There are 54 units, each associated with symbol in this transformed grammar. The network runs until it reaches a stable state, at every transition increasing Harmony. The Harmony values for one simulation run are shown in figure 3.

In the final state, units representing the symbols $S04$, $S\ 1\ 034$, $A03$, $A\ 1\ 013$, $A\ 1\ 023$, $A02$, $A\ 1\ 012$, $A\ 1\ 123$, $A13$, $A01$, $A12$, $A23$ and $B34$ are all in the one state, and all others are in the zero state. Since the start symbol

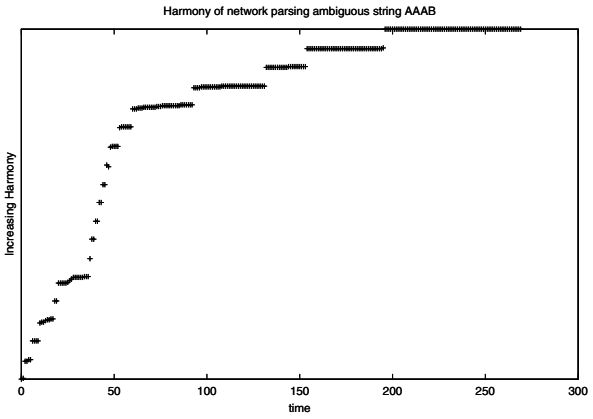

Figure 3: Operation of parsing network on example grammar

$S04$ is activated, we can interpret the parse as having accepted $AAAB$. To determine the parses, we conceptually traverse downward from $S04$ to $S\ 1\ 034$, and then to $A03$ and $B34$. From $A03$, there is a choice of which of the two ambiguous parses to be taken. Both are represented by activated units all of which are part of correct parses that figure into a shared packed parse forest. Selecting $A\ 1\ 013$ determines one parse, and selecting $A\ 1\ 012$ determines the other, just as in chart parsing.

Comparison

One difference between the architecture of this Harmonic grammar parser and various other deterministic connectionist parsers ([Fanty, 1985], [Nijholt, 1990], [Sikkel, 1997]) resides in the lack of central control over evaluation order. The formulation here is in terms of fixed points for randomly-ordered, Harmony-increasing updates. Despite this apparent freedom, the de-activation of unsupported units proceeds bottom-up, an order effect which follows from the connectivity of the network.

As in treatments that avoid Harmony minima through simulated annealing ([Selman, 1985], [Howells, 1988]) the parser's progress can be tracked by examining the current value of H, although here the parser state is not probabilistic.

Other comparisons invite exciting extensions. The work of Hopfield [Hopfield, 1984] suggests that the results for linear threshold units should extend straightforwardly to more realistic neural models, while that of Stolcke [Stolcke, 1989] points the way to more linguistically realistic unification-based grammars.

Perhaps the most intriguing comparison is to Optimality Theory itself. As in Optimality Theory, where all representational possibilities are said to come from *Gen*, the Hopfield network parser described here starts from a state in which all possible constituents are represented. As processing progresses, units representing constituents that lack support given the input string deactivate themselves. In this way the parser acts as a filter

that removes ungrammatical analyses from a initial universe of conceivable analyses. The parser is implementing constraints from a *Con* that contains the soft rules G_H. However, because constraint interaction is numerical, strict domination does not necessarily hold: two or more violations of R_a can be just as bad, or worse, than a single violation of R_A even though $R_A \quad R_a$.

Conclusion

In fact, the ultimate goal of the larger research program of which this work forms a part is the integration of insights from three different sources: formal grammar, constraint-based processing, and linguistic theory. Harmonic grammar is a competence theory that can declaratively specify context-free and other formal languages. Here we have shown that a simple performance theory can be constructed that incorporates this competence theory in a relatively straightforward way into a procedural specification for parsing using abstract neural computing units. In the overall program, however, the role of formal languages is to benchmark theories of human parsing. The analogies to OT in this simple performance theory suggest that such an architecture may be flexible enough to accommodate insights into human language processing from OT syntax and constraint-based approaches to psycholinguistics.

Abstract

Biological organisms display an amazing ability during their ontogenetic development to adaptively develop solutions to the various problems of survival that their environments present to them. Dynamical and embodied models of cognition (Clark, 1997; Edelman & Tononi, 2000; Franklin, 1995; Freeman, 1999a, 1999b; Freeman & Kozma, 2000; Freeman, Kozma, & Werbos, 2000; Hendriks-Jansen, 1996; Kelso, 1995; Kozma & Freeman, 2001; Port & van Gelder, 1995; Skarda & Freeman, 1987; Thelen & Smith, 1994) are beginning to offer new insights into how the numerous, heterogeneous elements of neural structures may self-organize during the development of the organism in order to effectively form adaptive categories and increasingly sophisticated skills, strategies and goals. In this paper we present models of ontogenetic development built on neurologically inspired, bottom-up, dynamic approaches to embodied category formation such as those done by Freeman (1975, 1999b), Freeman and Kozma (2000), Kozma and Freeman (2001), Verschure and Voegtlin (1999) and Edelman (1987), Edelman and Tononi (2000). We believe that building on such mechanisms from an embodied dynamical perspective will produce autonomous agents that display greatly increased flexibility in their behavior. Such models will represent a better understanding of how the brains of biological organisms not only form perceptual categories of their environments during development, but also develop effective patterns of behavior through the dynamic self-organization of neurological patterns of activity.

Introduction

Biological organisms develop effective behaviors simply by perceiving and acting upon their environment in real time. Their learning is always guided by their basic needs. Through their experience with the environment, they begin to embody, anticipate and exploit the regularities of their ecological niche in the service of their intrinsic needs. Some models of learning and development for autonomous systems are beginning to display some of these properties. (Almássy, Edelman, & Sporns, 1998; Edelman et al., 1992; Freeman & Kozma, 2000; Kozma & Freeman, 2001; Verschure, Kröse, & Pfeifer, 1992; Verschure, Wray, Sporns, Tononi, & Edelman, 1995) These abilities include the formation of embodied, organism significant categories through experience; the development of active searching and anticipation of relevant stimuli; the development of a repertoire of skills, or action loops, for the effective transformation of environmental problems and the exploitation of environmental regularities in the service of intrinsic needs.

In this paper we will present some of the most important properties of dynamical and embodied cognition. We will also discuss the properties of ontogenetic development of skills, strategies and goals in biological organisms that make it a particularly powerful mechanism of learning. We will look at examples of existing systems that display properties of dynamical and embodied cognition. And finally we discuss our own plans for creating models of the ontogenetic development of behavior in autonomous adaptive systems.

Embodied Cognition

Embodied cognition is an emerging viewpoint in cognitive science that emphasizes many differing aspects from the standard cognitive hypothesis (Clark, 1997; Hendriks-Jansen, 1996; Pfeifer & Scheier, 1998). In the standard view of cognition, the mind is the product of the manipulation of symbolic representations of the problem in order to produce solutions and generate intelligent behavior (Johnson-Laird, 1988; Newell & Simon, 1972, 1976; Newell, 1990). The environment is perceived and transduced into symbolic representations. These symbols encode the current state of the environment and the problem to be solved. They can be manipulated, independent of the environment, to discover solutions to the problem and produce intelligent behavior for the organism.

In an embodied view of cognition, intelligence in biological organisms does not arise through the static manipulation of amodal symbols and representations. Instead, organisms are seen to be embedded in their environments in fundamental ways. Through their real time experiences with their bodies and environments, they begin to embody the salient aspects of situations in ways that guide future perception and behavior towards improved performance. Experience with their ecological niche develops expectations of the environmental regularities that are of benefit to the intrinsic needs and desires of the organism. The organism actively learns to seek out expected stimuli that are relevant to the desires and needs of the organism at a particular moment.

There are many concepts associated with an embodied perspective of cognition. We will briefly present some of

the more important concepts in the next sections.

Embodied Organisms are Complete Organisms

Biological organisms are currently the only examples capable of producing a full range of intelligent, adaptive behavior. Standard views of cognition place no special emphasis on the fact that these natural examples of cognition are **complete** organisms. In the standard view of cognition, it seems plausible that by connecting together many specialized subsystems that solve problems in limited, specialized domains, eventually a complete intelligence will be produced.

From an embodied perspective, we are not likely to understand natural cognition from such a piecemeal approach to studying and building systems. Instead, we must examine and build complete cognitive systems. In this context, complete refers to systems that are autonomous and adaptive. Autonomous systems are those that have certain intrinsic needs, and that are able to produce behavior that is capable of satisfying those needs consistently over time. Pfeifer (Pfeifer & Scheier, 1998) characterizes autonomy as the ability of the organism to maintain its critical, intrinsic values within a zone of viability. This is often referred to as "homeostasis". Adaptivity refers to organisms that are capable of modifying their behavior so that they can more efficiently maintain their critical parameters in their zones of viability.

Studying complete cognitive systems is important for several reasons. Classical approaches to modeling cognition often tackle toy problems in limited domains. The hope is that the techniques developed can then be scaled up to the full problems of cognition. This approach to studying cognition has failed to produce clear insights into how such methods could eventually be scaled up. Embodied cognition, with its emphasis on complete systems, maintains that the answer is not to start with toy environments. Instead we should begin by studying simple, but complete, organisms, in more realistic environments (Brooks, 1990; Pfeifer & Scheier, 1998). Only complete organisms are capable of developing embodied representations and displaying intentional behavior.

Active, Action-Oriented Representations

Another important difference of embodied and classical perspectives concerns the nature of the representations developed and used by the organism. In a classical perspective, symbols are seen as passive structures that are syntactically manipulated to produce solutions. In an embodied perspective, representations are much more intimately tied to the intrinsic needs of the organism. Clark (1997) calls such structures *action-oriented representations*. Action-oriented representations are not passive representations of the state of the environment as it exists at some time. They are continuously updated from sensory information, and they continuously prescribe possibilities for action. Gibson (1979) has called this the concept of affordances, where the representations *afford* opportunities for action for the organism.

The World Represents Itself

Classical models of cognition often experience an exponential explosion of computational power as the environment increases in complexity. An embodied approach to cognition avoids this problem because it advocates the use of simple, cheap, action-oriented representations. From an embodied perspective, it is better to use cheap and active sensing to inform oneself of the state of the environment, rather than building complex representations of the environment. Brooks (1995) states this principle as "the world is its own best model". Embodied cognition avoids the use of costly and detailed representations. Cheap, quick, active, specialized sensing of the environment is preferred. Instead of maintaining a complex representation of the state of the environment, we simply direct specialized sensory apparatus to directly perceive the information required for behavior. This approach helps keep the need for computation from exploding in complex environments.

Emergence of Solutions through Collective Activity

A key concept of embodied cognition is the emergence of solutions from many parallel, distributed activities. In an embodied perspective, intelligence is seen as emerging from the parallel activity of many cooperating and competing processes. As in connectionist models, parallel emergence of solutions provides many benefits to the behavior of the system. Such emergent solutions are robust and resistant to damage; tolerant of noisy, incomplete data; satisfy general goals and yet are variable and context dependent. They are also fast, able to produce solutions easily in real time demanding environments. Unlike most classical connectionist modeling, embodied cognition views recurrent, non-linear interactions as a crucial property in the emergence of solutions.

Developing Within the Environment

The emergence of solutions through many parallel processes is not simply a product of the non-linear interactions of components in the organism's brain. Intelligent behavior also emerges as the product of the interaction of simple behaviors with a complex environment. Simple, instinctive behaviors are seen as intelligent when they are coupled with local environmental cues (Braitenberg, 1984). Development of action-oriented representations aids in this process. Organisms learn simple actions that, when coupled with appropriate learned stimuli, yield intelligent, purposeful behavior.

Clark (1997) says that embodied minds use extensive external scaffolding. The ecological niche of the organism provides many consistent cues for intelligent behavior. Most intelligent behavior in natural organisms involves the fast recognition and exploitation of such opportunities, not in complex planning and reasoning. Also, most organisms tend to offload complex planning and reasoning tasks onto the environment. They do this by allowing the state of the environment to represent the

progression of the problem solving task. One example, given by Rumelhart, McClelland, and The PDP Research Group (1986), is in the behavior of people when multiplying large numbers. Most people can instantly recognize and produce the answer to simple, single digit multiplication problems, of the type 7 x 7 = 49. However, when given the task of multiplying large numbers together, say 4356 X 1897, they invariably resort to pencil and paper, or even a calculator. People do not compute large chains of complicated reasoning and logic. Instead they offload the representation of the progress of the task onto the environment by maintaining the state of the problem solving task with environmental cues. In this case, people make marks on paper (the environment) to keep track of their problem solving progress, while reducing the problems to those simple ones that they can directly recognize and solve. Embodied cognition sees this type of external scaffolding not as simply useful, but as a prevalent and pervasive method used by cognitive systems to reduce computational complexity and perform problem solving tasks in real time.

Better Imperfect than Late

Biological cognition is exemplified by fast pattern completion. It has evolved to produce behavior in real time. The behavior does not necessarily have to be perfect, so long as it is good enough for the continued survival of the organism (at least until the next crisis occurs). Organisms are continually presented with threats and dangers that must be handled immediately in order to ensure their survival. Such requirements do not favor solutions that take large amounts of time. Natural cognition seems to be built upon a foundation of fast pattern recognition and behavior generation keyed to threats and opportunities for action. The embodied cognitive viewpoint recognizes this fundamental feature of natural cognitive systems. According to Port and van Gelder:

> ”The cognitive system is not a discrete sequential manipulator of static representational structures; rather, it is a structure of mutually and simultaneously influencing *change*. Its processes do not take place in the arbitrary, discrete time of computer steps; rather, they unfold in the *real* time of ongoing change in the environment, the body, and the nervous system. (Port & van Gelder, 1995, pg. 3)”

The Dynamics of Development

The ontogenetic development of behavior provides a powerful mechanisms by which organisms learn to organize effective patterns of behavior for performing the necessary tasks of survival. There are many properties of this type of development. It is fundamentally a self-organizing process, in which the constraints of body and environment guide the system towards discovering certain patterns of behavior. Development of behavior in organisms is not so much a process of finding complex chains of effective behaviors, but in finding salient perceptual cues and effective manipulations that simplify and transform the task environment into problems that are directly recognizable and solvable. Problem solving in natural cognitive systems is more often the application of many transformations until the problem is sufficiently simplified to be directly solved. Clark (1997) calls such phenomena action loops. Kirsh and Maglio (1994) call actions that are primarily performed to transform and simplify the task environment epistemic actions.

Problem solving behavior in biological organisms does not tend to be encoded as static, procedural steps. Instead, organisms develop a wide repertoire of action loops and epistemic actions. Development of behavior takes the form of learning more and better action loops for the effective manipulation and transformation of problems. As an organisms repertoire of action loops grows, they become better able to deal with a wide variety of subtle differences in the problems they need to solve. Their solutions become both robust and efficient with experience in problem solving in the environment.

Development of Embodied Cognition

Thelen and Smith (1994), Thelen (1995) envision the development of behavior in cognitive systems as an ontogenetic landscape of stable and unstable attractors and repellors. As the body of the organism changes, new opportunities for behavior are created and destroyed. Development is seen as a reduction of the degrees of freedom of the system as useful patterns for solving problems are discovered. As stable solutions to problems develop, these in turn change the ontogenetic landscape, opening up new opportunities for some behaviors, and closing off opportunities for others. Development is the discovery of stable patterns of behavior, given the current constraints of the body and the environment.

Natural cognitive systems display both physical and behavioral development. Physical changes in a maturing organism are continually reshaping the ontogenetic landscape, destabilizing previously stable solutions, and forcing the system into finding new patterns of behavior. Natural cognitive systems also display this flexibility in the development of behavior for problem solving. Sequences of behaviors are not learned so much as behaviors that change the state of the environment and thus cue the next behavior in the sequence.

Self-Organization of Behavior

Theories of the self-organization of patterns in nonequilibrium systems provide new insights into the creativity and flexibility displayed by biological organisms (Kelso, 1995). Many of the desirable properties of development in biological organisms make sense only in view of nonlinear dynamics. According to Kelso:

> “The thesis here is that the human brain is *fundamentally* a pattern-forming self-organized system governed by nonlinear dynamical laws. Rather than compute, our brain dwells (at least for short times) in metastable states: it is poised on the brink of instability where it can switch flexibly and quickly.

> By living near criticality, the brain is able to anticipate the future, not simply react to the present. (Kelso, 1995, pg. 26)"

The development of problem solving behavior in biological organisms displays these important properties. Solutions are developed that are flexible, efficient and quick. Such systems are not simply reactive, they learn to anticipate and actively seek out future stimuli.

Bottom Up Neurological Models of Categorization and Action

Some systems have been developed that display properties of dynamic and embodied cognition as discussed above. In this section we present four interesting examples of research that display dynamic, self-organizing category formation and development of behavior. These are all examples of systems that have been built using neurologically inspired, intermediate level neural dynamics.

