (of the form "shape X predicts the appearance of shape Y") what the two remaining novel S-R pairs, having this general form, will be. In personal communication with Phillips I have verified that the sentence is *not* describing human predictions of the two remaining geometric shapes, given the first geometric shape.

Phillips goes on to relate that *trained* feed-forward and recurrent networks are not able to match the impressive kind of generalization just described. This is not surprising. What is surprising, initially, is that *humans can* predict what the two specific novel S-R pairs will be, given exposure only to one of the three novel S-R pairs. This surprise evaporates, though, when we learn (as I did in further personal communication with Phillips) that human subjects are told in advance what the three geomet-

[2] From a cognitive standpoint, I have serious qualms about Boden's and Niklasson's (2000) recent results on this issue.

ric shapes will be in the novel test situation. Given this, and given that the subjects will have learned the overall structure of the training experiment (following their first few sessions), they are able to *reason* analogically, and to derive by a process of elimination, what the remaining two S-R pairs must be. For example, in the new test situation, subject Kim learns that the novel shapes will be a star, an ellipse, and a hexagon. After being presented with the first S-R pair, Kim is able to *infer* immediately, that (say) A corresponds to the star, and that B corresponds to the ellipse. Knowing this, Kim can reason analogically that the ellipse (corresponding to B) must predict the third geometric shape, the hexagon. Reasoning further, again by analogy, Kim discovers that the hexagon (corresponding to C) must be the predictor of (A), the star.

Now, the crucial point to realize here is that human success in this task involves powerful reasoning skills (both analogical and reasoning by elimination) which the human possessed *prior to any* of the S-R conditioning induced in Phillips experiment. In all likelihood, these prior reasoning skills reside in separate modules which were unaffected by the S-R reasoning presently being considered (see Hadley, 1999, for arguments on the modularity issue). In contrast, the non-modular feedforward and recurrent networks which Phillips contrasts with the human success, possess no prior skills in reasoning of any kind, much less the powerful reasoning capacities that humans bring to the experiment.

The situation is complicated, and confused, by the fact that various of Phillips' remarks create the impression that he is contrasting a human ability to generalize an inference pattern, *which has been acquired in the S-R conditioning sessions*, with an inability, on the part of widely used connectionist architectures, to exhibit comparable generalization. At various points, Phillips explicitly states that the transverse patterning task amounts to the task of *generalizing* logical inference patterns. For example, he says,

> Under controlled conditions, subjects consistently make inferences implied by the underlying logical rules (Halford *et al*. 1998a). Indeed such tasks are ideal tests for systematicity in connectionist networks (Phillips and Halford 1997, Phillips 1999).

Given the type of S-R conditioning employed in Phillips experiment, one naturally supposes that the 'underlying logical rule' that Phillips currently has in mind is tantamount to the rule of *modus ponens* employed in the example I offered above. However, as we have now seen, the crucial human success that Phillips highlights in *not* dependent on a simple application of a given inference pattern (or even repeated applications of that pattern) as occurs in the Fiffle example I provided. Rather it depends upon the composition of prior reasoning skills (a composition involving both analogical reasoning and deduction by a process of elimination) *combined with* an ability to extend inference patterns to novel data.

Phillips believes that his transverse patterning case demonstrates that similarity in distributed representations (of atomic constituents) does not suffice to enable certain kinds of networks to generalize a particular kind of inference patterns to novel data. To the contrary, I have argued that Phillips has conflated the challenge of having a network generalize the application of a single inference pattern with several larger issues. While I certainly agree that the use of distributed representations cannot compensate for the absence of separate, previously acquired reasoning skills (together with the considerable prior training that would engender those skills), this tells us nothing about the efficacy of deploying distributed representations when attempting to apply a *single* known inference pattern to novel data. It is crucial to realize that, in the "transverse patterning" experiment discussed above, humans are doing far more than generalizing the application of a single inference pattern to novel data. They are engaged in an elaborate process involving meta-observations and the composition of separate, sophisticated inference skills.

Moreover, it is questionable whether the S-R training sessions have *trained* human subjects in any *new* inference pattern at all. It seems more likely that the sessions merely provided opportunities for subjects to acquire the base atomic facts (of the form X predicts Y, analogous to the simple "if-then" premises in my *modus ponens* example) which provide fodder for the capacity of humans to apply pre-existing inference skills to novel data.

In any case, I believe it is clear that Phillips' "hard case", like that of Marcus, involves the composition and application of pre-existing skills.

Discussion

In the foregoing, I have argued that, for the generalization tasks in question, the challenges posed to eliminative connectionism have not been felicitously formulated. For, in the tasks considered, we have seen that human success gives every appearance of either arising through the composition of multiple prior skills (viz., language comprehension, analogical reasoning, and deduction by process of elimination, in the case of transverse patterning) or arising as a side-effect of the capacity for language processing (as in the case of 'a blicket is a ...'). Human success in these cases is clearly *not* due to some virtually instantaneous "training" of our synaptic weights. I submit, therefore, that the fundamental challenge posed by these "hard cases" should be formulated essentially along the following lines:

> Demonstrate that a *single* holistic ANN, deploying eliminativist, non-classical representations could, as a manifest *side-effect* of its prior training, perform successfully on either of the "hard" tasks we have considered here.[3]

[3] I regard a network's success on a task, T, as a manifest side-effect of prior training just in case the following two conditions hold: (1) it is clear that prior training had in some way contributed to the success; (2) the network's prior training in-

It might now be objected that the challenge just formulated is unfair, because my wording clearly precludes any solution founded upon the *interactions* of multiple connectionist modules. However, solutions predicated upon the interactions of separate connectionist modules represent a radical departure from the pure connectionist paradigm. Such modular architectures share much in common with traditional, symbolic AI approaches to induction and problem solving, in that much of their processing power derives *not* from the *vector* and *settling* operations that characterize the "new" paradigm (involving weight and activation vectors), but from cooperative data exchanges between separate modules.

I return to these issues presently, but let us first consider a different sort of objection that may arise. It might be argued that the "challenge" I pose above is not especially worrisome for the connectionist. After all, it is well known that connectionist networks often display emergent side effects. Furthermore, we know that some networks trained via backpropagation have already displayed some degree of compositionality, as evidenced in the capacity of the St. John & McClelland network (1990) to assign correct semantic interpretations to novel sentences. In reply, it should be noted that the degree of *skill* compositionality, required to solve the transverse patterning task, is of a radically different kind than any compositionality displayed by networks that assign semantic representations to novel sentences. The degree of semantic compositionality displayed by Hadley & Hayward's (1997) Hebbian network is markedly greater than that evidenced by St. John and McClelland, but even the Hadley-Hayward network displays no compositionality of entirely separate skills.