Distributed Adaptive Control

Distributed Adaptive Control, or DAC (Pfeifer & Verschure, 1992; Pfeifer & Scheier, 1998; Verschure et al., 1992; Verschure & Voegtlin, 1999) is an example of a model of learning based on large scale neural dynamics. At its heart, DAC is a model of classical conditioning, or the learned association of a response to a conditioned stimuli. In the DAC model, there are three levels of control: reactive, adaptive and reflective control.

The reactive level is prewired in the model, and represents the intrinsic values of the autonomous agent. In the case of DAC, the robot instinctively turns away from things when it bumps into them. This represents the value of avoiding damage from collisions with the environment. In addition to a collision sensor, a special sensor for target acquisition is present. DAC is hardwired to move towards the target when it is detected by the target sensor.

The next level is the adaptive control layer. In this layer representations of the states of long range sensors are slowly associated with events that happen in the reactive control layer. So, for example, the system will learn to avoid collisions by associating the profiles of objects sensed with the long range sensor to collisions and the subsequent activation of avoidance behavior. DAC is also capable of learning and exploiting the regularities of the ecological niche it finds itself in. So, if targets are always found behind openings in walls, DAC is capable of learning this association and begins to search out such openings since they tend to lead to finding the targets in the environment.

The final layer of DAC is the Reflective control layer. At this level sequences of actions are formed and remembered through developing sequential representations. This level represents the addition of long term memory to the basic mechanisms of adaptive learning.

DARWIN

DARWIN (Almássy et al., 1998; Edelman, 1987; Edelman et al., 1992; Edelman & Tononi, 2000; Sporns, Almássy, & Edelman, 1999; Verschure et al., 1995) is another neurologically inspired model that is capable of learning and developing representations simply by interacting within its environment. At the heart of Edelman's DARWIN systems is the classification couple. In a classification couple, two maps of neuronal groups receive input from separate sensors. The two maps are wired together with many reentrant connections. As a result of reentrant coupling and the change of synaptic strengths, corresponding classification patterns begin to be associated and mutually activate one another in the maps. Thus, for example, the feel (tactile map) and shape (visual map) of an object become functionally correlated through repeated experience with the objects in the environment. The correlated patterns of activity in the maps represent coordinated properties of objects encountered within the environment.

DARWIN III is capable of self-organizing categories of objects that it encounters in its environment, and of learning appropriate behavior patterns. DARWIN is capable of learning to track moving objects in its environment and also of directing its manipulator in a targeted manner in order to manipulate its environment. DARWIN III is also capable of adaptive learning of behavior, like DAC. It learns to associate visual properties of desirable and undesirable objects, to the feel of the object. As it gains experience in the environment, it no longer needs to touch a bad object in order to avoid it. It has formed associations between the visual and tactile maps, and it begins to avoid undesirable objects upon seeing them.

KIII: Mesoscopic Dynamics

The discovery that brain dynamics operate in chaotic domains has profound implications for the study of higher brain function (Skarda & Freeman, 1987). A chaotic system has the capacity to create novel and unexpected patterns of activity. It can jump instantly from one mode of behavior to another, which manifests the fact that it has a collection of attractors, each with its basin, and that it can move from one to another in an itinerant trajectory. It retains in its pathway across its basins a history, which fades into its past, just as its predictability into its future decreases. Transitions between chaotic states constitute the dynamics that we need to understand how brains perform such remarkable feats as abstraction of the essentials of figures from complex, unknown and unpredictable backgrounds, generalization over examples of recurring objects never twice appearing the same, reliable assignment to classes that lead to appropriate actions, and constant up-dating by learning.

The KIII model (Freeman & Kozma, 2000; Kozma & Freeman, 2001) consists of various sub-units; i.e., the KO, KI, and KII sets. The KO set is a basic processing unit, and its dynamics is described by a 2nd order ordinary differential equation. By coupling a number of excitatory and inhibitory KO sets, KI(e) and KI(i) sets

are formed. Interaction of interconnected KI(e) and KI(i) sets forms the KII unit. Examples of KII sets in the olfactory system are the olfactory bulb, anterior olfactory nucleus and prepyriform cortex. Coupling KII sets with feed-forward and feedback connections, one arrives at the KIII system.

KIII shows very good performance in learning input data and it can generalize efficiently in various classification problems. KIII has a high dimensional chaotic attractor in the basal state. It can be destabilized by sensory stimuli and switched to a lower dimensional attractor wing that represents a previously learned memory pattern.

Basic Intentional System: The Limbic System

We consider biological organisms to be behaving intelligently when they act in ways that will enhance their current and future survival. The behavior exhibited by biological organisms is often very creative and flexible. Yet such behavior is always directed towards the satisfaction of the basic needs of the organism. Freeman (1999a, 1999b) describes such behavior as intentional behavior. Intentionality provides a key concept that links the neurodynamics of brains to goal-directed behavior.

One of the primary acts of intentional behavior is in directing sensory observation in expectation of information to guide future actions. Both the formation of expectations and the real time dynamic interaction of the organism with the environment are important principles of intentional behavior. Freeman's view of the mechanisms of intentionality is one of nonlinear dynamic interaction of heterogeneous neural elements on many levels and time scales. The neurodynamic architecture of the brain forms many recurrent loops between brain and brain, brain and body, and organism and environment. But the basic architecture of intentional behavior can be found in the simplest and phylogenetically oldest parts of biological brains: the limbic system.

Conclusion and Future Directions

In this paper we have presented an overview of the dynamical and embodied cognitive hypothesis. We have also given an overview of some systems that display category formation and developmental learning of the type we are interested in. We have begun work on our own models of the ontogenetic development of behavior in autonomous systems (Harter & Kozma, 2001a, 2001b). Our own models emphasize the development of action-oriented representations that afford opportunities for action-loop like interactions between the agent and the environment. Such models are based upon the formation of embodied categories from chaotic non-linear dynamics.

We begin with bottom-up neurological models that are capable of chaotic non-linear dynamics (Freeman & Kozma, 2000; Kozma & Freeman, 2001). These neurologically inspired models are neither low nor high level simulations of neurological function, but instead capture behavior of the mesoscopic dynamics of brain function (Freeman & Kozma, 2000). These models of neurological function are capable of the dynamic formation of categories. These dynamic categories can be thought of as models of embodied category formation. We are planning to expand such mechanisms to not only form perceptual categories, but develop and display action-loop like skills in the context of the problem domain. Our goals are to see how far such mechanisms can go in developing problem solving behaviors, and to what extent these behaviors mimic those seen in natural cognitive systems.

Eventually we plan to build simplified models of complete limbic systems. We hope that these models will be capable of displaying forms of true intentional behavior in autonomous adaptive systems. Such models should display some of the characteristic flexibility of the problem solving behavior that develops in natural cognitive agents. We are developing agents in cognitively demanding real time task environments. Beginning with some virtual environments, like the game of Tetris (Kirsh & Maglio, 1992, 1994), we are developing bottom-up neurological models that are capable of category formation and the development of behavior in such environments. We hope to eventually move to more complex environments, and real autonomous robots.

Abstract

The form of representations is typically considered to be conditioned by three things: the nature and availability of domain regularities, the perceptual and cognitive abilities of individuals, and the properties of the medium used to construct a representation. This paper reports on an experimental investigation of a fourth constraint on representational form; communicative use. Subjects were given a graphical interaction task in which they produced drawings of pieces of music. The results demonstrate that both level of interaction and communicative context have a marked influence on the form of the representations produced. The results parallel findings for dialogue and indicate that communicative use may be a key constraint on representational form.

Background

In order to be effective in communication, a representation must address, in some reliable way, regularities in the represented world or domain. This intuition naturally suggests a focus on characterising the relationship between the form of representations and the form of a particular domain. For example, between the elements of a picture and the scene or object it represents, or between the structure of a sentence and a mathematical model of the domain. Of course, this relationship may be indirect and arbitrary but where it can be characterised it provides a basis for comparing representations according to properties such as: abstraction, conventionalisation, expressiveness, iconicity, schematisation, and specificity. In cognitive science, three factors are typically cited as moderating these properties. Firstly, the domain to be represented must be sufficiently regular or structured. Secondly, individual perceptual and cognitive limitations constrain both the types of regularity that are identified and the form of the representation used to capture them. Thirdly, representational form is conditioned by the properties of the medium used to produce them.

Significant attention has been directed to analysing the importance of cognitive-perceptual factors and the properties of the medium in conditioning the form of graphical representations (see Scaife & Rogers, 1996, for a review). For example, some authors have highlighted how graphical representations can exploit spatial layout to reduce memory load and facilitate reasoning about a domain (e.g., Stenning & Oberlander, 1995; Shimojima, 1996). The influence of conceptual limitations and perceptual processes in normalising and conventionalising the form of graphical representations has also been investigated (Bartlett, 1932; Tversky, 1981, 1989, 1995). The specific physical properties of graphical media have also been cited as a constraint on representational form. For example, clay discourages the fluent use of detailed graphical forms, favouring simplified, reduced symbols or scripts instead. Historical transitions from pictographic to more abstract scripts have been attributed, in part, to the introduction of clay tablets as the principal writing medium (Tversky, 1995).

These considerations overlook what we take to be the primary function of graphical and linguistic representations: use in communication. Evidence is accumulating to indicate that distinctively interactional or communicative factors constrain the form of descriptions used in dialogue. For example, Garrod and Doherty (1994) showed experimentally that choice between alternative forms of spatial description is primarily influenced by pressure to establish conventions within a sub-community. Importantly, these effects arise independently of domain structure and independently of cognitive-perceptual factors such as individual task expertise (Healey, 1997, 2001). Schwartz (1995) also provides evidence of significant communicative constraints on the form of graphical representations. He studied the differences between the graphical representations produced during problem solving by pairs or individuals. Dyads produced abstract problem representations, such as matrices and graphs, significantly more often than individuals working alone.

This paper reports two experiments that investigate the influence of domain structure, media type, and communicative use on representational form. Our task was designed to meet three basic requirements. Firstly, the precondition that the task domain should exhibit a number of basic regularities which could be captured in a representation. Secondly, that there should be no strong pre-existing representational conventions for carrying out the task. The rationale for this is that our focus on changes in representational form requires a domain for which participants can, in principle, deploy a variety of possible representations and which does not encourage them (or us) to suppose there is a particular 'correct' representation. Existing experimental studies of graphical representation have focussed almost exclusively on tasks and materials, such as maps, Euler circles, circuit diagrams

and program flow charts, which have standard interpretations and which individuals must learn to read in the intended way (cf. Scaife & Rogers, 1996). Thirdly, we wanted a task that is accomplished by exclusively graphical means. This facilitates comparison with other communicative modalities, especially language and is more likely to promote the development of novel conventions. To this end we developed a music communication task. This task involves people producing pictures of pieces of music so that a second person can use them to identify the piece drawn. Music provides a highly structured task domain because of the availability of parameters such as: tempo, intensity, texture, scale and mode. It also provides a domain for which, with the exception of formal notations used by musicians, participants have no pre-existing representational conventions to call on.

Experiment 1

Experiment 1 investigated the effects of domain structure on the form of drawings produced. Musical genre (Jazz vs. Classical) was used as the basic manipulation of domain structure. Two quantitative dependent measures were selected: accuracy of identification of the music from the drawings and time to respond.

Materials 36 pieces of piano solo music were chosen; 18 Jazz pieces and 18 Classical pieces. Each piece was by a different composer or artist and easily recognisable pieces were avoided. The Jazz pieces all included some improvisation and used non-diatonic chord progressions or tones whereas the Classical pieces did not.

All drawing was carried out and captured on a shared virtual whiteboard written specially for the task. The whiteboard was displayed on two LCD tablets (combined graphics tablet and screen) connected to two desktop computers. The whiteboard consisted of a shared drawing area, a strip palette of eight colours and a set of buttons for controlling playback and indicating selections at the top. Subjects could draw using a stylus and lines could be erased by using the reverse end of the stylus.

Subjects 24 participants were recruited from local universities and divided into 12 pairs. They were paid an honorarium for taking part.

Procedure On each trial one participant, the Giver, drew a picture of a target piece of piano music. Givers were free to draw anything they like, subject to the restriction than no letters or numbers should be used. The other member of the pair, the Follower, saw the Giver's drawing developing on the whiteboard and their task was to use this picture to select which of two pieces; the target and a distractor, it corresponded to. Playback and selection of the target and distractor pieces, controlled by buttons at the top of the screen, was self-paced. Followers were asked to make their choice as quickly and as accurately as possible. If a two minute time limit expired before the Follower decided then further drawing by the Giver was blocked and a dialogue window appeared to prompt a final choice. After each trial subjects received feedback about whether the choice was correct. This was repeated for 24 trials with the roles of Giver and Follower alternating between the members of a pair. Music was randomly assigned subject to the constraints that no individual heard the same piece of music twice (as target or distractor), each piece of music occurred equally often as target and distractor, choice of pieces was counterbalanced across pairs and conditions, and order of presentation was randomised for each pair.

Results

Despite some initial hesitation, participants found the task intelligible and engaging. They were able to perform consistently above chance getting, on average, 68% correct ($t_{(44)} = 6.38$, p (two tailed) = 0.00.)[1]. To evaluate effects of the manipulation of genre, two analyses were carried out. Firstly the type of target drawn by the Giver; Classical vs. Jazz. Secondly, the type of discrimination performed by the Follower; same genre (Jazz vs. Jazz and Classical vs. Classical) or different genre (Jazz vs. Classical). The average proportion of correct responses for each pair were analysed in a 2 factor analysis of variance: There was no simple main effect of target type ($F_{(1,11)} = 2.10$, p = 0.17) or discrimination type ($F_{(1,11)} = 2.10$, p = 0.66) and no interaction ($F_{(1,11)} = 0.58$, p = 0.46). The corresponding analysis for average response times also showed no simple main effect of either target type ($F_{(1,11)} = 0.84$, p = 0.38) or discrimination type ($F_{(1,11)} = 2.92$, p = 0.12) and no interaction ($F_{(1,11)} = 2.87$, p = 0.12).

Informal inspection suggested that some of the drawings appeared to be coding emotional affect (e.g., sad vs. happy faces). It was hypothesised that this might reflect the influence of a second aspect of musical form; mode (Major or Minor). To test for this the mode of each target and distractor piece was coded. Analysis of variance with Target type (Major/Minor) crossed with Discrimination type (Same/Different mode) again showed no evidence of a main effect on proportion correct of either target type ($F_{(1,11)} = 0.32$, p=0.58) or discrimination type ($F_{(1,11)} = 2.87$, p=0.12) and no interaction. The analysis for average response times also provided no evidence of an effect of either target type ($F_{(1,11)}=1.312$, p=0.28) or discrimination type ($F_{(1,11)}=0.87$,p=0.37) and no interaction.

Drawing Types The drawings produced fell into two broad categories. The first category of drawings, 'Abstract' (illustrated in Figure 1), involve some representation of musical form, e.g., intensity, pitch, melody, rhythm or tempo, typically represented as a contour. Attempts to use formal music notation were also coded as Abstract. It was notable, however, that use of formal notation was rare and, except in once case, subjects did not

[1] An alpha level of .05 was used for all statistical tests.

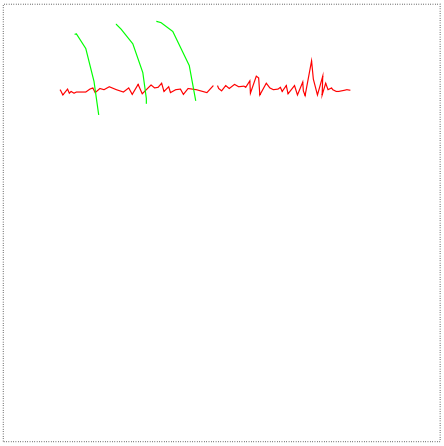

Figure 1: Example Abstract Drawing

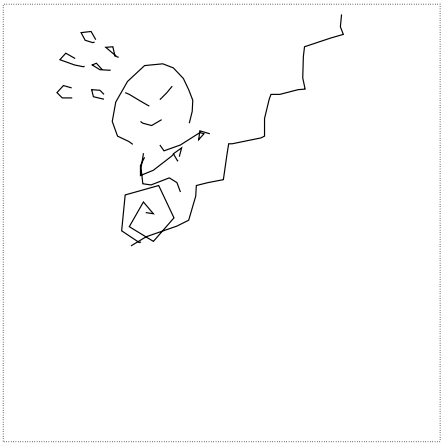

Figure 2: Example Figurative Drawing

persist with it. This was probably attributable to the difficulty of real-time transcription and the fact that it is only useful if both members of a pair are sufficiently expert with it. The second category of drawings, 'Figurative' (illustrated in Figure 2), is a more heterogeneous category involving depictions of e.g., faces, figures, objects or situations. A third, smaller category of Composite drawings was noted in which some abstract and figurative elements had been combined.