Indeed, I know of no non-modular connectionist network, whether eliminativist or not, which exhibits skill compositionality remotely approaching the level required in the transverse patterning problem. Admittedly, in the case of the Marcus generalization task (*a blicket is a ...*), it may not be obvious at first blush that humans employ multiple, *separate* prior skills to solve the task, but we know that, at the very least, a capacity to understand a range of natural language is presupposed. Moreover, *this* capacity is so complex and multi-faceted, that any number of competent linguists would affirm that a variety of separate skills are involved.[4]

Returning now to earlier comments on a *modular* approach to skill compositionality, I would stress that, in my view, such an approach is promising. Indeed, I have argued in (Hadley, 1999) that whenever a variety of markedly distinct skills are involved in a task (such as the skills I have noted above), it is likely that separate modules are involved. Such modules may very well be spatially distributed, and subject to some degree of noisy interactions with other modules, but for computational reasons they should still be regarded as distinct modules. However, in that same paper, I argued that humans are demonstrably able to employ their skill modules in *novel combinations*. To place the issue in a very small nutshell, the mere fact that humans can follow specific kinds of novel rules, within mere seconds after being told such a rule, suffices to show that the brain can transfer information (or data) along sets of *combinatorially adequate pathways* between the separate skill modules. I argued further, by an examination of logically possible cases, that the existence of such combinatorial pathways entails that at least one of several types of classically recognized architectures is present in the human cognitive system. Space limits do not permit a detailed recapitulation of these arguments. However, I submit that a *modular* approach to achieving the impressive "side effects" noted in the "hard cases" which have concerned us, does not represent the type of solution that would appeal to researchers who view connectionism as a radically new paradigm. In any case, neither the hybrid-modular approach, nor the single-holistic-network approach has yet been shown to yield side-effects even approaching those involved in the transverse patterning example.

volved no task possessing an underlying structure identical to that of task T.

[4]Examples of such separate skills include: (1) the ability to recognize distinct words, (2) the ability to recognize highly ungrammatical sentences, (3) the ability to form the past tense of verbs.

Abstract

Representational Distortion is a new account of similarity in which the transformation distance between representations determines similarity: entities that are perceived to be similar have representations that are readily transformed into one another, whereas dissimilar entities require numerous transformations. Here we present experimental evidence in favour of this viewpoint.

Introduction

The breadth of cognitive and social contexts in which similarity is invoked as an explanatory construct is vast. Similarity forms part of the explanations of memory retrieval, categorization, visual search, problem solving, learning, linguistic knowledge and processing, reasoning, and social judgment. The two classical approaches to similarity are the spatial account (e.g., Nosofsky, 1986), which represents similarity in terms of distance in psychological space, and Tversky's (1977) contrast model which views similarity as a function of common and distinctive features of the entities under comparison. Both of these accounts have been used successfully in cognitive modeling, however both also suffer from fundamental limitations (see Hahn & Chater, 1997, 1998a, 1998b). These models are restricted in scope by the fact that they define similarity over very specific and simple types of representation: points in space or feature sets. However, the representation of complex real-world stimuli, from faces to auditory scenes, is typically assumed to require *structured* representations, that can explicitly describe objects, their parts, properties and the relations between them. Relational information of this kind cannot readily be encoded using lists of features or dimensional values (Hahn & Chater, 1998a).

The present paper considers a recent theoretical approach to similarity, Representational Distortion (henceforth, RD; Hahn & Chater, 1997; Chater & Hahn, 1997), which aims to provide a theoretical framework applying to similarity judgements. According to RD, the similarity between two entities is a function of the "complexity" required to "distort" or "transform" the representation of one into the representation of the other. The simpler the necessary transformation, the more similar they are assumed to be.

How can the complexity of the transformation between two representations be measured? At a theoretical level, Hahn and Chater draw on a branch of mathematics, Kolmogorov complexity theory (Li & Vitanyi, 1997) that provides a rigorous and general way of measuring the complexity of representations and transformations between them. In intuitive terms, according to Kolmogorov complexity theory, the complexity of a representation is the length of the shortest computer program that can generate that representation. The idea is that representations that can be generated by a short program are simple; those that require longer programs are complex. We will not consider the virtues of this measure of complexity here, except to note that it supports substantial applications in the cognitive and computing sciences (Chater, 1999).

Kolmogorov complexity has a natural application as a measure of similarity between representations. The simplest measure is the length of the shortest program that "distorts" one representation into the other. According to this viewpoint, the degree to which two representations are similar is determined by how many instructions must be followed to transform one into the other. For example, the conditional Kolmogorov complexity between the sequences 1 2 3 4 5 and 2 3 4 5 6 is small, because the simple instructions add 1 to each digit and subtract 1 from each digit suffice to transform one into the other. In the same way, 1 2 3 4 5 and 2 4 6 8 10 (multiply/divide each digit by 2) are presumed to be similar. On the other hand, 1 2 3 4 5 and 3 5 7 9 11 are viewed as less similar, because two operations are required to transform one into the other (e.g., multiply by 2 and add 1). Finally, two entirely unrelated representations will be maximally dissimilar because there will be no efficient way of transforming

one representation into the other. In this case, the most efficient transformation will involve deleting the first representation, and reconstructing the second from scratch, because there is no shared information between the objects that can be exploited. RD should be viewed as a general framework for understanding similarity, rather than as a specific cognitive account in competition with the spatial or featural views. RD can capture these accounts as special cases (see Chater & Hahn, 1997 for derivations) and thus does not contrast but rather subsumes these accounts. Another motivation for RD is that it aims to provide an explanation for the utility of similarity in inference, for example, to categorize items on the basis of the categories of similar items. To build a concrete psychological account of similarity we need to consider (i) the nature of the mental representations that are relevant to making a similarity judgement; (ii) the set of transformations or instructions that can be used to distort one representation into another; (iii) any constraints on the ability of the cognitive system to discover simple transformations between mental representations.

Despite its generality, RD makes clear empirical predictions. First and foremost, is the prediction that transformations are relevant to similarity. It is this prediction for which the current paper provides empirical support. Crucially, though our own interest in establishing the relevance of transformations to similarity judgments is driven by our research program on RD, the relevance of the general issue of similarity and transformations, and thus of our results, extends beyond our particular theory. As we will demonstrate, the experimental evidence presented here raises substantial problems for classical theories of similarity and raises novel issues for any future work on similarity.

Previous work

The central claim of RD, that similarity is based on transformation distance, has several tentative precursors in the experimental and computational literature. The two most directly relevant experimental studies are by Imai (1977) and Franks and Bransford (1975). Imai proposed that pattern similarity between strings of either filled or unfilled circles was based on transformational structure. He found support for this claim in terms of a qualitative relationship between the number of transformations between two patterns and their judged similarity. However, no statistical analysis was performed. Franks and Bransford (1975) sought to extend Posner and Keele's (1968) work on prototype abstraction, replacing the original random dot patterns with simple geometric figures. Underlying the stimulus set was a prototype that was not shown during training; all other items in the stimulus set were derived from this prototype through the application of one or more simple transformations. Recognition ratings were directly related to transformational distance to the prototype, with the prototype itself receiving the highest rating. Finally, the account has some resonance in the perception literature where transformational explanations have been used to explain figural regularity or "goodness", as well as figuring in theories of object recognition.

In summary, there is currently no clear experimental evidence for the importance of transformations in the context of similarity, despite previous research hinting at this idea. Three experiments were designed to address this issue. Each of the experiments shared the same basic correlational design and differed only in their stimulus materials. The aim was to establish transformational distance as a predictor of perceived similarity, while at the same time providing evidence for the limitations of featural (and spatial) accounts.

Experiment 1

Experiment 1 was based on Imai (1977), and uses sequences of filled or unfilled circles. Transformational distance was manipulated in terms of the number of operations such as mirror imaging, reversal, phase shift, insertion and deletion that were necessary to convert the test stimulus into the target. This is best illustrated with an example stimulus pair, shown below.

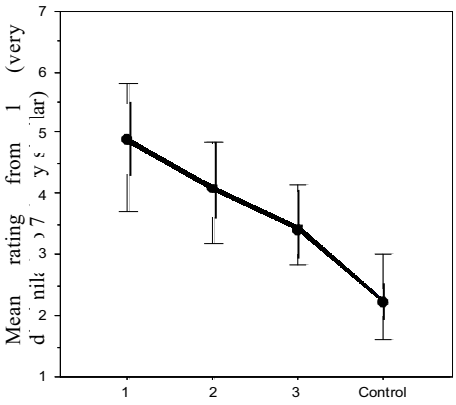
The two rows of "blob" patterns can be transformed into one another through the application of a single operation that "reflects" one row to create the other row in a mirror image. This prediction contrasts with that of the featural account (Tversky, 1977), if we adopt the natural assumption that features correspond to individual blobs. According to this viewpoint, blob patterns should be similar to the extent that they overlap.

Participants 35 undergraduates psychology students.
Materials The stimuli consisted of strings of black and white blobs, presented in pairs. The key transformations were phasic, reversal and mirror, with the addition of insertions and deletions. Any one of these in isolation constituted a single transformation. There were 16 examples of single transformations in this experiment, (4 each of phasic, reversal, mirror and deletion). Multiple transformations were achieved by combining two or more of the above operations. The total set of 56 comparison pairs consisted of 16 examples of two transformational changes (four each of reversal & mirror, reversal & phasic, deletion & mirror and insertion & phasic) and 16 examples of three transformational changes (four each of deletion, reversal & mirror, deletion, reversal & phasic, insertion, reversal & mirror and insertion, reversal & phasic). As a control, there were also 8 pairs of stimuli that were unrelated (or so multiply transformed as to make the transformations unperceivable). Each pair of stimuli was printed horizontally onto a single sheet of paper

together with brief instructions and a rating scale from 1 (very dissimilar) to 7 (very similar). These sheets were then placed into a different random order for each participant and bound into a booklet.

Results

Bivariate correlations between number of transformations and mean similarity rating of each item were found to be highly significant with Spearman's rho = -.69, $p < .005$. The comparison featural model which left aligned the two rows of blobs and counted the number of (mis)matching features fared considerably worse: Spearman's rho = -.28, $p < .05$. Analysis of individual subject ratings confirmed these findings, revealing great conformity across participants: 25 of 35 participants showed significant correlations as predicted. Such consistency was not found using the featural model, with only 8 of the 35 participants showing a significant correlation. The general relationship between number of transformations and mean similarity ratings is graphed below. The results suggest, somewhat surprisingly (see e.g. Shepard, 1987), an approximately linear relationship.



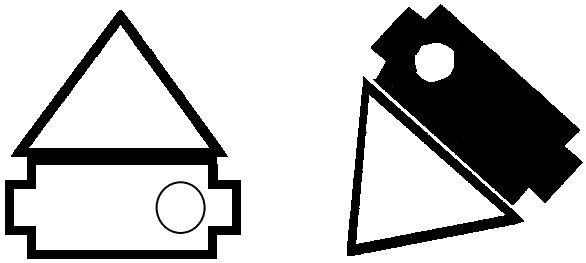
No. of transformations

Discussion

Experiment 1 provides evidence of a statistically significant relationship between transformation distance and perceived similarity to complement Imai's (1977) more qualitative data. The results of Experiment 1 thus confirm both Imai's original intuition and the predictions of the RD framework. In direct comparison, the featural model fares considerably worse in predicting participants' ratings. Consequently the results also provide evidence for limitations in featural approaches. It is, of course, possible that more powerful featural descriptions of the data could be found, but, at present, none are available. Crucially, any putative featural explanation of this kind requires an independent motivation of the features adopted, that is, the postulated features must themselves not be motivated exclusively by salient transformations. Otherwise, the featural description becomes an entirely redundant mimicry. The materials of Experiment 2 make this point more clearly.

Experiment 2

This experiment used simple geometric shapes related by different transformations, e.g., the pair of items shown below has a transformation distance of two as they can be made identical through rotation and color change of one object part. Here, there is no obvious way to apply a featural model for contrast purposes. Furthermore, many of the "features" such as the orientation of an item in a pair where one has been rotated are salient only because of the relevant transformations. This means that central object "features" will be derivative on the transformations present: e.g., orientation is unlikely to have cognitive salience in a comparison until orientation is manipulated through rotations. Consequently, though it might, in principle, be possible to derive featural descriptions for our stimulus items, these descriptions would be likely to implicitly underscore the importance of transformations, rather than providing an alternative to relying on transformations. As in Experiment 1, the prediction is that number of transformations will be negatively correlated with degree of perceived similarity.