Two of the authors independently coded 287 drawings as either Abstract, Figurative or Composite. Inter-judge agreement on the coding was high (Kappa = 0.9, N = 287, k= 2).

It was initially hypothesised that the use of Abstract or Figurative drawings types might be influenced by the manipulation of genre. Jazz is often considered a more abstract form than Classical music and this might be reflected in the use of Abstract representations. Conversely, the selection of non-diatonic Jazz pieces containing some improvisation ensured that, relative to the Classical pieces, they had a less regular structure. On these grounds the form of Classical targets might be more easily detected and drawn. However, as Table 1 indicates, there appears to be no pattern in the distribution of drawing types according to the genre of the pieces. An analysis of the frequency of Abstract and Figurative drawings for Jazz and Classical pieces respectively suggests no reliable difference in pattern of use ($Chi_{(1)}$= 0.45, p=0.50).

Table 1: Frequency of Drawing Types According to Musical Form

	Drawing Type		
	Abstract	Figurative	Composite
Classical	37	94	12
Jazz	42	89	12

To test for effects of communicative context on choice of drawing type, measures of entrainment or matching were used (see Garrod & Anderson, 1987). This is the number of drawings produced by an individual that are of the same type (in this case Abstract, Figurative or Composite) as the immediately preceding drawing produced by their partner. It indexes the degree to which the members of a pair are tending to coordinate their choice of drawing type over and above what would be expected by chance given the frequency of use across the population as a whole. The average score for pairs in experiment 1 was 0.71 compared with a chance level of 0.49 (chance is calculated as the sum of the squared proportions of each drawing type in the corpus as a whole). These were reliably different ($t_{(11)}$=4.03, p (2 tailed) = 0.00).

Discussion of Experiment 1

Although the results show that subjects are able to carry out the task they provide no evidence of an effect of domain structure on task performance. Neither musical genre nor mode, as operationalised here, influenced the effectiveness with which pairs could perform the communication task. The difficulty of producing a drawing, as assessed by the effects of target type, was unaffected by musical form. The difficulty of distinguishing between pieces, as assessed by the effects of discrimination type, was also unaffected. Of course, it is possible that the experiments were insufficiently sensitive to detect an effect or that other aspects of musical form be influencing performance. Nonetheless, two intuitively salient aspects of form; genre and mode, did not affect the difficulty of the task.

More importantly, although the drawings can be reliably classified as Abstract or Figurative, the distribution of these representation types shows no influence of musical form, Jazz and Classical pieces are equally likely to be drawn in a Figurative or Abstract style. The form of the drawings is, however, predicted by communicative context. Pairs tend to entrain to one another, producing

matching drawing types more frequently than would occur by chance. These findings are consistent with our proposal that communicative coordination provides one of the principal influences on choice of representation type. However, the level of communication possible in experiment 1 was very limited. The interaction consisted only in the alternation between the roles of Giver and Drawer and the feedback about whether the last drawing had been correctly identified at the end of each trial. In effect, each trial is analogous to a single conversational turn. If communicative use constrains representational form then manipulation of the level of interaction should affect choice of representation type.

Experiment 2 was designed to address two issues. Firstly to investigate whether altering the richness of the communicative exchange would affect use of drawing types. Secondly to investigate the prediction that a medium which tended to discourage fluent production of graphics would favour more reduced, abstract, forms.

Experiment 2

In experiment 2 the richness of the communicative interaction was increased by allowing both participants to draw and erase freely on the shared whiteboard at any time. The manipulation of medium was introduced by contrasting two conditions, one with the same stylus based interaction as experiment 1, in which subjects draw directly onto the screen, and one with mouse based input. This served to reduce fluency of movement and introduced a spatial separation between input and the screen.

Materials A total of 112, 30 second, piano solo pieces, were used. This included the pieces used in experiment 1 as a subset. The pieces were selected according to the same criteria as in experiment 1 with the exception that each composer was used twice.

Subjects 24 participants, (16 male and 8 female, average age 19) were recruited from a variety of disciplines at local colleges and universities. They were paid an honorarium for taking part.

Procedure Broadly the same procedure as experiment 1 was followed. However, because the restriction to a single person drawing on the whiteboard was removed, subjects were shown a demonstration of simultaneous drawing on the whiteboard. Two versions of the interactive experimental task were used. In the 'matching' version both members of a pair had one piece of piano music each and the task was for them to determine whether these pieces were the same or different. In the 'discrimination' version each member of the pair had two pieces of music and the task was for them to decide which of the two pieces was the same. Although we do not discuss the task manipulation here, the analysis reported below is based on data from both tasks to preserve the balance of conditions and materials.

Design Experiment 2 employed a within-subjects, factorial design with task (Matching vs. Discrimination) crossed with Media (Mouse vs. Stylus). Selection of music was constrained so that the combinations of form (Jazz, Classical) and Mode (Major vs. Minor) were counterbalanced across conditions. Each piece was also classified according to its tempo with selection of tempo randomised across conditions. As before, no one heard the same piece of music twice. This design resulted in a total of 68 trials per pair with order of conditions and materials counterbalanced.

Results

The effects of media and experience on task performance were assessed in two analyses of variance. To index experience, the trials were divided into four blocks. For each quarter of the experiment, and each pair, the proportion of correct responses and the average time to respond were calculated. Analysis of variance on the proportion of correct responses, with media and experience as within subjects factors, showed a reliable main effect of experience ($F_{(3,24)} = 4.84$, p=0.01) but no effect of media ($F_{(1,24)} = 0.04$, p=0.84) and no interactions. Linear trend analysis confirmed that participants became more accurate with experience ($t_{(33)} = 3.48$, p(one tailed) = 0.00) . The parallel analysis for time to respond also showed a main effect of experience ($F_{(3,47)} = 4.07$, p=0.18) and again, no effect of media ($F_{(1,47)} = 0.01$, p=0.92). Linear trend analysis confirmed that participants were becoming faster at the task with experience ($t_{(33)} = 2.38$, p(one tailed) = 0.01). The results suggest that the manipulation of medium does not affect participants' ability to carry out the task.

Drawing Types The drawing activity of each member of a pair was separated into two files and independently coded, as before, for the categories Abstract, Figurative or Composite. An additional category of 'None' was introduced to deal with a small number of cases (3%) where one or both of the partners had not drawn a picture of a piece on a given trial. The distribution of each drawing type across all trials is given in Table 2.

The prediction that medium should affect distribution of drawing types was assessed by scoring, for each pair, the proportion of drawings that were classified as Abstract. This was analysed in an analysis of variance with medium, task and experience as within subjects factors. There was no simple main effect of media ($F_{(1,24)} = 2.22$, p= 0.15) and no reliable interactions.

Table 2: Distribution of Drawings, Experiment 2.

	Drawing Type		
	Abstract	Figurative	Composite
Frequency	970	345	257
Proportion	59%	21%	16%

Entrainment scores were calculated, as before, to provide an indication of the extent to which the members of a pair were coordinating their choice of representation

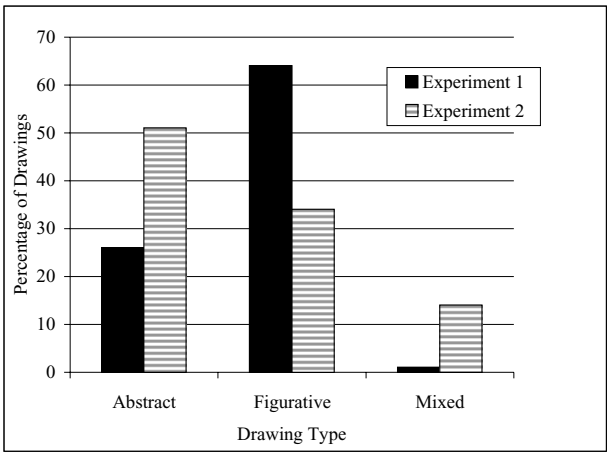

Figure 3: Choice of Drawing Types in Experiments 1 and 2

type. In this case scores were calculated as the proportion of trials in which drawings of the same type were produced, excluding trials in which one or both participants produced no drawing. The average entrainment score was 0.79, reliably above the chance level of 0.42 ($t_{(11)} = 6.75$, $p = 0.00$).

Comparison of Experiments 1 and 2

To test for effects of the difference in level of interactivity between experiments 1 and 2 only data from the first 12 trials of experiment 2 were used. This was in order to restrict comparisons to the situation in which participants had completed the same number of drawings of different pieces.

To compare level of coordination in choice of drawing type a t-test was performed on the average entrainment scores for each pair with experiment (1 vs. 2) as a between subjects factor. This indicated that levels of matching were not reliably different ($t_{(22)} = 0.74$, p (2 tailed) = 0.46). The ability to interact directly did not affect the extent to which pairs tended to match their choice of representation type.

Although degree of matching did not differ between experiments 1 and 2, a reversal in patterns of choice in drawing types was observed. As Figure 3 illustrates, during the first 12 trials of experiment 2 almost twice as many Abstract drawings were produced than in experiment 1. The contrast in relative frequency of Abstract and Figurative drawings confirmed the reliability of this pattern ($Chi^2_{(1)} = 50.7$, $p = 0.00$). The results indicate that the ability to interact directly has a substantial effect on the use of drawing types leading, in particular, to a much greater use of Abstract drawings.

General Discussion

Considered together, the results provide evidence that communicative use has a strong effect on representational form. Although intuitively genre and mode are important elements musical form, they had no effect on task performance or on choice of representation type in the present study. Additionally, although the manipulation of medium between mouse-based and stylus based input provides a contrast in levels of control and fluency it had no demonstrable effect on either performance or representational form. In particular, no evidence was found for the prediction that the simpler contours of Abstract drawings would be favoured when subjects used a mouse. In contrast to medium and domain, two effects of communicative use were noted. Firstly, subjects' choice between Abstract and Figurative representations was sensitive to their partner's choice of representation. People were much more likely to produce a drawing of a similar type to the one last produced by their partner than could be expected by chance. This pattern of entrainment parallels findings for dialogue. Garrod and Anderson (1987) found that, while domain structure favours some types of verbal description over others, the main constraint on choice of representation type is the pressure to coordinate with an interlocutor. Secondly, the pattern of use of drawing types between experiment 1 and 2 effectively reverses with approximately twice as many Abstract drawings and half as many Figurative drawings used in experiment 2. This suggests that level of interaction has an especially marked effect on choice of drawing type and this occurs even though the level of entrainment or matching in the two experiments is not reliably different.

One potential issue with this interpretation is that additional pieces of music were used in the second experiment, raising the possibility that these pieces particularly favoured Abstract drawings. However, the selection criteria for pieces were the same across both experiments and it seems unlikely that a specific bias was introduced. A second issue is that the difference in level of interaction is not the only difference between the tasks in experiments 1 and 2. Although number of pieces drawn and taken into account in the analysis, other task differences might have contributed to the observed effect on drawing types. Arguably, the interactive versions of the task are more comparative because more than one piece is drawn on each trial. This would not explain the tendency to entrain but it could contribute to choice of drawing type. This possibility is being investigated in further work.

The issues raised above notwithstanding, the results provide evidence of a substantial influence of communicative constraints on representational form. This does not necessarily undermine the claim that domain structure and media type influence representational form. Amongst other things, it is possible that genre and mode are relatively unimportant aspects of musical form and other aspects of domain structure would have a more marked effect. Similarly, the difference in ease of execution between a mouse and a stylus, although significant, may be insufficient to affect representational form. These questions can only be resolved by further empirical work. However, the present study suggests that constraints deriving from communicative use can have a strong, per-

haps key, influence on representational form.

The interpretation of these results depends on providing an account of what the difference between Abstract and Figurative drawings consist in. The Abstract category consisted of drawings that appeared to pick up on formal aspects of the music. Contour lines and blobs were used to represent a potentially wide variety of possible regularities, e.g., pitch, stress, harmonic structure, chord structure, rhythm, tempo, texture and intensity. For each of these possibilities a further number of variations are possible including choice of axes, choice of scale, and level of granularity (whole piece, first few bars etc.). A specific type of Abstract drawing imposes a systematic interpretation. It generalises to any piece of music and can sustain internal structural inferences for a piece, e.g., one chord is twice as long or intense as another. Relative to Abstract drawings, Figurative drawings, are highly heterogeneous. They employ a range of ad hoc devices such as visual emblems (city skylines for Jazz) symbols of emotive affect (sad faces, graves), pictures of rabbits or cars to indicate tempo, pictures of landscapes to suggest moods and so on. In contrast to Abstract drawings they provide only weak support for generalisations. There is not a street scene or landscape for every piece and they provide almost no information about the internal structure of a piece.

The present proposal is that the key constraint on the use of Abstract or Figurative drawings in the present task is the degree of coordination they require. In particular, successful use of Abstract drawings demands a higher degree of semantic coordination. To use Abstract drawings successfully subjects must attempt to coordinate on which aspect of musical form is being used, on which axes, at what level of granularity. Figurative drawings, by contrast, can be used in a more ad hoc manner. They can exploit different interpretations in each case and do not impose a particular structure on the music. We propose that direct interaction sustains the use of Abstract drawings by providing mechanisms that facilitate the coordination of interpretation. For example, in experiment 2 subjects were seen to circle and underline parts of each other's representations. This could function as a means of isolating and repairing problems with particular elements of a drawing. Lines and arrows between different contours were also used to indicate possible alignments or changes of scale. In experiment 1 such exchanges were impossible even though, in principle, the same types of representation could have been used.

The implication of these considerations is that properties of representations, such as abstraction, may depend more on the character of the interactions in which they are used than on the character of the represented domain. This is not to suggest that effective representations do not address regularities in the represented domain but rather that representational form is conditioned, first and foremost, by the structure of interaction and the kinds of coordination that it makes possible, and only contingently by the structure of the domain.

Abstract

Formulation and interpretation of conditional instructions (conditionals relating the occurrence of an event to the taking of an action) are studied from a pragmatic standpoint: It is argued that formulations of the instructions differ in perceived naturalness as a function of the adequacy between the necessity and sufficiency relations they embed and the goal-structure of the situation. Two experiments are reported to support this claim.

Conditional Instructions as a Peculiar Subclass of Conditional Statements

As Austin (1962) has observed, we use words to get things done – and there are indeed lots of things we can get done by using the word "if", that is, by asserting a conditional statement. With a conditional statement, we can tell others what conclusion they should draw (e.g., "if it is a three-star restaurant, then the food there is certainly divine"), or what action they should take (e.g., "if you wear this suit, you will make a very good impression on her") – and in particular, especially in working situations, we can give others instructions to follow would a specific situation occur (e.g., "if a customer buys two make-up products, offer her a sample of this perfume").

It is common knowledge among psychologists that people do not do very well in conditional reasoning tasks. For example, they have a disturbing tendency to derive the wrong conclusions from a conditional argument (e.g., they commit the fallacies of Asserting the Consequent: "If P then Q; Q; therefore P," and of Denying the Antecedent: "If P then Q; not-P; therefore not-Q") and not to derive the right ones (e.g., they do not apply Modus Tollens: "If P then Q; not-Q; therefore not-P"). (See Evans, Newstead, & Byrne, 1993, for a review.) Does this poor performance extend to this subclass of conditional statements we just dubbed conditional instructions? Since conditional instructions are so very common in working situations, that could be bad news.

Fortunately, people seem to be better at handling conditional instructions than at solving conditional reasoning problems. In this paper, we want to show that when dealing with conditional instructions, people are able to (a) select the better way to express a conditional relation between two events according to the goal-structure of the context, and (b) interpret a conditional relation in a normatively (logically) valid way.

Goal-Structure of the Context and Formulation of a Conditional Instruction

From our pragmatic point of view, the context will determine what a speaker will aim to achieve by uttering a conditional instruction: Thus, conditional instructions make points, and do so well or badly depending on their perceived relevance to contextually specified goals. Context will be considered here through an analogy between complying with a conditional instruction and being engaged in a signal detection task. (See Kirby, 1994, for another view on the analogy between conditional reasoning tasks and signal detection tasks.)

In a signal detection task, the observer has to judge whether a signal actually indicates its putative referent or not. Does a certain kind of blip on a sonar screen indicate the presence of an enemy submarine (that has to be sunk) or not? Two types of error are conceivable here: (a) other kinds of objects may have caused the blip, for example whales or friendly submarines, leading to a "false alarm" (FA); and (b) an enemy submarine may really be out there, his sonar "signature" being distorted by underground wave patterns or rock formations in such a way that the operator fails to recognize it, leading to a "miss" (MS).

Now, whether a MS or a FA has the highest expected cost may depend on the situation. In a state of war, MS are likely to prove costly: If you do not sink the enemy submarine first then it will sink you. However, a FA may also prove costly: If you mistakenly sink a neutral country's submarine or ship, you may provoke that country to declare war on you, which could prove especially costly if the neutral country happens to be, say, the United States. (Think of the Lusitania...)