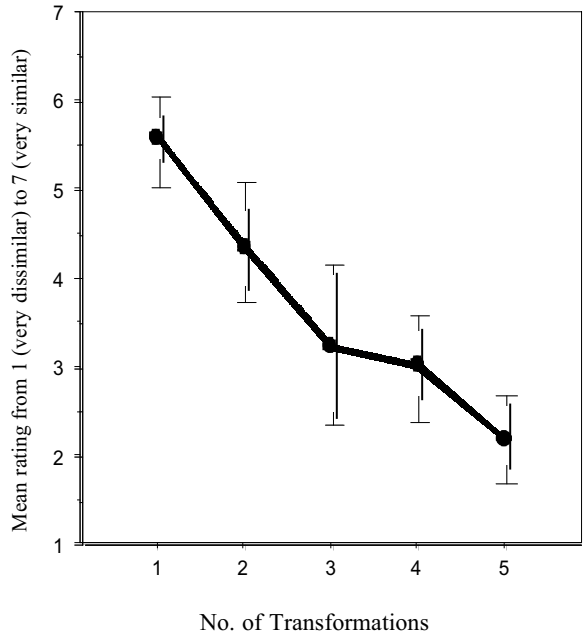


Participants 21 psychology undergraduates.

Materials There were three alternative "target" geometric shape line drawings. The construction of the stimulus sets began with the target shapes to which a single transformation was then applied. Examples of single adjustments were stretching the whole object or changing all striped areas to filled-in black areas. Multiple transformations were constructed by using a combination of such techniques, one at a time. For each of the three target stimuli there four examples each of one, two, three, four and five transformations. This made a set of 20 pairs of pictures for each base target, yielding 60 in total. Each transformed geometric shape was printed onto a separate page together with its corresponding "target", which was always placed to the right of the transformed item. At the top of each page were a set of instructions and a rating scale from 1 (very dissimilar) to 7 (very similar).

Results

Bivariate correlations between number of transformations and mean similarity rating of each item were highly significant with Spearman's rho = -.89, p = .000. Analysis of individual participants' ratings again revealed great consistency across subjects, with 19 of the 21 participants showing a significant correlation as predicted. The relationship between number of transformations and mean similarity ratings as graphed below closely matches that found in Experiment 1. The relationship between transformation distance and similarity is again approximately linear.



Discussion

Experiment 2 provide further supports the role of transformations in the context of similarity, mirroring the results of Experiment 1 with very different stimulus materials. The materials of Experiment 2 also illustrate how even natural "features", such as orientation are influenced by transformations. Many of the very "features" that a featural account might posit seem salient due to the transformational relationships between the two compared objects. This is indicative of the general bi-directional relationship posited by RD theory between object representation and transformation, with perceived transformations influencing which aspects of an object become salient and vice versa.

Experiment 3

Experiment 3 sought to take the argument against featural and spatial representations one step further, by using materials for which such representation schemes are obviously inadequate, because they depend on relational structure. We used 3D objects assembled from (typically) three Lego bricks: one large brick, colored blue; a medium size yellow brick; and a small red brick. Each similarity comparison comprised two objects assembled from these three bricks, albeit in different spatial arrangements. Despite the extreme simplicity of these stimuli, relational information (i.e., information about relative position, such as, for example, that the red brick as on top of the yellow brick) is paramount to the representation of the composite objects. However, the appeal of these materials is not limited to the difficulties they pose for featural or spatial accounts. From a transformational perspective, the Lego brick objects are of interest for two reasons. First, they allow an initial examination of the role of transformations in the similarity assessment of real-world objects, albeit maximally simple ones. Second, these materials support a whole new range of transformations to complement those investigated in Experiments 1 and 2. Our assumption, here, was that the judged similarity between pairs of objects would be determined primarily by the physical manipulations required to turn a target object into the comparison object.

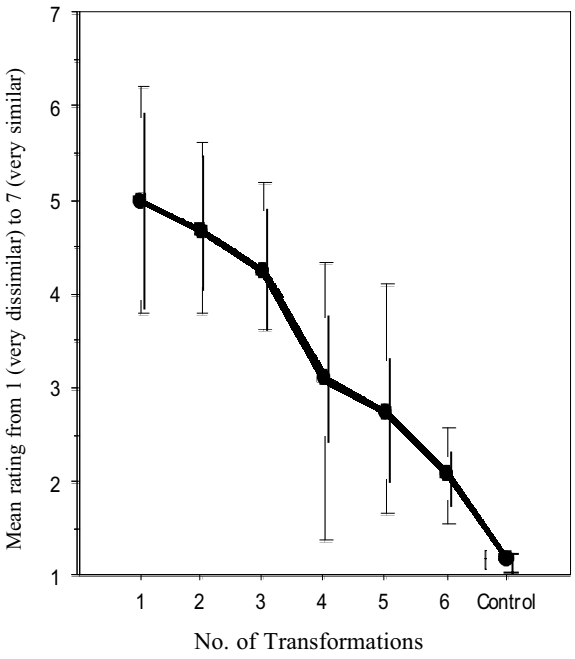
Participants 27 psychology undergraduates.

Materials The stimuli were based upon an initial "target" array of three Lego bricks, (a four-point square red brick, upon a six-point oblong yellow brick, on top of an eight-point oblong blue brick) arranged into a particular three-dimensional structure. Apart from the two examples that were chosen to be totally unrelated to the target, all of the Lego stimuli were constructed by transforming the original target object a set number of times, prior to the experiment. The researcher began with the target arrangement and made adjustments to it, each of which constituted one transformation. For example, one adjustment (or transformation) could involve moving an object within the arrangement, substituting a brick for one of a different size or colour, adding an additional brick, subtracting an existing brick, or changing the order of the bricks within the arrangement. The transformations required to create each arrangement were counted and the entire set of stimuli constructed so that it comprised of 42 items (10 examples of one and 10 of two transformations, and five examples each of three, four, five and six transformations away from the "target". In addition there were two items that were unrelated--multiply transformed--stimuli). Once these arrangements of Lego bricks had been constructed, each was glued into a permanent structure.

Procedure Participants were shown the "target" Lego brick object. They rated how similar they perceived each stimulus to be to the target, on a scale of 1 (very dissimilar) to 7 (very similar). Every participant rated all the Lego stimuli within the set of 42 items.

Results

Bivariate correlations between number of transformations and mean similarity rating of each item where again highly significant, Spearman's rho = -.76, $p < .005$. Analysis of individual participants' ratings again revealed great consistency across subjects, with all 35 exhibiting a significant correlation between number of transformations and rated similarity. The general relationship between number of transformations and mean similarity ratings (shown below) is again very similar to that that found in Experiments 1 and 2.



Discussion

Despite the very different materials and set of relevant transformations, the results of Experiment 3 closely match those of Experiments 1 and 2. Again, they provide evidence for the importance of transformations in explaining similarity judgements, and are difficult to account for in terms of the featural or spatial views of similarity, which cannot easily handle relational information. Thus, these results are in line with the predictions of a central tenet of the RD account: that the transformational relationship between representations of two objects determines their judged similarity. But the results Experiment 3 also have broader implications. The inherently relational nature of the materials in Experiment 3 poses a problem for any representational scheme which does not allow structured representations; conversely it lends support to any account such as structural alignment theories to which such structured representations are central. Similarly, the result that number of transformations is a significant predictor of perceived similarity lends support to the general notion of an influence of transformations on similarity, whether or not the particular framework of RD theory is adopted.