Now, imagine a warship commander wishing to give his operators a conditional instruction linking the observing of an enemy submarine "blip" and the launching of depth charges. In context A, the commander knows that enemy submarines are lethal if allowed within range and must be destroyed at first sighting. Clearly, what he should fear are MS, that is, enemy submarines which are not attacked. In context B, the commander knows that enemy submarines are outside range at first sighting, and that there is a considerable risk of destroying his own submarines, or those of a neutral superpower that are also lurking in the area. What he should fear here are FA, that is, non-enemy submarines which are attacked.

What would be the best way for the commander to frame his conditional instruction in context A? "If you see an enemy blip, then launch the depth charges?" "If and only if you see an enemy blip, then launch the depth charges?" "If you do not see an enemy blip, then do not launch the depth charges?" "Launch he depth charges only if you see an enemy blip?" And what would be the best choice in context B?

Our prediction is that people can and do perceive differences in the naturalness of these formulations as a function of what they perceive to be the goal-structure of the context, that is, "avoid misses" vs. "avoid false alarms". Experiment 1 below offers an experimental investigation of this claim.

Experiment 1

Participants A total of 46 students at the University of Heidelberg took part in this study.

Material & Method Three additional scenarios were created on the model of the Submarine scenario: each scenario came either in an avoid-FA context or in an avoid-MS context. In the Airport scenario, a security officer was to decide whether he would search suspicious-looking luggage, knowing that (avoid-MS context) the airport was situated within a "hot" area where terrorists were liable to smuggle weapons, or (avoid-FA context) the airport was mostly frequented by high-ranking executives that would not appreciate losing their time with a luggage search. In the Border scenario, a policeman equipped with a speed radar of some poor quality had to decide whether he would arrest drivers slightly exceeding the speed limit when entering France from Germany via a subway (the speed limit in France being lower than in Germany), knowing that (avoid-MS context) officials insisted on strictly implementing the French regulation, or (avoid-FA context) the officials insisted on the importance of fluent circulation prior to the strict implementation of the French regulation. In the Mail scenario, which was adapted from Gigerenzer and Hug (1992) in order to vary costs and benefits from a single perspective, an office worker was told to stamp letters over 20 grams in weight at 2 marks, knowing that (avoid-MS context) understamping (i.e., putting 1 mark stamps on letters over 20 grams) would damage the firm's public image, or (avoid-FA context) overstamping (i.e., putting 2 marks stamps on letters under 20 grams) would be costly to the firm's finances.

Each questionnaire featured the four scenarios, all of them in their avoid-MS or avoid-FA version (context was thus a 2-level between-subject factor), rotated over two experimental blocks, with two orders within each experimental block, such that each subject saw two avoid-MS and two avoid-FA contexts paired with different content scenarios. Following each scenario, four conditional instructions were introduced (if P then Q, if and only if P then Q, Q only if P, if not-P then not Q); participants had to rate on a 7-point scale the naturalness of each instruction in the situation that had just been described to them (formulation of the conditional instruction was thus a 4-level within-subject factor). The experiment was conducted in German.

Results & Discussion Table 1 displays the mean naturalness ratings (across the four scenarios) assigned to the four formulations as a function of the goal-structure of the context. (The observed pattern of results was remarkably stable across scenarios.)

Table 1: Naturalness ratings (7-point scale) of conditional formulations as a function of context.

	Context: avoid-MS	Context: avoid-FA
If P then Q	5.74 [a]	3.10 [c]
If and only if P then Q	4.03 [b]	4.47 [b]
Q only if P	3.19 [c]	4.33 [b]
If not-P then not-Q	2.42 [d]	4.91 [b]

N = 22 for avoid-MS context, N = 24 for avoid-FA context. Values that do not share the same subscript differ at $p < .05$.

In the avoid-FA context, all formulations appear to be of acceptable naturalness (4 to 5 on a 7-point scale), except the "if P then Q" formulation which is judged significantly less felicitous. On the contrary, this formulation is by far the most felicitous in the avoid-MS context, the formulations "Q only if P" and "if not-P then not-Q" being this time judged unnatural.

Now why these differences in naturalness as a function of context? One possible answer is related to the notions of necessity and sufficiency. In the avoid-MS context, one would like to stress the sufficiency of P (observing an enemy blip) in regard to Q (launching the depth charges), whereas in the avoid-FA context, stress should be on the necessity of P in regard to Q. Hence, the ideal formulation in the avoid-MS context would be "if P then Q", whereas this same formulation would be inappropriate in the avoid-FA context. In a given context, a natural formulation will be one that direct the attention of the hearer to the relevant aspects of the situation: is P necessary rather than sufficient for Q? This explanation assumes that people's interpretation of the necessary and/or sufficient character of P in regard to Q in the four considered formulations coincide with what it should be according to formal logic. In the light of previous research (see again Evans, Newstead, & Byrne, 1993), this could be seen as a rather bold assumption. The next section will focus on the reasons why this assumption may hold in the specific case of conditional instructions.

Interpretation of Conditional Instructions as Constraint Perception

Does each of our four conditional formulations (if P then Q, if and only if P, Q only if P, if not-P then not Q) have its own stable interpretation in terms of necessity and sufficiency relations? That is, do people consider these formulations to embed different basic patterns of necessity and sufficiency, even if they have no idea of the goal-structure of the instruction? Moreover, do these patterns coincide with the patterns predicted by traditional logic?

The standard approach to this issue would have been to give participants a scenario (e.g., selling clothes in a clothing store), an instruction (e.g., "if a customer is not touching any clothes, do not offer him your help"), a situation (e.g., "a customer is touching some clothes"), and ask them what they would do in this situation if they had to follow the rule (e.g., "I would offer my help", "I would not offer my help", "I do not know"). But this approach would actually miss the point, for it would not assess the interpretation subjects made of the rule, but their final decision on what they should do, a decision that does not solely depend on the interpretation they made of the rule. (In the above example, a participant may well answer that she would offer her help to a customer that is touching some clothes, after being told that "if a customer is not touching any clothes, do not offer him your help". Is this participant interpreting the rule as meaning that a customer touching some clothes is a sufficient condition to offer him some help? Or is she just taking her best bet on what to do when the rule does not strictly apply?)

Therefore, in order to assess the interpretation participants make of a conditional instruction, what has to be checked is not what they would do in the situations P and not-P, but how they perceive the way the instruction is constraining their behavioral options in these situations. Thus, given the rule "if a customer is not touching any clothes, do not offer him your help", and the situation "a customer is touching some clothes", the relevant set of answers to choose from would be: "I must offer my help", "I must not offer my help", and "I am free to decide what to do."

We proposed that the function of the different formulations of the instruction was to direct attention

Table 2: Most frequent patterns associated to each formulation of the conditional instruction (N = 39).

Formulation	Most frequent pattern	Frequency: Shop scenario	Frequency: Restaurant scenario
If P then Q	Situation P: Must do Q Situation not-P: Free to decide	82%	82%
If and only if P then Q	Situation P: Must do Q Situation not-P: Must not do Q	85%	82%
If not-P then not-Q	Situation P: Free to decide Situation not-P: Must not do Q	85%	90%
Q only if P	Situation P: Free to decide Situation not-P: Must not do Q	56%	46%
	Situation P: Must do Q Situation not-P: Must not do Q	31%	46%

on different aspects of the context. Efficient illocutionary uptake would then depend on the possibility for the hearers to rely on some basic, conventional meaning of the four formulations regarding the necessity and sufficiency relations they embed. Were these basic meanings to coincide with what they are in traditional logic, then given a conditional instruction "if P then Q", "if and only if P then Q", "Q only if P", or "if not-P then not Q", and the set of choices "I must do Q", 'I must not do Q", "I am free to decide what to do", participants' answers in the situations P and not-P would exhibit normative (logical) validity in terms of the necessary and/or sufficient relationships between P and Q. Experiment 2 below was designed to provide an empirical investigation of this hypothesis.

Experiment 2

Participants A total of 39 students of the Ecole Supérieure des Sciences Economiques et Commerciales (ESSEC) at Cergy-Pontoise took part in this study.

Material & Method Two scenarios were constructed, the Shop scenario and the Restaurant scenario. In the Shop scenario participants were told that they were selling clothes in a shop; they had to decide whether they would offer a customer some help, knowing that there was an instruction to be strictly followed (e.g., "if a customer is touching some clothes, offer him some help"). In the restaurant scenario, participants were told they were establishing a list of providers for the chef; they had to decide whether a provider should be put on the list, again knowing that there was an instruction to be strictly followed (e.g., "if a provider does not offer you a reduced price, do not put him on the list").

Each questionnaire featured the Shop scenario and the Restaurant scenario. Within each scenario, the four formulations of the conditional instruction were introduced in turn. (For the Shop scenario, the four formulations went:
"If a customer is touching some clothes, offer him your help", "If and only if a customer is touching some clothes, offer him our help", "Offer a customer your help only if he is touching some clothes", and "If a customer is not touching any clothes, do not offer him your help.") The formulation of the instruction was thus a 4-level within-subject factor. For each rule, participants were asked to choose from the three following answers, first in the situation P, then in the situation not-P: "I must do Q", "I must not do Q", "I am free to decide what to do." The experiment was conducted in French.

Results & Discussion A first way to look at the results is to consider the most frequent pattern of answer elicited by the participants for each formulation (see Table 2). Regarding the formulations "if P then Q", "if and only if P then Q", and "if not-P then not-Q", there is a clear dominance of a single pattern for each rule (eliciting 82 to 90% of answers), whereas the formulation "Q only if P" elicits two main patterns. (Whatever the formulation, no other pattern elicited more than 13% of answers.) The dominant patterns elicited by the formulations "if P then Q", "if and only if P then Q", and "if not-P then not-Q" are precisely those that would be predicted by classical logic. Of the two main patterns elicited by the formulation "Q only if P", one is predicted by classical logic, the other one is the biconditional pattern.

Another way to look at the results is to consider, for each formulation of the instruction, the frequency with which participants answered as if P was necessary (see Table 3) or sufficient (see Table 4) for Q. In order to compute the percentages in Tables 3 and 4, participants have been considered as (a) answering as if P was necessary for Q if they answered that they would have to avoid doing Q in the situation not-P, and (b) answering as if P was sufficient for Q if they answered that they would have to do Q in the situation P.

Whatever the scenario, P was overwhelmingly considered to be necessary for Q with all formulations except "if P then Q", which is what one would expect according to classical conditional logic. In particular, the fallacy of Denying the Antecedent ("if P then Q, not-P, therefore not-Q") was endorsed by only 8 to 13% of the participants, which is well below the usual rate observed in conditional reasoning experiments.

Table 3: Necessity of P in regard to Q (in percentage of answers), as a function of instruction formulation.

	Shop scenario	Restaurant scenario
If P then Q	08 % [a]	13 % [a]
If and only if P then Q	95 % [b]	95 % [b]
Q only if P	87 % [b]	92 % [b]
If not-P then not-Q	92 % [b]	97 % [b]

N = 39. Values that do not share the same subscript differ at $p < .05$.

Turning to the sufficiency of P in regard to Q, results are unambiguous for the formulations "if P then Q", "if and only if P then Q", and "if not-P then not-Q": This time, P is overwhelmingly deemed as sufficient for Q, as classical logic would predict. The unexpected result (from a logical standpoint) comes from the formulation "Q only if P", with P being deemed sufficient for Q by 36 to 51% of participants. This last result may be used to rule out the idea that logical competence only could be responsible of participants' answers: If participants recovered logical competence when dealing the instructional subclass of conditional statements, then

why would the specific formulation "Q only if P" elicit logical errors?

Table 4: Sufficiency of P in regard to Q (in percentage of answers), as a function of instruction formulation.

	Shop scenario	Restaurant scenario
If P then Q	87 % [a]	92 % [a]
If and only if P then Q	87 % [a]	85 % [a]
Q only if P	36 % [b]	51 % [b]
If not-P then not-Q	08 % [c]	08 % [c]

N = 39. Values that do not share the same subscript differ at $p < .05$.

Without resorting to an explanation in terms of logical competence, it could be argued that the deontic nature of conditional instructions is responsible for the normatively correct performance of participants, since deontic contents are known to be a powerful facilitator of conditional reasoning. First, it should be noted that a conditional instruction is not a social contract the way Cosmides (1989) has defined it: A conditional instruction does not relate perceived benefits to perceived costs, it does not express a social exchange in which an individual is required to pay a cost (or meet a requirement) to another individual in order to be eligible to receive a benefit from that individual. Having no cost-benefit structure, conditional instructions do not leave room for cheating, that is, obtaining the benefit without paying the cost. Therefore, if participants' performance has benefited from some deontic facilitation, this facilitation does not fall within the scope of Cosmides' (1989) social contract theory or Gigerenzer and Hug's (1992) cheater-detection algorithm.

Would this deontic facilitation be explainable by Cheng and Holyoak's (1985) pragmatic reasoning schemas theory? In Cheng and Holyoak's terms, improved performance would be due to some content or context-based prompting of either a permission or an obligation schema. Yet, since context and semantic content of the instruction stay the same across our conditions, why should syntax alone determine the nature of the prompted schema? We fail to see why, content and context remaining stable, "if P then Q" would lead to the activation of an obligation schema, whereas "if not-P then not-Q" or "Q only if P" would lead to the activation of a permission schema.

As demonstrated by Thompson (2000) in her study of interpretative processes in various types of conditional reasoning tasks, performance in a conditional argument task (contrary to performance in Wason's selection task) is predicted by necessity and sufficiency conditions, and not by the deontic or factual nature of the conditional. Is it possible to explain our results in terms of perceived necessity and sufficiency relations?

Indeed, conditional instructions are meant to embed very strong necessity and sufficiency relations: In the instruction "put a provider on the list only if he offers you a reduced price", the necessity of the offer is clearly not a matter of degree. Due to the intrinsic nature of conditional instructions, any necessity or sufficiency relation between the two propositions involved will be of maximal perceived strength, which would explain the extreme frequencies observed in Tables 3 and 4. The fact that participants did so well in perceiving the valid necessity and sufficiency relations and dismissing the invalid ones in the instructions they were given can conceivably be explained by one distinctive aspect of conditional instructions: Contrary to most conditionals (e.g., causal conditionals, conditional warnings, etc.) instructions are not meant to change the epistemic state of their recipient, but to constrain his or her behavior. As one's natural preference will usually be to exert one's free will, it is not much surprising that one will be accurate in recognizing in which situation one's behavior will be dictated or not by the instruction, that is, recognizing the necessity and sufficiency relations embedded in the instruction.

Conclusion

The focus of this paper has been the formulation and interpretation of conditional instructions, that is, conditionals that relate the occurrence of some event to the undertaking of some action. Drawing an analogy from signal detection theory, we labeled a "Miss" the situation in which the event is occurring but the action is not taken, and a "False Alarm" the situation in which the action is taken without the event occurring.

We proposed that context allows to determine the relative expected costs of Misses and False Alarms, which in turn allows to determine the goal-structure of the situation and the aim of the speaker asserting the instruction: What is to be avoided in the situation? Misses? False Alarms? Both?

Depending of the goal-structure of the situation (and consequently of the aim of the speaker), syntactic formulations of the instruction differ in perceived naturalness (Experiment 1). For example, the usual conditional formulation "if P then Q" will be perfectly appropriate for situations where Misses must be avoided, but will be of poor felicitousness in situations where False Alarms must be avoided.

We proposed that judgements of naturalness are based on the understanding people have of the necessity and sufficiency relations embedded in the various possible formulations of the instruction. A formulation in which P is sufficient for Q is appropriate for situations where Misses must be avoided, a formulation in which P is necessary for Q is appropriate for

situations where False Alarms must be avoided. Experiment 2 showed that when dealing with conditional instructions, people have a much clearer understanding of those relations than what could have been expected from their usual performance in conditional reasoning tasks.

Taken together, these two studies suggest that speakers' perception of the felicity of different kinds of conditional expressions is strongly determined by goal-structure (avoid miss vs. avoid false alarm), and that hearer's reactions to these conditionals is well aligned with this goal-structure, even if hearers have no explicit knowledge of these goals. The results therefore suggest that the function of these different formulations of conditional instructions is to direct the hearer's attention to aspects of his decision-making situation that the speaker considers important. That hearers so successfully detect the speaker's intentions not only suggests – in the language of Austin – high illocutionary uptake, but also successful coordination of action by the speaker and the hearer.

For the rational speaker to get what he wants done with words, he should therefore choose a form of the conditional that encodes the goal-structure implicit in the context, in the knowledge that the hearer should react in a way that will fulfill his intention. Rationality here is thus social and pragmatic, determined by the successful coordination of the speaker and the hearer to achieve shared organizational goals.