General Discussion

The results of all three experiments provide robust evidence as to the importance of transformations in explaining similarity judgments, across a variety of different stimulus types. These findings support the central tenet of the RD theory of similarity, that similarity is based on the complexity of the transformation between the representation of two items. These results also provide new evidence for the limitations of classical accounts of similarity. All three experiments provide evidence against purely featural views of similarity. Experiment 1 provides a direct test. The version of the featural model we tested (assuming that features correspond to blobs) is not the most sophisticated featural description possible, given that, in principle, any property including all higher-order regularities such as "symmetry" etc. could be posited as features (Tversky, 1977). Crucially, however, a more sophisticated featural account which succeeds in providing comparable or even superior data fits must not only first be found, it must also be independently motivated. Given that theories can be stretched beyond all recognition through the addition of suitable post hoc auxiliary assumptions, a crucial factor in evaluating competing accounts must not only be whether an account can be made compatible with a particular pattern of data, but also whether it in any way predicted it.

In Experiment 1, there is nothing in featural theories of similarity that would naturally give rise to the predictions made on the basis of transformations in this experiment. The sequences of filled circles lend themselves naturally to a featural decomposition on a one by one basis due to the fact that the "object" is readily parsed into a set of individual circles. Many of the relevant "features" of the geometric shape stimuli in Experiment 2 become cognitively salient only through transformational contrast between the two comparison objects (for example, the feature "orientation" highlighted by the transformation "rotation"). Consequently, transformations are explanatorily prior. The use of simple formations of Lego bricks in Experiment 3 demonstrates the central representational weakness of featural accounts - their inability to deal with structured representations and thus adequately represent relational information. The challenge presented by Experiment 3 is to identify even a remotely suitable featural description, given the inherent relational nature of materials and transformations. The limitations of featural accounts exposed by this series of experiments is equally shared by spatial models of similarity, whether they are based on multi-dimensional scaling or standard connectionist networks. It must again be stressed that from the perspective of RD theory, featural and spatial accounts of similarity are not

wrong, they are simply too restricted to cope with the flexibility of transformations available to the cognitive system.

Interestingly, issues related to this research have been raised in philosophy. Goldman (1986) suggests that the lawfulness of human similarity judgments might be furthered by an inherent preference ranking for transformations, which comes in to play where multiple transformational sequences could link the same stimulus pair. This question links closely with a central issue for future research, that of the relative "cost" or "weight" of individual transformations. Single transformations need not be equal in cost or 'effort'. Such inequalities arise automatically in the theory of Kolmogorov complexity, the general mathematical framework on which RD theory draws. Here, deletions, for example, tend to be less costly than insertions, because deletions only require a specification sufficient to identify the component for deletion, whereas insertions require a complete specification of the additional component. What weightings of this kind, if any, are intrinsic to the cognitive system is an issue we are currently seeking to determine through the investigation of perceived similarity for different single transformations. Information as to relative transformational costs will be crucial for more detailed cognitive modeling and thus constitute a major issue for future research. Another potentially interesting area is to apply the approach to different domains; particularly those that appear to require structured representations where RD can be utilized in a straightforward way. For example, two postures of a hand, in terms of a specification of joint angles can be compared simply. Given the transformations likely to be salient in cognitive processing involving motor control, we might expect that 'similar' hand positions would correspond to positions that can readily be transformed into each other.

We have presented a new account of similarity, Representational Distortion, according to which the judged similarity between a pair of items is determined by the complexity of the transformation between the mental representations of those items. We have tested the central tenet of the account in three experiments, finding that transformational complexity is, indeed, inversely related to similarity. These results present a challenge for other accounts of similarity, based on feature comparison or spatial distance; and they indicate that the view that similarity can be explained in terms of transformation merits further theoretical and empirical investigation.

Abstract

Harmonic Grammar is a connectionist-derived grammar formalism, of which Optimality Theory is a kind of limiting case. Harmonic Grammar is expressive enough to specify the trees that are correct parses on a given context-free grammar. Here, we show how to construct a connectionist parsing network which finds correct parses given a sentence, of if none exist, signals a rejection. Finally, a brief comparison to other connectionist parsing work is provided.

Harmonic grammar is a grammar formalism which uses only soft rules of the following form:

> If condition X is violated, then the well-formedness (Harmony) of the structure is diminished by C_X.
>
> [Legendre et al., 1990, 388]

A linguistic theory in Harmonic grammar is a set of soft rules and a set of representational possibilities. Applying the soft rules to any representation yields the Harmony value for that representation. A representation with maximal Harmony from some class defined by common substructure — the inputs — is said to be the winning candidate. In Optimality Theory [Prince and Smolensky, 1993] the soft rules are ranked and the C_X values are arranged so that no number of violations of lower-ranked soft rules could ever outweigh a violation by a higher ranked one.

Harmonic grammar is expressive enough to specify the context-free languages [Smolensky, 1993]. Here Harmony maximization is made to serve as a processing algorithm for a parser. The design for the parser is a way of systematically arranging networks of threshold logic units so that they implement exactly the Harmonic grammar rules for context-free grammars. They maximize the Harmony of representations that share the same terminal entries. The general idea is that these networks do this by de-activating pieces of bad analyses until only correct analyses remain.

How Harmonic Grammar specifies context-free languages

Harmonic context-free grammar rules (as first presented in [Smolensky, 1993]) are integer occurrence and co-occurrence penalties that are defined on trees. Trees

Figure 1: A legal derivation?

whose Harmony value is zero are successful derivations which prove that their yield is generated on the grammar. All others have negative Harmony which indicates that the yield is not in the language generated by the grammar.

Derived from connectionist principles, Harmonic grammar assumes the following form for the Harmony function.

$$H(\mathbf{a}) = \sum_{\alpha<\beta} a_\alpha W_{\alpha\beta} a_\beta \quad \sum_{\alpha} a_\alpha b_\alpha \tag{1}$$

In this case, **a** is the representation of a parse tree as a vector. W is a symmetric weight matrix, and H is a sum of terms containing pairs of elements from the vector **a**. As a consequence of this form of the Harmony function, the conditions X in the soft rules are restricted to referring to at most two structures; Harmony maximization is quadratic optimization.