The Influence of Recall Feedback in Information Retrieval on User Satisfaction and User Behavior

Eduard Hoenkamp (hoenkamp@acm.org)
Henriette van Vugt (vanvugt@cogsci.kun.nl)
Nijmegen Institute for Cognition and Information; Montessorilaan 3
6525SW Nijmegen, the Netherlands

Abstract

The unprecedented scale-up of the World Wide Web, and the number of people relying on it for information, make it inevitable to reassess the validity of the traditional metrics for quality of information retrieval (IR). Of these, the most widely used metrics are recall and precision.
Users can judge the precision of an information retrieval system by inspecting the retrieved documents. They cannot judge recall, however, which would involve inspecting the whole collection, thus obviating the IR system, and impossible in the case of WWW. How then, can we ascertain whether recall is a valid metric for the quality of an IR system as perceived by the end-user? In a carefully controlled experiment we presented users with a simulated web search engine. Besides the search results, the engine could give a (spurious) recall estimate, presented as a pie chart. We manipulated this recall feedback, and whether the information need was fulfilled with respect to quantification type (the number of documents requested). It seems that fulfillment is a better predictor of user satisfaction and behavior than precision and recall as used to evaluate IR systems. The results reported here also suggest that whereas recall may be a valid metric for designers and evaluators of IR systems, it may lack validity as a metric for search quality as perceived by the end-user.

Introduction

Barely a decade ago, techniques for information retrieval were still in the able hands of librarians, in the case of print, and of data base managers in the case of electronically stored information. The explosive growth of the World Wide Web has changed this situation dramatically and irrevocably. Since then, people in all walks of life depend on automated 'librarians' as provided by search engines such as Google, AltaVista, Yahoo, and many others. Oviously, the end-user of such a system wants information that is relevant, and wants it returned within a reasonable time. The latter is a matter of efficiency, and that is where most of the research effort has gone. For example: how to increase bandwidth, how to index documents, how to encode multimedia. Not surprisingly, the aspect of efficiency is dominated by computer science, and solid metrics are known for these technical aspects.

Effectivenes, on the other hand, can only be gauged by the users of an IR system themselves. We claim that IR is a golden opportunity for cognitive science, with its roots in both psychology and computer science. For this, researchers can pursue two avenues: one is to exploit cognitive principles in modeling the user, the other by evaluating traditional metrics of IR concerning effectiveness through experimental design. The viability of the former approach we demonstrated elsewhere (Hoenkamp, Stegeman, & Schomaker, 1999; Hoenkamp & de Groot, 2000). In this paper we give an example of the latter.

From the the early days of the library sciences until today many metrics have been proposed to evaluate the quality of information retrieval systems (Swets, 1963; Cleverdon, Mills, & Keen, 1966). These metrics are to measure how satisfactory the material is that the system retrieves (the output), with respect to the user's information need presented as a query (the input). After several decades, *recall* (proportion of relevant documents actually retrieved) and *precision* (proportion of the retrieved documents that are relevant) have stabilized as *normative* measures for the quality and thus comparison of IR systems. The evaluation of these metrics has itself become a subject of study regarding both their reliability (Buckley & Voorhees, 2000) and their validity (Hersch, Turpin, Price, Chan, Kraemer, Sacherek, & Olson, 2000). Yet, however respectable and theoretically sound the metrics may be for comparing IR systems, it does not make them automatically apropriate to predict the satisfaction of the end-user with such a system. And given that IR systems are eventually built not for the evaluators but for the end-user, we wanted to investigate whether these metrics are also *valid* measures for quality from *the perspective of the user* conducting the search.

Users can only fare on the documents actually returned, and not on the uncounted documents never found. And as users can determine the relevant documents only among those returned, they can determine precision, but not recall. In addition, if users want to refine a search or provide feedback, again they can only do so on the basis of the documents returned. As precision is the only parameter the user can be aware of, it is the more likely parameter to determine the quality of a search as perceived by the user. So precision can be validated in principle, as one predictor of the user's satisfaction with an IR system. As the user cannot observe recall, there cannot be a corresponding validation for recall. This ends the symmetry between the two metrics that their definitions suggest. Any hope for exploring the relationship between recall and search quality, as perceived by the end-user, would require restoring that symmetry. This is exactly what we

set out to do. In a moment we will describe an experiment where we provided users with recall feedback, and measured the influence on their satisfaction with search results and search machine, and with their subsequent search behavior. Also, the usefulness of recall feedback is measured. It is important to understand that the recall feedback was represented by a slice on a pie chart. The size of the slice was manipulated, and had no relation whatsoever to actual recall.

It is useful to look first at our intuitions in order to appreciate what we learned through the experiment.

Intuitions

For the evaluator of IR systems, the intuitive trade-off between recall and precision is well-known: High recall can be achieved trivially by returning all documents, as this will include all relevant documents. Obviously, this goes at the expense of precision as many irrelevant documents are returned as well. Similarly, high precision can be achieved by stringent conditions on relevance, at the cost of missing potentially relevant documents. The end-user has also intuitions about recall (which we will capture below under hypotheses 2 and 7): When a search engine returns many relevant documents, the recall is perceived as high (especially when the precision is high). That is, the user thinks that the search engine retrieved a large proportion of the relevant documents. Consequently, the user is satisfied with such a search engine. Conversely, if very few documents, or none at all are returned the recall is seen as low, and the user is less satisfied with the search engine. Note, however, that the actual recall can be opposite to these intuitions. Especially when recall feedback violates these intuitions, this should influence the user's satisfaction with the search engine.

Focusing on the user's satisfaction with the search results, we intuit that it will depend on the degree to which the user's information need is met, and not on the mere number of returned relevant documents. For example: if the user wants to know whether the latest "Harry Potter" is out, just one document could meet this information need. If he wants to know which retailer on the web has the lowest price or the fastest delivery for the book, he needs as many sites as possible to choose from. Finally, if he needs the name of a bookseller nearby, a few documents may suffice to find one. Following Cooper (1968) we refer to these numbers as the *quantification type* of an information need, and call them quantification type 1, 2, and 3 (for one, all, or several documents). We expect the user to be most satisfied with the search result if the number of relevant documents returned matches the quantification type, at a high precision rate (this intuition leads to hypotheses 3 and 8). The satisfaction with the *search engine* we gather will depend on the type, the documents returned and, as the system is evaluated a whole, the *recall* (this leads to hypotheses 4 and 9).

These intuitions about the hypothetical relationship between the satisfaction and the compromise between recall and precision are visualized in figure 1. The figure shows the three quantification types. For example, for quantification type 3, the user would be unhappy with only one relevant document, satisfied with, say five documents, and again less satisfied when many more are returned as they will subsume more and more be irrelevant ones. The figure represents cases with, say, 200 relevant documents. The numbers on the x-axis are fictitious but are meant to indicate recall and precision. From left to right recall increases and precision decreases (recall and precision can easily be calculated, using the numbers in the figure). At the top of each curve the information need is fulfilled at the highest precision rate. The figure represents our prediction that no universally best compromise between recall and precision exists, as satisfaction will depend on the number of documents needed.

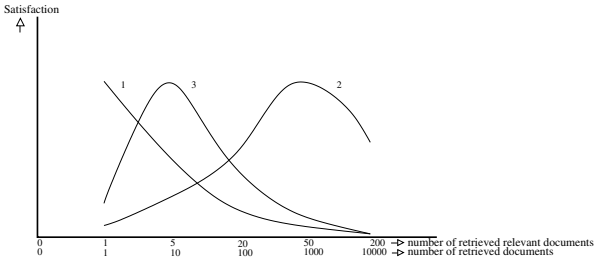

Figure 1: The compromise between recall and precision when *one* (1), *all* (2), or *several* (3) documents are needed. The curves represent the qualitative relationships hypothesized in this paper, between the satisfaction with retrieved documents and recall and precision. Note that the numbers along the x-axis are fictitious.

In this paper we assume that that user is looking for information, as opposed to entertainment. Hence we assume that the user's behavior, i.e. to continue or to stop searching, depends on whether his information need is fulfilled (which leads to hypotheses 5 and 10). Finally, we expect that also the usefulness of recall feedback depends on whether the the information need is fulfilled. More precisely, recall feedback will only be important if the users' need is not (yet) fulfilled. The usefulness may increase with increasing amount of documents searched for (these intuitions lead to hypotheses 6 and 11). we do not expect them to continue searching. Nor to

In line with the above, we expect strong interactions among the dependent variables. For example, when the information need of users is fulfilled, we expect them to be highly satisfied, to stop searching, and not to care much about recall feedback.

It will be clear that there are many potential interactions among the variables we introduced, hence the rather complex design. The hypotheses in the design section below are only a more detailed expression of the hypotheses we have just introduced informally.

Description of the experiment

Method

Participants The thirty two participants, fourteen female, were almost all acquaintances of one of the experimenters and volunteered to participate. Thirty of them had at least college education. They varied in age from 18 to 72, with a mean of 26. Their computer experience is presented in table 1.

Table 1: The participants' familiarity with computer activities. The columns indicate frequency the activity. a: never, b: once a year, c: once a month, d: once a week, e: several times a week, and f: daily.

	a	**b**	**c**	**d**	**e**	**f**
computer use	0	0	0	0	8	24
internet use	0	0	1	3	12	16
use of search engine	1	0	4	7	13	7

Design The experiment followed a within subjects design. Three variables were manipulated (1) fulfillment of the information need (2) quantification type (one, all, several), and (3) presence or absence of recall feedback, represented by a pie chart. If feedback was present, three ranges were used: low, medium, and high. These were depicted as slices of respectively 10, 20, and 30% of the pie, 40, 50, and 60%, and 70, 80, and 90%. Let us reiterate that the recall value had nothing to do with actual recall. It was only used to give the subjects the impression that the search engine produced this value. In reality a search engine cannot give such a precise number to a user, that would be a paradoxical situation where it would need the user to evaluate the relevance of documents it has not shown to the user.

In our pilot study we had prepared the material such that for each query we could give a number of relevant documents to match the quantification type. As the search engine would always return ten documents, we in effect controlled the *precision@10* (the proportion of relevant documents in the first ten documents).

The dependent variables were (1) satisfaction with the documents, (2) satisfaction with the search engine, (3) usefulness of the chart, and (4) tendency to continue to search. In a questionaire, the first three varialbels were scored on an 11-point Likert scale and the fourth was the answer to a yes/no question.

The hypotheses we investigated are an elaboration of the intuitions we described previously. Especially because they are so intuitively appealing, they have to be carefully laid out.

H1 Fulfillment of information need will be the dominating factor influencing the dependent variables.

Hence we split the other hypotheses up in two cases.

When the information need is fulfilled:

H2 The intuition of participants has the following effect: high recall causes a higher satisfaction, a higher usefulness of recall, and a higher stop rate than low or average recall.

H3 The satisfaction with the documents is high irrespective of quantification type and recall feedback.

H4 The satisfaction with the search engine is high and increases with magnitude of recall. There is no influence of quantification type.

H5 Users do not want to continue to search. Yet, a low recall may persuade them to do so.

H6 The usefulness of recall feedback is low and does not depend on its magnitude. If it would change at all, it would increase in the order of quantification type 1, 3, and 2.

When the information is not fulfilled:

H7 The intuition of participants has the following effect: low recall causes a lower satisfaction, a higher usefulness and a lower stop rate than average or high recall.

H8 The satisfaction with the documents is low irrespectively of quantification type and recall feedback.

H9 The satisfaction with the search engine is low, but increases with magnitude of recall. There is no influence of quantification type.

H10 Users want to continue to search. Yet, a high recall may persuade them to stop searching.

H11 The usefulness of recall feedback is high and does not depend on its magnitude. If it increases at all, it would be in the order of quantification type 1, 3, and 2.

Apparatus Participants interacted individually with Netscape 4.7 on a Macintosh G3. The HTML pages used in the experiment were stored locally to avoid network delays. Several toolbars ('navigation', 'location', and 'personal') were turned off to maximize window area as well as prevent interfering or unneeded interaction. The simulated search engine had the unadorned look and feel of the 'Google' search engine. The advantage of the simulation is obviously that all variables could be carefully controlled. Besides the query page, there was a page with search results (including documents and possible recall feedback) and a questionnaire existing of four questions and a box in which remarks could be written. For each search task we returned exactly ten documents. The participants were provided with pencil and paper to jot down the search task at hand. It had a circle printed on it, where they could copy the pie chart.

Procedure Each participant completed one practice task, and 24 randomized experimental search tasks that included a broad range of topics. The quantification type of each search task was obvious (e.g. the task to find a particular home page, is of type 1). The participants had to read the instructions from the screen. They were told

that we wanted to evaluate a search engine that used a novel search strategy. After the instructions, they had to explain the meaning of a pie chart, so we could check whether it was correctly understood (namely as recall information). For each task they went through the following cycle: (1) read the task printed on paper, which represented the information need, (2) indicate the quantification type, (3) input the keywords to the search machine, (4) inspect the search result, write down the number of relevant documents and copy the pie chart, if any, on paper and (5) fill in the questionnaire.

Results

The four dependent variables were analyzed separately with repeated measures for analysis of variance (GLM). The cohesion between the dependent variables was analysed using linear regression and independent t-tests. We also collected the users' remarks, but we will concentrate here on the summary statistics.

Table 2: Means of the dependent variables in the two conditions *fulfilled* and *unfulfilled* and their levels of significance and F-values.

	Fulfilled (mean)	**Unfulfilled** (mean)	**Sig.**	**F**
Satisfaction documents	9.2	4.2	.000	463.62
Satisfaction search engine	9.0	4.2	.000	387.76
Continue to search	.29	.84	.000	153.40
Chart is useful	6.1	6.9	.072	3.48
Chart might be useful	6.0	7.4	.004	9.86

The influence of fulfillment on the dependent variables is clearly demonstrated in table 2. According to the significance levels, **H1** is confirmed except for the usefulness of the chart.

To avoid a tedious enumeration, we will focus on the main results now. So, instead of giving all the tables for all interactions, we will give table 3 as an example of what the data look like, and then summarize the others (for the reader who wants to study the details, we would be happy to make all the data available).

First we will look at **H2** and **H7**, concerning the intuitions of participants about recall feedback. In the condition unfulfilled, low recall indeed leads to different usefulness (F= 3.81, p= .034), satisfaction with the documents (F= 4.233, p= .013) and search engine (F= 6.803, p= .011). In the condition fulfilled, high recall leads only in type 2 tasks to different usefulness (F= 7.788, p= .007) and satisfaction (documents: F= 11.703, p< .001; search engine: F= 10.067, p= .002). The bahavior, however, is not influenced. This means that intuitions of participants do play a role in evaluation, but not in their subsequent behavior.

Table 3: Satisfaction with the documents, when the information need is fulfilled. 'Q Type' is the quantification type, 'Feedback' the recall feedback. The numbers indicate mean scores on the 11-point scale for user satisfaction.

Feedback / **Q Type**	absent	low	middle	high	overall
1	9.7	10.1	9.7	9.5	9.8
2	9.5	9.0	9.2	9.9	9.4
3	8.9	8.2	8.6	8.3	8.5

Now let's consider **H3-6** (fulfilled condition). The magnitude of the recall did not influence any of the variables. The satisfaction with both the documents and search engine was high but for type 3 lower than for type 1 and 2 (documents: 1-2: p= .276; 1-3: p< .001 and 2-3: p= .002; search engine: 1-2: p= .133; 1-3: p< .001 and 2-3: p= .005). **H3** and **H4** are therefore partly confirmed. As mentioned before, some participants do not agree with us that five relevant documents is enough to fulfill an information need of type 3. As a result, many participants want to continue to search in type 3 tasks of the condition fulfilled (34.4%). Also, in type 2 tasks of this condition many participants want to continue to search (44.5%). This can be explained by the restriction to *ten* documents in our experiment; it is impossible that these always include *all* existing relevant documents. In type 1 tasks, however, 93.0% want to stop searching; most participants obviously fulfilled their information need. Low recall did not cause a larger proportion of participants wanting to stop searching. **H5** is rejected because of these results.

The usefulness of the chart was not as low as expected, but did increase in order of type 1, 3 and 2, confirming **H6**.

Now I will discuss **H8-11** (unfulfilled condition). The satisfaction with both the documents and the search engine was low. Quantification type didn't influence them (p= .397 and p= .512). The satisfaction with the documents was influenced by recall (F= 4.233, p= .013) and was higher in absence of a chart, then in presence. But the satisfaction with the search engine was only in type 2 tasks influenced by the recall feedback low recall causes then a lower satisfaction than average recall (F= 6.803, p= .011), high recall (F= 11.449, p= .001) or no chart (F= 5.666, p= .020). **H8** is just partly confirmed and **H9** is rejected. Participants did want to continue to search (82.3%), confirming **H10**. The usefulness of the chart was not as high as expected, there was an effect

of type (F= 11.07, $p< .001$); it was highest for type 2, confirming **H11**.

There was a strong cohesion among the variables. Satisfaction with documents and search engine correlate strongly ($\beta = .92, p<.001$), Satisfaction with the documents correlates negatively with the usefulness of the chart ($\beta = -.102, p = .005$), and similarly for the estimated value of the chart, if it was absent ($\beta = .29, p<.001$). Similar values hold for the satisfaction with the search engine. The tendency to continue to search was strongly related to the other three dependent variables.