This is an apparent problem for phrase-structure grammar, since no pairwise check of any two symbols from the tree depicted in figure 1 on the grammar $\begin{matrix} X & AP \\ X & QB \end{matrix}$ could reveal that the tree is not a valid derivation of AB from X. It would seem that to check a rule with two children, rules that refer to three pieces of the representation at once are needed, implying a cubic Harmony function. But if this is so, then surely to check a rule with three children would require a quartic Harmony function. Rather than adopting Harmony functions of higher and higher degree, Harmonic context-grammars are defined for context-free grammars[1] in a special normal form where pairwise evaluation is sufficient to check global wellformedness: Harmonic Normal Form.

[1] Throughout, V is the set of all grammar symbols, Σ is the subset of V which are terminals, R is the set of rules or productions represented as (symbol,string) pairs, and S is the distinguished start symbol. See [Lewis and Papadimitriou, 1981] for notation, definitions and fundamental results on context-free grammars.

Definition 1 (branchingrhs) *Let $G = (V, \Sigma, R, S)$ be a context-free grammar in Chomsky Normal Form, A $V - \Sigma$ a nonterminal from G and γ a string in V . Then* branchingrhs$(A) =$ A γ $R :$ $\gamma > 1$

Definition 2 (Unique Branching) *A context-free grammar $G = (V, \Sigma, R, S)$ satisfies the Unique Branching condition if, for all nonterminals A $V - \Sigma$,* branchingrhs(A) 1.

Unique branching insists that for every parent, at most one ordered pair of children is licensed by the grammar. This is the condition that defines Harmonic Normal Form and makes pairwise evaluation sufficient to specify context-free grammar trees. For example, the apparent problem mentioned previously would be solved if only the following grammar, which satisfies the Unique Branching condition, could be used instead.

X	$X\ 1$
X	$X\ 2$
$X\ 1$	AP
$X\ 2$	QB

On this grammar, the tree in figure 1 is assigned negative Harmony. If X had been expanded by the first rule, the parent would be $X\ 1$ and the tree would be penalized for lacking P. If the parent were $X\ 2$ the tree would be penalized for lacking Q. The extra nonterminal encodes which original context-free rule was used, but this contextual information is not needed at higher levels of the parse tree, and the unary rules helpfully remove it.

When the grammar satisfies the Unique Branching condition, a natural interaction between Harmonic grammar rules becomes sufficient to evaluate local trees. Because H adds up harmony penalties, the grammar effectively computes an "AND" at the site of each bracketed parent. All that remains is to specially balance the soft rule weights so that pairs in local trees licensed by the grammar exactly balance out to 0 Harmony and those in ill-formed local trees receive some kind of harmony penalty, ultimately leading to $H < 0$ for the whole tree. A set of rules that does this, G_H, is given below.

G_{HNF}	G_H
a	R_a: If a is at a node, add -1 to H
A	R_A: If A is at a node, add -2 to H
$A\ i$	$R_{A\ i}$: If $A\ i$ is at a node, add -3 to H
start symbol S	R_{root}: If S is at the root, add 1 to H
A α ($\alpha = a$ or $A\ i$)	If α is a left child of A, then add 2 to H
$A\ i$ BC	If B is a left child of $A\ i$, add 2 to H If C is a right child of $A\ i$, add 2 to H

[Smolensky and Legendre, 2001, chapter 10]

Grammar preprocessing

The penalties that figure into the Harmonic grammar rules are going to be connection weights and unit biases in a neural network that parses the grammar. The relation between the grammar and the neural network is established by two grammar transformations. The first ensures that the Unique Branching condition is upheld.

Definition 3 (HNF transform) *Let $G = (V, \Sigma, R, S)$ be a context-free grammar in Chomsky Normal Form and let A, B, C, X $V - \Sigma$. The HNF transform HNF of G is a new grammar $HNF(G) = (V\ , \Sigma, R\ , S)$ where for each nonterminal A that appears in i branching rules of the form A BC, each such rule is replaced by two new rules containing a new nonterminal not in $V - \Sigma$, having the forms A $A\ i$ and $A\ i$ BC. Call the set of new nonterminals that appear in these additional rules* bracket$(V\ )$. *The transformed set V is the union of* bracket$(V\ )$, *the old nonterminals X $V - \Sigma$ such that* branchingrhs$(X) = 0$ *and the old terminals Σ.*

If a symbol is an element of the set bracket$(V\ )$ it is called "bracketed" otherwise it is "unbracketed."

The second transformation adds information about string positions to every rule, and restricts the grammar to only describing sentences of a certain maximum length. Since this maximum can be arbitrary large, it seems reasonable to maintain that context-free grammars for infinite languages are described in the limit [Charniak and Santos, 1987].

The annotation of string positions enables grammar symbols to directly serve as parser items. An item B_{jm} is an assertion about the input string that means "there is a constituent of type B that spans sentence positions j to m."

Definition 4 (Itemification of a binary rule) *The itemification of a binary context-free rule A BC to a sentence length is the set of rules given by the schema A_{jkm} $B_{jk}C_{km}$ for all $j, k, m = 0\ldots$ such that $j < k$ m.*

Definition 5 (Itemification of a unary rule) *The itemification of a unary context-free rule A B to a sentence length is the set of rules given by the schema A_{jm} B_{jkm} for all $j, k, m = 0\ldots$ such that $j < k$ m.*

Grammars resulting from both transformations include complex symbols of the form $A\ i\ _{jkm}$. These symbols express the assertion that there is an A-type constituent spanning sentence positions j to m which was derived via the i^{th} A-rule, and the left child's yield stops at position k. In this way, k plays the role of a back-pointer that addresses a bracketed parent's children.

Definition 6 (Itemification of a grammar) *Let $G = (V, \Sigma, R, S)$ be a context-free grammar in Chomsky Normal Form. The itemification of G carried out for a sentence length is a grammar $ITEM(G,\ ) = (V\ , \Sigma\ , R\ , S\ )$ in which*

1. Σ *contains* -1 *symbols labeled $v_{jj\ 1}$ (where $j = 0\ldots\ -1$) for each terminal symbol v in Σ.*
2. S *is a new start symbol labeled S_0*
3. R *contains the itemification of each rule r in R.*

and V consists of all the symbols appearing in S , R , Σ .

Itemification ensures that children are directly adjoining, and in the right order. For example, (neglecting k's for a moment) if the grammar contains $X_{13} \quad Y_{12}\ Z_{23}$ it will definitely not contain $X_{13} \quad Y_{13}\ Z_{23}$ where a part of Z's yield — the symbol from position 2 to position 3 — is enveloped by Y's yield.

It is also convenient to define the width of two-index itemified symbols X_{ij} from V as $width(X) = j - i$. Further, we suggest (without going into the proofs here[2]) that there are cover homomorphisms between proper parse relations on each of $ITEM(G, \ )$ and $HNF(G)$ and G. In the case of $ITEM(G)$ this homomorphism is only defined for parses of sentences of length . For these sentences, call these homomorphisms f_{ITEM} and f_{HNF}. These are the "inverse mappings" that, given a parse on a transformed grammar, supply a parse on the untransformed grammar — essentially undoing the work of their namesakes. The basic idea is that both transformations only add or rename rules, rather than deleteing them.

Finally, define the parent set of a grammar symbol to be the set of all nonterminals that appear on the left-hand side in rules that involve the symbol in question on the right-hand side.

Definition 7 (Parent set) *Let* $G = (V, \Sigma, R, S)$ *be a context-free grammar and* $\gamma_0, \gamma_1 \quad V$ *Then the set of all possible parents of an element* $X \quad V - \Sigma$ *is* $\text{parents}(X, G) = P : \ \gamma_0, \gamma_1 \quad V$ *such that* $P \quad \gamma_0 X \gamma_1 \quad R$

Every context-free grammar with a finite number of rules has a "maximal parent multiplicity" $p_{\max(G)}$, the highest number of possible parents for any symbol. All of these concepts and definitions will be used to completely specify the parsing network in the next section.

Hopfield network

The parsing network is a Hopfield network with units whose states take on just the values 0 and 1. The network shall be constructed to parse the grammar $ITEM(HNF(G), \ ) = (V, \Sigma, R, S)$ with maximal parent multiplicity $p_{\max} = p_{\max(ITEM(HNF(G), \ ))}$. There are $\alpha = 1 \ldots V$ threshold logic units which update themselves according to the transition rule

$$a_\alpha \quad \begin{array}{l} 0 \text{ if } \sum_{\alpha=\beta} W_{\alpha\beta} a_\beta \quad b_\alpha < 0 \\ 1 \text{ if } \sum_{\alpha=\beta} W_{\alpha\beta} a_\beta \quad b_\alpha \quad 0 \end{array}$$

where $W_{\alpha\beta}$ are connection weights and b_α are biases. Let f_α denote the application of the transition rule to the α^{th} threshold logic unit. Then a network update f_{network} is defined by $f_{\rho(1)} \quad f_{\rho(2)} \quad \ldots \quad f_{\rho(V)}$ where ρ indexes the entries in a random permutation of $1 \ldots V$.

[2] See [Nijholt, 1980, chapter 2] for discussion of grammar covers.

Entries in the undirected $V \times V$ weight matrix W are indexed by grammar symbol and are only nonzero if one indexed symbol is bracketed and the other is unbracketed. Without loss of generality, identify the α^{th} grammar symbol as the bracketed one $(A\ i_{jkm})$ and the β^{th}, as the unbracketed one (A_{jm}).

If there is a binary rule $\alpha \quad \beta\gamma$ or $\alpha \quad \gamma\beta$ the weight between units α and β is 1.

If there is a unary rule $\alpha \quad \beta$ then the weight between units α and β is the same as the maximal parent multiplicity, $p_{\max}$.

Otherwise the weight is zero.

The vector of V biases, **b** is all negative. Component b_α is set to one of three possible values.

If α is an unbracketed start symbol of $width =$ then $b_\alpha = -1$, or, if α is not a start symbol,

if α is bracketed then $b_\alpha = -(p_{\max} \quad 2)$, or else

α is unbracketed and $b_\alpha = -(p_{\max} \quad 1)$

These weights and biases reflect the kinds of input that bracketed and unbracketed units need to be correctly supported by units representing parents above them and units representing children below them.

Bracketed units By the Unique Branching condition, these units have indegree three. They receive input from exactly one (unbracketed) parent and exactly two (unbracketed) children. If all three of these neighbors are in the 1 state, then the net input is $p_{\max} \quad 1 \quad 1$ representing, respectively, the contributions from the parent and each child. This exactly balances the bias $-(p_{\max} \quad 1)$ and keeps the bracketed unit in that state, always updating via the 0 transition. Bracketed units that are on are guaranteed to have correct parents and children on.

Unbracketed units These units can be connected to as many as $p_{\max}$ (bracketed) parents. Even in the worst case, in which all possible parents are in the 1 state, an unbracketed units' $-(p_{\max} \quad 1)$ bias makes sure that it can only be in the 1 state itself when supported by at least one unbracketed child. Unbracketed units that are on are guaranteed to have at least one correct child on.

By construction, W is symmetric (if two symbols are in a parent-child relationship they are also in a child-parent relationship) and has zeros along the diagonal (no two symbols are in dominance relationships with themselves), making the results on convergence of Hopfield networks [Hopfield, 1982] applicable.

During the network's operation, only the states of units associated with symbols of width > 1 may change. Width-1 units, specifying the input to be parsed, are

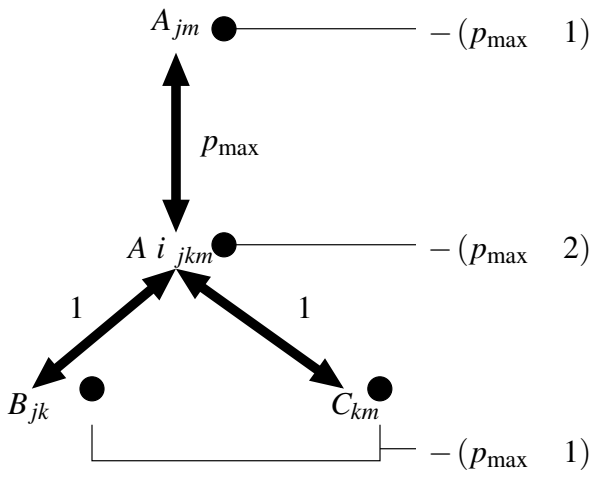

Figure 2: Fundamental parsing network block

clamped. For simple asynchronous updating, the change in a unit a_α's activation is

$$\Delta a_\alpha = \begin{array}{rl} 1 & \text{if the old state was 0 and} \sum_\beta W_{\alpha\beta} a_\beta \quad b_\alpha \quad 0 \\ 0 & \text{if the old state was 1 and} \sum_\beta W_{\alpha\beta} a_\beta \quad b_\alpha \quad 0 \\ 0 & \text{if the old state was 0 and} \sum_\beta W_{\alpha\beta} a_\beta \quad b_\alpha < 0 \\ -1 & \text{if the old state was 1 and} \sum_\beta W_{\alpha\beta} a_\beta \quad b_\alpha < 0 \end{array}$$

The corresponding change in Harmony is

$$\Delta H = \Delta a_\alpha \quad \sum_{\alpha=\beta} W_{\alpha\beta} a_\beta \quad b_\alpha$$

Since Δa_α is positive when $\left(\sum_\beta W_{\alpha\beta} a_\beta \quad b_\alpha\right)$ is, and Δa_α is negative when $\left(\sum_\beta W_{\alpha\beta} a_\beta \quad b_\alpha\right)$ is, H is increasing whenever $\Delta a_\alpha = 0$. But H is also clearly bounded from above, at least by $\sum_\alpha b_\alpha \qquad \sum_\alpha \sum_{\beta>\alpha} W_{\alpha\beta}$, and so cannot increase indefinitely. Therefore the dynamics reaches a maximum, at which point $\Delta H = 0$. At this point $f_{\text{network}}(\mathbf{a}^{\text{stable}}) = \mathbf{a}^{\text{stable}}$.