Discussion and conclusion

Quantification type did influence the results, contrary to our expectations. There are several plausible explanations for this influence. First, in several tasks, some participants did not agree with us about the number of relevant documents among the documents returned. We know that some uncertainty about the relevance of documents existed as some of the participants marked a document as relevant, that we found irrelevant and vice versa. We noticed this uncertainty because the numbers of the documents written on paper did not have complete overlap with the documents we found relevant. Second, there were varying interpretations of the phrase 'several documents' that we used to indicate type 3. Our pilot study indicated that 'several' could stand for 'about five' relevant documents but the participants of our experiment needed more relevant documents to be satisfied. Tasks that were meant to be fulfilled, may, in the eyes of some participants, not have been completely fulfilled and the other way around. Especially for quantification type 3 the satisfaction in the condition fulfilled was lower than expected. The large standard errors, especially in type 1 tasks, also reflect the differences among participants concerning relevancy and fulfillment. Hence, both the conditions fulfilled and unfulfilled are not as unequivocal as expected. Though judgments on relevancy are by definition subjective, more pilot studies could have increased the certainty in interpreting the results for both experimenter and participant.

Nevertheless, the experiment showed us that different types of information needs can be discerned. If search engines can get information about the type of the user's information need, they could adapt the exactness of its search and influence recall and precision (see figure 1)

Second, the results indicate that first, if participants are highly satisfied with the documents, they want to stop searching and they are not interested in the chart, and second, if participants are unsatisfied, they want to continue searching and understand that the chart provides worthwhile information.

To summarize. It seems that fulfillment is a better predictor of user satisfaction and behavior than precision and recall as used to evaluate IR systems. Search results with low precision can indeed result in high satisfaction, e.g. in case of quantification type 1.

Let is briefly comment on the question whether it is worth the effort to see if recall, which is a valid metric to compare the quality of IR systems, is also a valid metric for IR quality as perceived by the end-user. The participants in our experiment found the chart quite useful. This puzzles us, as it was meant to represent recall, and recall had very little overal effect. It might be that participants needed more time to familiarize themselves with the concept of recall feedback. The result is paradoxical enough to warrant further research. We stay with our prediction that recall information indeed will help the searcher in certain cases. But as long as a compromise must be found between recall and precision, precision should get a higher priority; the results suggest that even if the recall is low, the satisfaction can be high.

It is worth the effort to investigate ways to compute recall more precisely than can currently be done (e.g. pseudo recall or relative recall). The present authors are investigating a 'capture-mark-recapture' technique borrowed from biology, to observe in what proportion documents reappear in a search. In addition, we found a few cases where intuition conflicts with experimental findings. These may also be a source for further investigation.

Summarizing the main conclusions: First, among the variables we investigated, the one with the dominant influence on user satisfaction was whether the information need was fulfilled, and second, recall had virtually no influence on satisfaction or search behavior.

Modelling Language Acquisition: Grammar from the Lexicon?

Abstract

A neural network model of language acquisition is introduced, based on and motivated by current research in psychology and linguistics. It includes both semantic-feature representations of words and localist linguistic representations of words. The network learns to associate the semantic features of words to their linguistic labels, as well as to predict the next word in the corpus. This is interpreted to model both the acquisition of a lexicon, and the beginnings of syntax or grammar (word order). The relationship of lexical learning to grammar learning is examined, and similarities to the human data found. The results may provide support for the 'Grammar from the Lexicon', or 'emergent grammar' position.

Introduction

How do children acquire language? More generally, how does any abstract language learner acquire language? When we attempt to model language processing via computer simulation, what should we be attempting to model, mature adult performance, or the developmental schedule of a child? What can such a model hope to tell us about the process of language acquisition in human infants?

These are some of the questions motivating our effort to model language processing. Much evidence exists as to the usefulness of the connectionist modelling enterprise for the understanding of human language in general. However, as we seek to model more fully the actual processing, and even production, of language, in a behavioural fashion, we consider it very important to take a developmental approach to human language processing. That is, a complete model of language processing should first become a model of language acquisition. Evidence suggests that a model of language acquisition in children should provide the foundation necessary to scale up to a model of more mature language processing, as we shall see.

Developmental Language Acquisition

In considering a developmental model of language, one important aspect is the limits of the enterprise. That is, where does language acquisition start, and where does it end? Language is a very complex cognitive activity, and our connectionist modelling techniques still maturing. We do not want to include any more than absolutely necessary in a model of language if we are to be successful. Thus, it is important to be explicit about our assumptions, in terms of pre-linguistic mental representations, or of what we can exclude from our model or include only as inputs.

We assume here that modelling any of the low-level acoustic properties of language is unnecessary for our purposes. While issues such as phonemic segmentation are important for language, those auditory tasks are arguably well-learned by the time of vocabulary acquisition. Further, modelling to the level of acoustics is too computationally demanding to include in a model of language acquisition at present.

If we consider the start of vocabulary acquisition to be at the age of the child's first word, typically 8-12 months, then we can ask the following question. What cognitive capacities does the child have prior to that point? What does language have to build upon? Some suggest that there is a considerable amount.

Lakoff and colleagues (Lakoff, 1986; Lakoff & Johnson, 1999) suggest that the child has reached an adequate level of concept formation prior to the development of language. Few would argue, we believe, that pre-linguistic children must have some kind of internal representation of the world, some understanding that a cat is fuzzy and can be patted, even if they don't know the words cat, or pat, or fuzzy. Lakoff argues that children's sensorimotor experience is continually building up these pre-linguistic concepts, concepts that are very specific and concrete, and that these concepts enable the child to function in their limited world.

With all of this cognitive machinery already well established, the language learning problem has happily become much simpler. If a child already has a concept for things like 'cat', then when it begins to learn the word for cat, it is really only attaching a linguistic label to a category of sensorimotor experience that it has previously built up. The learning of words is thus reduced to the learning of labels for things. The attributes of those things and the relationships between them are all predetermined (at least at this stage) by the child's environmental experience. Of course, nouns fit into this viewpoint with greater ease than do verbs; it is harder to point to a verb than a noun.

This is the traditional view in developmental psycholinguistics according to Gillette et al. (Gillette, Gleitman, Gleitman, & Lederer, 1999). As they point out however, this view has limits. Specifically, they show evidence that only some words can be derived solely via extralinguistic context.

It is well known that there is an overwhelming preponderance of nouns in children's early speech, not only in English but in most languages, while adults, of course, have a much more equal balance. Several explanations have been offered for this distinction. The discontinuity hypothesis holds that the cognitive capacities of children are fundamentally different from adults. Thus, at some point after the start of development of language children's cognitive capacity for language changes. Gentner describes the noun learning advantage as due to the conceptual complexity of the ways in which the two classes, noun and verb, describe the world (Cited in Gillette et al, 1999). That is, nouns describe object concepts, while verbs describe relations between objects. The latter would obviously be the more complicated task, since it depends on the success of the former. As Gillette et al point out, by this interpretation learning words is not just a matter of associating labels to concepts. Significant conceptual learning must occur as well. If true, this interpretation would argue against the conceptualization of language-age children as relatively conceptually stable, and would also invalidate one of the assumptions of our modelling approach.

Fortunately, Gillette et al. offer a different interpretation, the continuity hypothesis, which assumes that children are conceptually equipped to understand at least those concepts that underlie the words that adults typically use with them, both nouns and verbs. However, they argue that it is still possible to account for children's initial restriction to noun learning, using instead the different informational requirements of words that are necessary to uniquely identify them from extralinguistic context. They refer to their hypothesis as an information-based account, and describe several experiments that support this account.

Most importantly Gillette et al. provide strong evidence that learnability is not primarily based on lexical class. That is, it is not whether a word is a noun or a verb that determines if it can be learned solely from observation. Rather, they demonstrate that the real distinction is based upon the word's imageability or concreteness.

It is obvious that the very first words must be learned solely by the child attempting to discover contingencies between sound categories and aspects of the world, over many different exemplars. Gillette et al. demonstrate that the very first words used by mothers to their children are the most straightforwardly observable ones, and that as a group, the nouns are in fact more observable than the verbs. Furthermore, the imageability of a word is more important than the lexical class. The most observable verbs are learned before the less observable initial nouns, accounting for the few rare early verbs in children's vocabularies.

So, imageability or concreteness is the most important aspect of the early words, nouns and verbs alike, and it determines the order in which they tend to be learned by children. This result argues against the discontinuity hypothesis, and supports Lakoff's early concepts and the borders that we have drawn for our language modelling enterprise. However, what of the less imageable words? How are they learned?

Gillette et al. also find evidence for the successive importance of noun co-occurrence information and then argument structure. That is, for later learning of the less imageable words (mostly verbs), observing which previously known nouns co-occur in a sentence with the yet unknown word label helps greatly to uniquely identify the concept. Thus rather than imageability determining exactly which object we are talking about over multiple experiences, for many verbs the nouns involved act to identify it. Thus if the noun 'ball' is paired with a yet unknown word, the concept 'throwing' may be activated for many learners, allowing them to infer that the unknown word means 'to throw' (Gillette et al, 1999). Argument structure is yet a further step to verb inference. Gillette et al. show that the number and position of nouns in the speech stream reliably cues which verb concept the unknown word could be.

At this point in the child's language learning we have moved beyond initial lexical learning and are in the realm of syntax. The first words (mainly nouns) have been learned without reference to other words, their sheer imageability enabling them to be inferred from the adult to child speech stream and the extralinguistic evidence. The next step involves the use of these concrete nouns to help infer the less imageable verb meanings in the speech stream, and from there the child is no longer learning words solely from the extralinguistic context. The lexical structure of utterances now assists the child as well. For example, the first few verbs learned, when experienced in adult speech and involving a novel object, will cue the inference of the new noun label and, depending on the particular verb, even the type of noun involved. The circular, bootstrapping process of language learning is on its way (for further evidence concerning verbs and nouns respectively, see Goldberg, 1999; Smith, 1999). Before long new words will no longer require explicit extralinguistic context at all. The school-age child will begin reading and acquiring new words solely by lexical constraints, allowing them to exhibit the incredible word acquisition rates that have been reported (e.g. Bates & Goodman, 1999).

Of course, once the child's lexicon has reached a certain level of complexity, perhaps 300 words (Bates and Goodman, 1999) the multi-word stage begins, and grammar acquisition begins to be a consideration as well as just lexical acquisition.

Grammar From the Lexicon

Bates and Goodman (1999) examine the highly linked development of grammar and the lexicon. They provide evidence for the emergence of grammar directly from the lexicon itself. Specifically, they show the lack of evidence for any dissociation of lexical and grammatical processes (drawn from studies of early and late talkers, focal brain lesions, and developmental deficits), along with the very tight developmental ties between the two. For example, lexical status at twenty months (during children's vocabulary burst) is the single best predictor of grammatical status at 28 months (during children's grammar burst), with a correlation coefficient of between .70 and .84. This is in fact as good a statistical relationship as that between separate measures of grammar! This is good evidence that grammar does emerge, at least partially, from the very growth of the lexicon itself.

This finding, as well as those of Gillette et al, is important to the development of our model of language acquisition, as if grammar development is emergent from lexical development, then we want to be sure that we do not model them as two separate modules or components. Rather, a central tenet of our model is to use a single processor architecture to learn both lexicon and grammar. Furthermore, lexical development should precede grammatical, and grammatical development should not take off until sufficient lexical development has occurred. Our model should exhibit the same sort of acquisition (and production, eventually) behaviour as a child.

A Dynamical Systems Approach

Elman (1995) suggests viewing the process of initial lexical and grammatical development as a dynamical system, or attractor model, which can be learned through a process of predicting the input. Roughly speaking, this viewpoint is as follows. A language learner's semantic representations are very limited at first, much like a flat three-dimensional landscape. Then as the learner develops stable categories and concepts, the landscape gradually develops depressions or basins, each basin corresponding to a word or concept, and each experience of that concept deepening the basin, until eventually the landscape is full of deep and wide basins of attraction. These are "attractors" since, while any partial or confused activation of a semantic representation will tend to indicate a place on the landscape not in one of these basins, the slope of the 'terrain' is such that the representation will tend to be drawn down into one basin or another, and the larger basins will be more likely to capture the activation. They "attract" the activation.

Furthermore, this attractor representation is hierarchical. General or superordinate concepts might have very large basins, containing within them smaller basins corresponding to more specific but semantically related terms.

Obviously this landscape representation only applies to the lexicon. How does grammar enter into the picture? Well, if the lexicon is viewed as basins in this representation landscape, or state-space, then grammar is contained in the transitions that occur between these states. That is, a true dynamical system consists not only of these representations in state space, but also relationships that influence movement from one representation to another. Further details can be found in Elman (1995), but for our present purposes it is sufficient to realize that this dynamical systems approach provides a possible mechanism for the implementation of the word-inference processes described earlier (Gillette et al. (1999). Certainly a recurrent net like the one we will describe in our model is capable of exhibiting the behaviour of a dynamical system, with the hidden unit representations corresponding to the state-space vectors and the operation of the network providing the transitions between them based on the values stored in its weights. It can also be argued that the cortex operates in this fashion (Elman, 1995; Sulis, 2001, personal communication), and thus that the same explanation can be offered for human language processing.

The 'Complete' Early Language Acquirer

Let us assume, then, that the child (or model) starts with pre-existing pre-linguistic concepts of the world, upon which linguistic labels will be learned by direct instruction as well as simple exposure. This pre-existing conceptual structure implies either a pre-existing mental representation (semantic landscape) or one that is quickly built up as words are matched to concepts.

In our model, we assume that the child begins syntax or grammar learning at the same time as it begins learning vocabulary. However, since there is little evidence that grammar is directly instructed (Bates & Goodman, 1999), unlike noun acquisition (Smith, 1999), and since grammar is inherently more complex, grammar learning does not really succeed until after the most primal of the lexical attractors have been firmly set and the lexical and syntactical bootstrapping has begun. In essence, grammar exposure begins at the same time as lexical learning, but grammar learning doesn't effectively take place until the lexical representations are solidified.

Thus we would expect to see exactly that behaviour that is seen in real children; lexical development proceeds at an ever accelerating pace, then when the lexical foundation is firm enough (the 'noise' or uncertainty in the language environment is reduced enough) the mental machinery can focus on syntactic relationships, and grammatical learning should accelerate. Our model should exhibit exactly this behaviour if it is capturing the essence of human language acquisition.

Method

Our experiment consists of training our model of language acquisition many times from different initial conditions, and analyzing the performance results for their fit to the human data and improvements over the control models.

The Model

The model of language acquisition discussed herein (see Figure 1) takes as input uniquely identified words (localist input representations), and learns how those words can be used in sentences. This is not a novel undertaking (see Elman, 1990, 1993; Howell & Becker, 2000). However, what is new to this model is the addition of a second set of inputs, semantic-feature inputs. By 'semantic', however we actually mean pre-linguistic semantics or meaning (e.g. sensorimotor features). Thus, instead of abstractly manipulating locally-distributed word representations, a process that has been characterized by McClelland as "learning a language by listening to the radio" (Elman, 1990), our model attempts to ground the word representations in reality by associating them with a set of these semantic features for each word.

Furthermore, the network is not performing only the prediction task that is argued (Elman, 1990) to lead to an internalization of basic aspects of grammar, specifically word-order relationships. Instead, it is also learning, simultaneously, to memorize its linguistic inputs, memorize its semantic inputs, and associate the two together, such that either one alone will elicit the other.

Why construct a neural network model in this way? First, using a simple recurrent architecture and prediction task retains the successful grammar learning capabilities that have been shown so well by Elman and colleagues. Second, adding a semantic layer will eventually allow for the use of phonemic input representations and the binding of those phonemes into words (through semantic constancy across each individual word) although the network discussed in this paper does not deal with phonemic inputs, only whole-word inputs. Third, the inclusion of the semantic input layer and a semantic output layer means that semantic features can be read off for any given linguistic input, indicating whether the network has learned the "meaning" of the word.

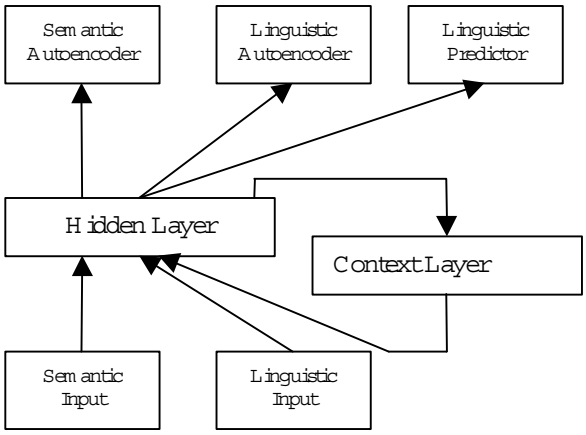

Figure 1: Modified SRN architecture, including standard SRN hidden layer and context layer, standard linguistic prediction layer, and novel semantic autoencoder and linguistic autoencoder.

Finally, the inclusion of both linguistic autoencoding (word learning) and linguistic prediction (grammar learning) allows us to explore the dynamics of the model, and determine if the learning behaviour of the model maps to the human developmental data. That is, does the word learning have to reach a critical mass before the grammar learning proceeds? Does a jump in lexical competence lead to a linked jump in grammatical competence? If so, then perhaps the model can provide evidence for the view that grammar emerges from the lexicon (Bates and Goodman, 1999).

Model Details

There are two input layers and three output layers. The semantic output layer is paired with the semantic input layer. Both are 68 nodes in size, since the semantic feature dimensions taken from Hinton & Shallice (1991) have 68 dimensions.

The linguistic input and the linguistic outputs are of size 29, since the vocabulary has 29 words. Both linguistic outputs are tied to the same set of linguistic inputs, but where the linguistic autoencoder's training signal is the present input, the linguistic predictor's training signal is the input at the next time step.

Both the hidden and the context layer are of size 75, and the hidden-to-context transfer function is a one-to-one copy with no hysteresis (see Howell & Becker, 2000). The hidden-to-context connection is not

trainable, but the context-to-hidden feedback connection is trained exactly as is either of the input-to-hidden connections.

Training Environment

The network is trained on a corpus of text derived from a small (390 word) subset of Elman's original corpus of two and three word sentences with a 29 word vocabulary (Elman, 1990).

Input to the semantic input layer was derived from the above corpus by converting each word in the corpus to the word's semantic featural representation, using a set of features derived from Hinton and Shallice (1991). This feature set includes only the sensory features and excludes the semantic-association ones found in the original. This resulted in a binary distributed representation for the semantic layer. It is important to note that on language tasks a binary distributed representation would often be expected to learn faster than a localist representation, as it provides more information to the network.

The network's weights were randomly initialized, and training proceeded as usual for Simple Recurrent Networks, using the backpropagation algorithm (Rumelhart, Hinton, and Williams, 1986).

Training proceeded until reasonable levels of accuracy were achieved. Trial runs of up to 1500 epochs indicated that the net asymptoted near 500 epochs, so training did not in any case proceed beyond 500 epochs.

Error measures and accuracy measures were logged at each input presentation, but averaged over the 390 patterns to one value per epoch of training.

Results & Discussion

The first finding from the various runs of the network is that the net does in fact learn. There had been some concern that the demands of three different tasks sharing a single hidden layer might cause significant or even catastrophic interference in the learning tasks. On the contrary, with a hidden layer size only slightly larger than the largest input layer (75 compared to 68 for the semantic input layer) the net learned all three tasks.

Furthermore, the tasks were learned in the expected order. That is, judging from the error curves the binary distributed semantic representations were learned most quickly (since they provide more information for the network to learn on, i.e. more bits turned on) followed by the localist linguistic autoencoding and then the localist linguistic prediction. Prediction, of course, is a more difficult task than autoencoding or 'memorization', just as verb learning is a more difficult task than noun learning.

For the present purposes, our analysis is limited to the lexical-grammatical relationship (and further semantic results are not reported). Specifically, over 24 simulation runs the mean peak lexical accuracy was 96.6 percent correct, while the mean peak grammatical accuracy was 37.33 percent correct (See Figure 2).

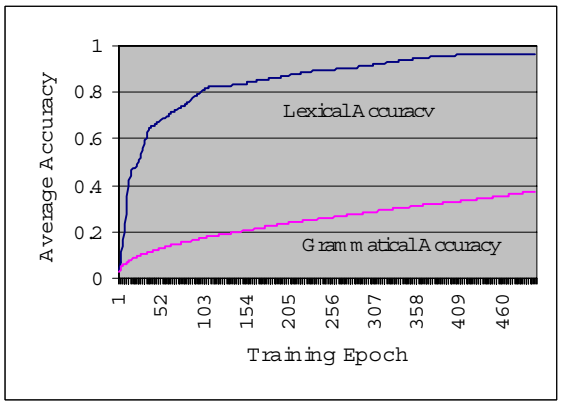

Figure 2: Average Accuracy Curves Over 24 Runs

Comparisons with 'control' or partial networks lacking the semantic or lexical autoencoder task also indicate that each task is learned faster and more accurately in the experimental network than in the control networks. Only the grammatical results are reported here, however.

For control network 1, which included only the linguistic prediction task (i.e. an original Elman net) the peak prediction accuracy was lowest, with a mean of 18.5 percent correct, and significantly different from the experimental network via t-test ($n = 10, p < 0.0001$).

For control network 2, which excluded only the semantic layers, the peak prediction accuracy, achieved at epoch 500, was significantly lower than the experimental network ($n=10, m = 28.4, p < 0.0001$).

For control network 3, which excluded only the linguistic autoencoder, the peak prediction accuracy was still lower than the experimental network ($m = 37.1$) but the difference did not reach significance ($n=10, p = 0.137$).

Thus, training all three tasks through a single hidden layer apparently creates synergies that allow each to proceed faster than it would alone.

Most interesting, however, was the relationship between the lexical and grammatical accuracy curves for the experimental network. We expect that if our model is catching important elements of the human language learning experience, then it should exhibit lexicon-then-grammar behavior. Certainly, as discussed above, the speed of learning (rate of error decline) exhibits this relationship, but that is only to be expected by the difficulty of the tasks. A better question is

whether the network exhibits the lexical-to-grammatical performance correlations that Bates and Goodman (1999) discuss. That is, does the lexical performance at time T correlate well with the grammatical performance at some later point?

By analogy to the methods cited in Bates and Goodman (1999), a point on the lexical accuracy curves that could be considered the 'lexical burst' was identified (approx. Epoch 108). Then, since there was no explicit 'grammar burst' within our time window a set of correlations was calculated to the grammatical performance at various time lags from the lexical burst (see Figure 3). The results indicate that the highest correlation, approximately .80, is from the lexical burst to grammatical performance 75 epochs later.

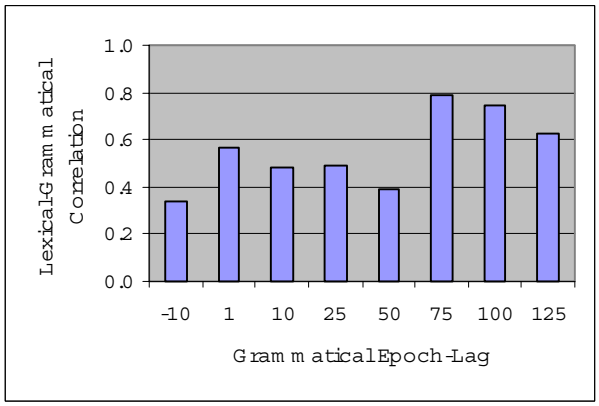

Figure 3: Lexical-Grammatical Correlations (n = 24)

This is similar to Bates & Goodman's cited correlation between lexical status at 20 months and grammatical status at 28 months in children. At first, the similarity may seem limited, since our model uses only 29 words, not the 300-plus that is suggested to be the critical mass required for grammar learning. Also, our sentences use only the 29 words from the model's vocabulary, and no unfamiliar words, and word learning is being represented by average accuracy curves. Further, grammatical status is being measured by accuracy of prediction rather than Mean Length of Utterance (MLU).

However, we believe these results are promising, and that further study is warranted. We have already begun to run simulations that use larger vocabularies, and that provide analogues of MLU measurements for grammatical status, in order to elucidate further the model's relationship to human performance.

Abstract

A requirement of an information processing account of human problem solving is that it includes a mechanism by which people remember which goals and operators have been evaluated and which still need to be evaluated. One might expect that these are issues of such fundamental importance that they must have been solved or at least addressed by the two architectural accounts of cognition (Soar and ACT-R), but in fact it is an issue that is glossed in both. We identify two problems: (1) Soar and ACT-R guarantee information about goals, and (2) ACT-R combines measures of frequency and recency into a single representation of activation. In this paper we report a model of how people search simple binary trees. The model demonstrates the cognitive plausibility of a search algorithm that is supported by a memory system that delivers independent estimates of frequency and recency.

Introduction

A requirement of an information processing account of human problem solving is that it includes a mechanism by which people remember which goals and operators have been evaluated and which still need to be evaluated. Whether the task is the Tower of Hanoii, a waterjugs problem, a world-wide web search problem or a spatial navigation task, a person engaged in search examines the consequences of applying an operator to a state by trying it out and perceiving to which state it, and subsequent operators, lead. At some point in the future, the person may, through backup, or because of loops, find themselves in a visited state. Recognition that the state has already been visited and/or that the operator has already been applied to this state, will in the long-term help prune the search space and thereby constrain the effort spent on attaining the goal. This constraint has been used in a number of models of human problem solving (Atwood & Polson, 1976; Jeffries, Polson., Razran, & Atwood, 1977; Anderson, 1993; Howes, 1994). Atwood & Polson's model of human performance on the waterjugs problem, built up a representation of the 'familiarity' of states that was factored into the operator selection process. The more familiar an operator then the less likely it was to be selected.

One might expect that these are issues of such fundamental importance that they must have been solved or at least addressed by the two substantial architectural accounts of cognition (ACT-R, Anderson, 1998; Soar, Newell, 1990), but in fact it is an issue that is glossed in both. In Soar, the architecture automatically ensures that operators that have already been applied to a particular state in pursuit of a particular goal (on the goal stack) on a particular trial will not be reselected. In ACT-R the goal stack has privileged status. Items posted on the stack are not subject to the constraints of memory, i.e. they do not have decaying activation and cannot therefore be forgotten (Altman and Trafton, 1999).

Another resource for supporting decisions about which operator to apply is memory for previous attempts at a goal (either successful or failed). If a goal has been achieved prior to the current attempt then memories that indicate that an operator is familiar may be taken as evidence that it is more likely to lead to the goal than an unfamiliar operator (Payne, Richardson, Howes, 2000). However, an issue for the problem solver is how to determine the source of the familiarity. If the source is the current trial then the operator should be rejected, if it is a previous trial then perhaps it should be selected.

Payne, Richardson, Howes (2000) investigated the role of familiarity (Jacoby, 1991) in controlling interactive search. They tested the hypothesis (Aasman & Akyurek, 1992; Howes, 1994) that people help control search merely by recognising the actions that have been tried before and found that the familiarity of items could affect decisions about which item to select. Moreover familiarity was used strategically. When participants had information indicating that familiarity would be more likely to indicate that an operator would lead to the goal, they were more likely to use familiarity to guide selection.

Again, one might expect that this issue would have been addressed in architectural theories of cognition. However, while Soar's chunking mechanism is flexible, the issue of whether it can provide a mechanism for representing the episodic familiarity of an operator has only recently started to be explored (Altmann and John, 1999). The situation for ACT-R is more complex.

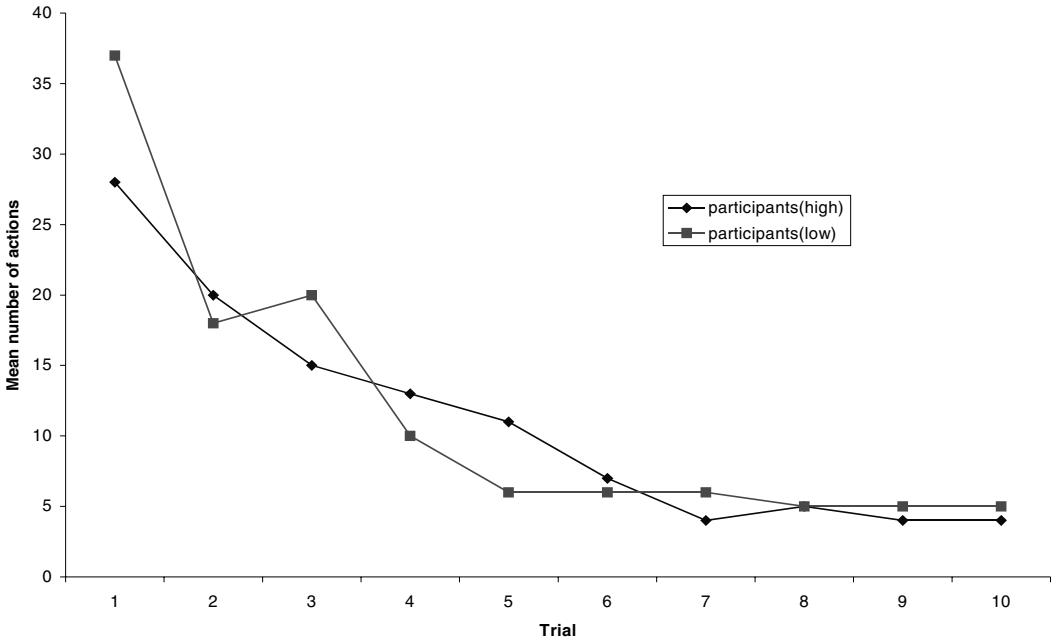

Figure 1: Mean number of actions taken by high and low systematicity participants

In ACT-R, each chunk stored in declarative memory has an activation that is used to determine probability of retrieval. This activation is made up of a base-level activation and an associative activation. Anderson and Lebiere (1998; page 70) state: "... the activation of a chunk is a sum of the base-level activation, reflecting its general usefulness in the past, and an associative activation, reflecting its relevance to the current context," and, "The base-level activation of a chunk represents how recently and frequently it is accessed."

Importantly however, the frequency and recency components of base-level activation are not independently inspectable by the production rules and it is not therefore possible to write ACT-R production rules that make strategic use of frequency and recency information stored as components of chunk activations. It seems unlikely therefore that it is possible to write productions that, for example, prefer the most frequent operators at the expense of the most recent.

A commonly used solution to this in ACT-R models has been to use flags on declarative memory structures. A flag is added to operators that have been applied on this trial and then all flags are wiped at the end of the trial (Anderson's model of navigation 1993; Lebiere, personal communication) leaving no episodic evidence that they had ever been there. While, this is an extra-architectural mechanism that, unsurprisingly, is not claimed as part of the theory, its use undermines the claim that models constructed in ACT-R are subject to a principled set of memory constraints.

In this paper we report a computational level model of how people search simple binary trees. The model makes strategic use of frequency and recency information and demonstrates the cognitive plausibility of a search algorithm that is supported by a memory system that delivers independent estimates of frequency and recency.

Task

In a series of studies to be reported elsewhere we observed participants searching simple binary word-mazes. Each maze was a binary tree structure with a depth of 5 nodes. At each choice point participants were presented with three buttons on a computer display. Two buttons at the top and bottom of the right of the screen were labelled with different words (perhaps 'gun' and 'pistol') and the other button, on the left of the screen, was labelled 'back'. Selection of one of the two buttons on the right changed the current state to a state nearer to the leaves of the tree and selection of 'back' moved the state to a node nearer the root of the tree. Participants were asked to search for a leaf node with a given label (a random word).

Observations:

- All participants were able to complete these search tasks.
- Three strategies were used:
  - **Random search** with a forward bias. Participants selected either the top or the bottom button on the right of node X, searched the subtree and then on returning to X selected the other button.

- **Systematic search**. Participants always selected the top button on the first visit to node X, searched the subtree, and then on return to X selected the bottom button.
- **Memory-based search**. On trials after the first participants generally attempted to remember the correct path.

- On trials after the first, participants flexibly interleaved search based on memory for previous trials with, when memory for previous trials failed, either systematic or random search.
- None of the participants perseverated, i.e. they did not repeatedly search the same incorrect subtree more than a handful of times.
- With practice (about 4 trials) all participants were able to follow the correct path with relatively few errors (Figure 1).
- Those participants who used a systematic strategy were significantly more efficient than those who did not. On the first trial the variation in the performance of the systematic participants was less than the variation in the performance of the random participants. (Unfortunately, the statistically significant difference in efficiency between the use of the two strategies is not reflected in Figure 1. This is because some participants using the random strategy can, luckily, find the goal with relatively few actions.)

Model

The first model that we built relied on a single activation-based measure that combined both frequency and recency information. This model could perform the first trial of a task by avoiding operators with high activation (those inferred to have been selected recently or frequently). However, on subsequent trials, a strategy of preferring operators with a higher activation (i.e. the ones used most recently on the previous trial or the ones used most frequently over trials) proved to be fragile. Activation may be high either because an operator was selected many times incorrectly or because it was selected more recently (i.e. closer to the achievement of the goal). Worse, if an error is made because an algorithm prefers highly active operators, then the algorithm may perseverate ad infinitum on incorrect selections.