Note that unbracketed units will only turn off if all units representing their (bracketed) child-options are off. Bracketed units will switch off if any of their neighbors switch off. The basic arrangement repeated throughout the network is depicted in figure 2.

Theorem 1 (Correctness) *Let* $\mathbf{a}^{\text{stable}}$ *be a stable state of a Hopfield network constructed as above to parse* $ITEM(HNF(G), \ ) = (V, \Sigma, R, S)$ *whose initial state* $\mathbf{a}^0$ *is determined by the input string* $v = v_{01} v_{12} \ldots v_{\ -1}$ *in the following way:*

If v_{ij} *is contained in the input and the* m^{th} *grammar symbol is* v_{ij}*, then the* m^{th} *component of the initial state is 1.*

If v_{ij} *is not contained in the input and the* m^{th} *grammar symbol is* v_{ij}*, then the* m^{th} *component of the initial state is 0.*

Otherwise the m^{th} *component of the initial state is 1.*

Then, if the final state is 1 for a unit associated with a start symbol of $\text{width}(\alpha_m) = \ $ *, then the set* $\alpha_m : a_m = 1$ *determine a shared packed forest [Tomita, 1986] of v-parses on G. Otherwise the parser has rejected v.*

Proof: We must show that if a unit representing a start symbol spanning the entire input is in the 1 state at $\mathbf{a}^{\text{stable}}$, then all trees determined by sequences of choices about which activated bracketed child-units to move to from activated unbracketed parent-units, going from the root to the leaves, are correct parses of v.

If a unit representing a start symbol spanning the entire input is in the 1 state, it must be because its -1 bias has been counterbalanced by activation from at least one child, since by definition there are no parents for start symbols.

Select one of these bracketed children that are also in the 1 state. As bracketed units, being on implies a full and correct set of neighbors in the 1 state. Two of these neighbors are bracketed children.

Continue the proof by selecting arbitrarily from among the activated bracketed children at each successive unbracketed unit. This selected unit must be part of a correct parse in virtue of a grammar rule, or it would not be activated. Eventually because the network is finite this selecting and traversing must end at clamped, unbracketed units of width 1.

Each selection of a bracketed unit from the perspective of an unbracketed parent is an unpacking of one choice that has been packed in the shared-packed parse forest. The representation is shared because no symbol is represented more than once.

Since all of the units that are on are part of some correct parse corresponding to some sequence of bracketed-rule selections, for each such correct parse there must be a sequence $\pi = \pi_0, \pi_1, \ldots, \pi_n$ of rules which each describe one piece of local tree structure. Since the above argument did not depend on which bracketed-rule unit was selected at each point, all sequences of selections result in correct parses and all the resulting π stand in a proper parse relation with v on $ITEM(HNF(G), \ )$. The proper parse relation on G is $f_{HNF} \quad f_{ITEM}(v, \pi)$.

Corollary 1 (Completeness & the initial state) *If the initial state* $\mathbf{a}^0$ *includes enough* $a_j = 1$ *to describe a parse of w then that parse will be represented in the final state.*

Proof: The parser's operation can only switch bracketed units $\alpha \quad \text{bracket}(V)$ in the 1 state into the 0 state, and not the other way around, because W is constructed so that α's row, W_α has exactly three nonzero entries, and their sum is $(p_{\max} \quad 2)$. By construction these nonzero entries are at exactly the columns for the two unique children and unique parent. α's bias has also been constructed to be exactly $-(p_{\max} \quad 2)$. So given that α is on, it must be that all of α's neighbors are on and that they are licensed by the grammar. But bracketed units in the

1 state with *correct* parents and children do not change their state. So if all correct parents and children from a parse are present in the initial state, and no bracketed units can switch off, then all correct parents and children must still be on in the stable state.

Example

As an example, consider the ambiguous grammar $S \rightarrow AB$, $A \rightarrow AA$, where S is the start symbol. We follow [Nijholt, 1990] in assuming that preterminal rules such as $A \rightarrow$ v don't play a role and parsing may begin at the nonterminals. The input sequence $AAAB$ is ambiguous on this grammar between an analysis where the left most pair of A's form a constituent $(((AA)A)B)$ and one where the middle two A's form one $((A(AA))B)$. Either analysis ultimately will be compatible with a correct parse.

To build a parser for this grammar for sentences of length $= 4$, the grammar is first transformed by HNF. Even though the grammar was already in Harmonic Normal Form, HNF here serves to explicitly encode the unary/binary status of each rule.

$$\begin{array}{ll} A\ 1 & \rightarrow AA \\ A & \rightarrow A\ 1 \\ S\ 1 & \rightarrow AB \\ S & \rightarrow S\ 1 \end{array}$$

Itemification is then performed, resulting in a larger grammar in which all possible rule applications have been annotated with string position indices for every possible location at which they could be applied.

$$\begin{array}{ll} A\ 1\ 012 & \rightarrow A01\,A12 \\ A\ 1\ 013 & \rightarrow A01\,A13 \\ A\ 1\ 023 & \rightarrow A02\,A23 \\ \vdots \quad \vdots & \quad \vdots \\ A01 & \rightarrow A\ 1\ 011 \\ A02 & \rightarrow A\ 1\ 012 \\ \vdots \quad \vdots & \quad \vdots \\ S\ 1\ 012 & \rightarrow A01\,B12 \\ S\ 1\ 013 & \rightarrow A01\,B13 \\ \vdots \quad \vdots & \quad \vdots \\ S01 & \rightarrow S\ 1\ 011 \\ S02 & \rightarrow S\ 1\ 012 \\ S03 & \rightarrow S\ 1\ 013 \\ S03 & \rightarrow S\ 1\ 023 \\ \vdots \quad \vdots & \quad \vdots \end{array}$$