The model that we focus on in this paper, is an extension of a proposal by Payne, Richardson, Howes (2000). It relies on the separate and strategic use of information about the frequency and recency of operator usage. The model is not based on assumptions about the structure of memory, rather it is based on assumptions about what information memory can deliver. The heuristics that define the search algorithm rely on the following functions for acquiring information from memory:

- **F = frequency(I)** - returns an estimate of the frequency F of item I.
- **X = most_recent(P)** - Instantiates pattern P to its most recent occurrence. (e.g. most_recent(op) would bind X to the most recently tried operator). Only one value can be returned for a particular P.
- **F = freq_before(I, E)** - returns the frequency F of I before the most recent occurence of event E. (e.g. to give the frequency of an item I before the selection of the current goal.)
- **F = freq_after(I, E)** - returns the frequency F of I after event E.

In order to simulate a lack of reliability in the information returned by these functions, frequency and recency information decayed from memory stochastically. Also, false positives were randomly generated in answer to queries about whether operators had been applied on this trial. In the Payne, Richardson, and Howes (2000) experiment, false positives occurred when participants were forced to make a decision about whether or not they had applied an operator before. In fact, participants may have only seen the operator and not applied it. The functions that determined the rate of decay and false positives are not important for our current purposes.

The purpose of introducing the errors was not to capture some quantitative aspect of the data but instead to ensure that the search algorithm was robust given the return of incorrect information from memory. Most importantly the algorithm should not perseverate implausibly even when degraded information is returned from memory.

The heuristics work by adding to a preference value for each operator proposed. There are three sets of heuristics: those that switch algorithm (or strategy); those that control systematic search; and those that control frequency-based search.

Given goal G, operator Op and a preference constant V, the rules for each algorithm are described below. The rules depend on memory encodings of the frequencies and recencies of associations, in general between G and Op, but for clarity. a short-hand has been used to describe the rule conditions, which does not refer to the association per se, but instead just to Op. Each rule proposes an addition (plus) or a subtraction (minus) to the current value of the preference for Op. The rules are described in a pseudo-code where variables are represented with capitals. The symbol '=' indicates a test of equality. If the test has a variable on either side and the variable is not already bound then the test will result in binding. The variables TOP and BOTTOM are respectively bound to the top and bottom forward menu selections.

Rules 1 to 5 describe the memory-based algorithm. This algorithm is used if the model has a memory

indicating that the goal has been achieved before. Rules 6 and 7 describe the random algorithm. Rules 8 to 10 describe the systematic algorithm. (A particular instantiation of the model uses either the random or the systematic rules but not both.) Finally, rule 11 switches to the memory algorithm and rule 12 restarts a search in the case of apparent exhaustion (this is described further below).

There is only space to describe some of these rules here. We will focus on those for the systematic algorithm. Rule 8 says, if the most recent algorithm is systematic and the operator (Op) being evaluated is a forward operator at the top of the screen, and the most recent of the previously applied operators (R) was not a 'back' operator THEN add V to the preference for Op. Rule 9 is similar to rule 8 but adds a preference for the forward operator at the *bottom* of the screen if the previous operator was a backup, Lastly, rule 10 prefers the back operator when the bottom operator has been tried on this trial and the most recent previous operator was also a back.

1. IF most_recent(algorithm) = A,
A = use_memory,
forward(Op) = true,
freq_after(Op,A) = 0,
freq_before(achieved(G), A) = FG,
freq_before(Op, A) = FO
THEN P becomes plus(1 / (1 + abs(FO – FG) * V))

2. IF most_recent(algorithm) = use_memory,
forward(Op) = true,
freq_before(fail(Op), now) = FN
THEN P becomes minus(FN * V).

3. IF most_recent(algorithm) = A,
A = use_memory,
forward(Op) = true,
freq_after(Op, A) = 0,
freq_before(Op, achieved(G)) = OF,
THEN P becomes plus(OF * V).

4. IF most_recent(algorithm)=A, A= use_memory,
forward(Op) = true,
freq_after(Op, A) = 0,
THEN P becomes plus(V).

5. IF most_recent(algorithm)=A, A= use_memory,
back(Op) = true,
freq_after(TOP, A) > 0,
freq_after(BOTTOM, A) > 0,
THEN P becomes plus(V).

6. IF most_recent(algorithm) = A, A = random,
forward(Op) = true,
freq_after(Op, A) = 0,
THEN P becomes plus(V).

7. IF most_recent(algorithm) = A, A = random,
back(Op) = true,
freq_after(TOP, A) > 0,
freq_after(BOTTOM, A) > 0,
THEN P becomes plus(V).

8. IF most_recent(algorithm) = systematic,
forward(Op) = true, top(Op) = true,
most_recent(op) = R, not(back(R) = true),
THEN P becomes plus(V).

9. IF most_recent(algorithm) = A, A = systematic,
forward(Op) = true, bottom(Op) = true,
most_recent(operator) = R,
back(R) = true,
freq_after(Op, A) = 0,
THEN P becomes plus(V).

10. IF most_recent(algorithm) = A, A = systematic,
back(Op) = true,
most_recent(operator) = R,
back(R) = true,
freq_after(BOTTOM, A) > 0,
THEN P becomes plus(V).

11. IF most_recent(algorithm) = A, A = none,
freq_before(achieved(G), A) > 0,
Op = algorithm(use_memory),
THEN P becomes plus(3*V).

12. IF current_node = root ,
most_recent(algorithm) = A ,
Op = algorithm(A),
freq_after(TOP, A) > 0,
freq_after(BOTTOM, A) > 0,
THEN P becomes plus(3*V).

The last algorithm switching rule (rule 12) plays a crucial role. Occasionally the problem solver will return to the root node without having found the goal. This will happen if the search was incomplete (i.e. some subtree remained unsearched) due to inadequate information from memory (a false positive). In this situation rule 12 restarts the search. In the model this is operationalised as the operator for the current algorithm is reapplied. The time at which the most recent algorithm operator was applied is used by the other rules to judge whether memories for operator applications were part of the current trial or previous trials.

Results

For particular rates of memory decay and false positives, the model was run 40 times on each of the 4 tasks performed by participants. The resulting mean performance for three decay rates is shown in Figure 2.

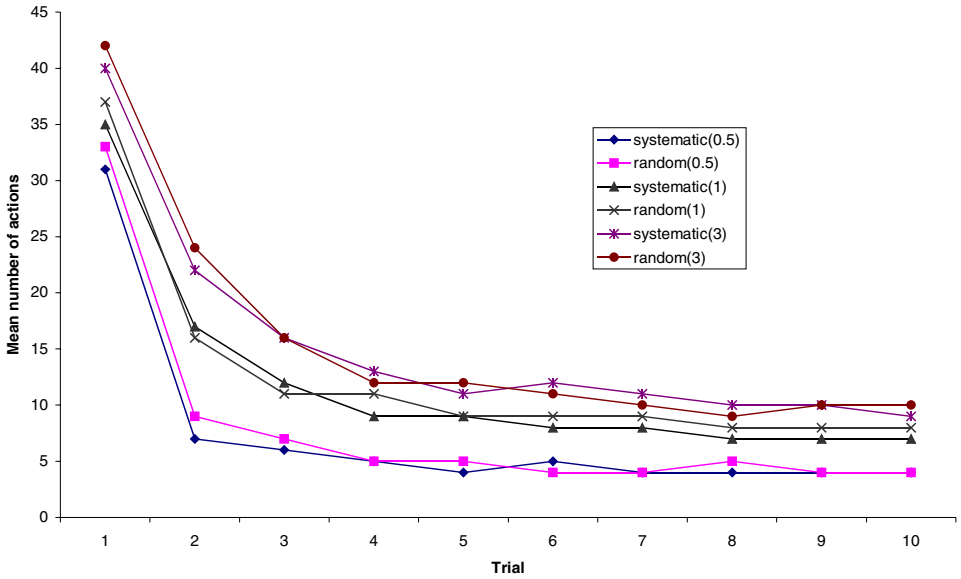

Figure 2: Mean number of actions taken by model given increasingly unreliable information from memory

The participants' mean performance is within the bounds of the best and worst model performance illustrated in Figure 2. We have not attempted to fit the model precisely, rather in accordance with Roberts and Pashler (2000) we explored the range of its behaviour.

Importantly, the model did not perseverate. Regardless of errors made during search, it always recovered and eventually found the goal. Also, as the decay rate increased the model was still able to learn the task. A large number of errors in the first trial did not on average incapacitate the learning over subsequent trials.

The gradual improvement in practice after the first trial was a result of a search algorithm (rules 1 to 5) that is guided by a combination for memory for previous trials and the current trial. If memory for previous trials proved inadequate then memory for the current trial, as distinguished by relative recency, ensured a reasonably efficient search.

Also, in accordance with the participants behaviour, the systematic algorithm produced more efficient and less varied searches on trial 1.

Discussion

The model reported here demonstrates that aspects of the way in which people search and learn paths through external problem spaces can be captured with heuristic rules that make strategic use of independent estimates of the frequency and recency of previously selected operators. Without access to this information it is impossible to write heuristics that distinguish an operator with high frequency from one that has high recency, and it is therefore a problem to determine whether key events occurred on the current trial or previous trials. The analysis of the model's behaviour under a range of memory decay and false positive conditions reveals that it produces behaviour broadly similar to human performance on a simple search task. Notably, unlike previous activation-based models built by the authors, the model does not perseverate when receiving degraded information from memory. In addition, the mean performance of the model over ten trials consists of a practice curve similar to that of the participants.

However, further investigation revealed that, after the first trial, the model produced a much greater variation in behaviour than the participants in the experiment. This issue is a matter for further investigation, and may well imply the need for some superordinate learning mechanism (perhaps rehearsal or impasse-driven learning).

A superordinate learning mechanism might involve the deliberate encodings of what the correct option is. This is an approach that was explored in Howes (1994), and while it deserves further attention, there are two problems. The first is that there is a dislocation in time between when the items are experienced and when a participant achieves the goal. In previous models the feedback of information about correctness produced recency effects in which lower levels of the tree were learnt first (Howes, 1994). These effects were not observed in our experiments. The second is that deliberate learning only pushes the problem back one level. If people deliberately learn what is correct then when situations change or mistakes are made, they also have to deliberately learn that a different option is

correct. Subsequent competition between different representations of correctness would then have to be resolved, perhaps using exactly the kind of mechanism that we have proposed. Progress will require modelling the range of individual trial data rather than just mean data.

Another possibility that we are investigating is that the long-term learning is based on recency and not frequency. Once the goal has been achieved, then the operator that led to the goal will be the most recently selected operator at any choice. Memory for recency could therefore be used to guide learning. However, under normal assumptions about decay, a recency-based model predicts that choice points at different distances from the goal would be learnt at different rates. Our data (not described above) does not support this prediction.

In principle, it may be possible to construct algorithms in ACT-R designed to ensure that during search sufficient episodic information is stored in declarative chunks to enable the kinds of computations that are posited in the model report here (e.g. Altmann and Trafton, 1999). However, regardless of the success of this approach, there will remain an issue about how people obtain information about frequency, and recency. While the concept of activation is well established in psychology, an architecture in which chunks are stored with independent measures of frequency and recency may lead to more parsimonious accounts of problem solving behaviour.

There are a number of models of the cognitive activity that give rise to practice effects, amongst them Logan's (1988) instance model and Rosenbloom and Newell's (1981) chunking model. More recent work has emphasised the strategy specific nature of the practice curves (Delaney, Reder, Staszewski & Ritter, 1998). The model reported here is similar to Logan's in that the practice curve emerges as a result of encodings made from experience with the external environment: however, maze-like tasks are more complex than simple letter arithmetic tasks and it is for this reason that our model requires the combination of frequency and recency dependent control mechanisms that we have described.

In the introduction we claimed that ACT-R's representation of undifferentiated activations was not sufficient to directly support algorithms that capture the behaviour of people engaged in typical search tasks. In contrast, the model that we have reported illustrates the cognitive plausibility of a mechanism that makes strategic use of separate sources of operator recency and frequency during search.

Abstract

Conceptual combination is an instance of synthetic problem solving comparable to design or planning. This work reviews evidence supporting the view that the result of such a synthesis has much in common with theory formation. Similar to theory formation inference in conceptual combination can be modeled by using abduction as the principal mechanism to generate hypotheses. However, abduction in itself provides no answer to questions regarding the explanation and selection of hypotheses. Results of two experiments address these issues and provide converging evidence to the view that conceptual combination is a form of theory formation. The results are interpreted within a framework of constraint satisfaction which is assumed to take place on a micro-level (compounding relations) and on a macro-level (principle of parsimony).

Introduction

What is the "glue" between words like *house* and *boat* that allows us to make sense out of the resulting conceptual combination *house boat*? There is a number of indications suggesting that conceptual combination is an instance of synthetic problem solving (like design or planning) that may be qualified as theory formation *en miniature*: First, most of the researchers in the field agree that conceptual combination can be best described in terms of knowledge structures, viz., two or more concepts that are reconstructed locally once they are involved in conceptual combination. Simple concepts in itself are often viewed as condensed theories (e.g., Murphy & Medin, 1985). Second, in many cases conceptual combinations can be paraphrased by a relative clause (e.g., *a house boat is a boat that ...*). In this way it becomes evident that conceptual combinations may add a more fine-grained conceptual schema to the conceptual classification system we already have. This is an example of *taxonomy revision* that is often related to theory formation (e.g., Shrager & Langley, 1990). Third, conceptual combinations provide support in description, explanation and prediction of phenomena, all of which are often taken to be the defining functions of theories (e.g., Brown & Ghiselli, 1955). The descriptive function is perhaps the most obvious one since conceptual combination is one of the major linguistic mechanisms for word formation (Olsen, 2000). The explanatory function is actually at the heart of conceptual combination: whenever we are confronted with a combination of concepts, we cannot but start searching for a coherent explanation that integrates the concepts usually by relation linking or carry over of an attribute. Finally, the predictive function is supported by the fact that selective inheritance of attributes is made possible in conceptual combination (Hampton, 1987). Hence, new phenomena or artifacts are often labeled by making use of it (Costello & Keane, 2000). While work in theory formation has traditionally focused on respectable scientific theories that have become hallmarks in the history of science, theory formation in conceptual combination is of a more mundane type. Usually, its basic function is to set up micro theories that help explaining simple compounds like, e.g., *turpentine jar* and the phenomena they are referring to. However, there are striking parallels between both types of theory formation.

Though most of the work on conceptual combination relies on comparable schemas of knowledge representation, the procedural assumptions may differ considerably. Upon closer inspection it becomes evident that some of the variance in the field is due to the fact that different problems of conceptual combination are focused. These aspects can be sorted by recasting them in terms of a model of theory formation. In so doing, constraint satisfaction needs to be recognized as a major aspect of processing in synthetic problem solving (Smith & Brown, 1993). As in many instances of synthetic problem solving, in conceptual combination there is a huge number of possibilities to integrate entities (e.g., nouns). This is evidenced by the high number of interpretations obtained especially from novel compounds (Costello & Keane, 1997).

However, many of the investigations of conceptual combination rely exclusively on interpretation and rating tasks. These methods can only tap time-consuming processes. Clearly, we all know that conceptual combination can proceed both slowly and controlled. But there is also evidence from the few reaction time studies on conceptual combination that this process can also be very fast and and carried out automatically (e.g., Gagné & Shoben, 1997). The fact that processing of conceptual combinations may be accomplished either very fast or slowly needs to be accounted for. For this reason, I will suggest a schema that addresses the issue of constraint satisfaction in conceptual combination on two lev-

els, which classify problems of conceptual combination according to two tasks:

I. The interface-selection task. A open question in conceptual combination is whether or not conceptual combinations are represented as a whole or in parts (*full listing hypothesis* vs. *decomposition hypothesis*, Butterworth, 1983). This issue clearly has consequences for models of processing of compounds and thus for the interface-selection task in conceptual combination. Usually, however, in work on conceptual combination it is the *decomposition hypothesis*, which is implicitly adopted. In so doing, a number of rationales has been hypothesized for the selection of the part(s) of the knowledge structures involved (e.g., slots, relations) that are taken to establish the linkage between combining concepts. Investigations and models that address the interface-selection task have been put forth: Wisniewski (2000) suggested that an alignment process, viz., similarity assessment, between modifier and head guides this task, while Estes & Glucksberg (2000) found evidence that salience of attributes is underlying interface-selection. Finally, investigations by Gagné & Shoben (1997) supported the view that there is a fixed set of compounding relations and selection of a relation is done according to the frequency of its usage. Construction of interpretations of conceptual combinations proceeds by rendering the reconstructed knowledge of the concepts involved into the natural language. This task is accomplished if one or many interpretations of candidate conceptual combinatations are found.

II. The interpretation-selection task. Even if the selection problem is solved successfully, there is usually a great number of possible interpretations remaining. Hence, a second step has to take over that consists of evaluating the candidate interpretations. Work along these lines has been carried out by Costello & Keane (2000) who provide empirical evidence that search of an appropriate interpretation is narrowed down by the constraints of diagnosticity, plausibility and informativeness.

Basically, the two task of this schema boil down to a generate-and-test approach, which is adjusted to issues of conceptual combination. While there are a number of investigations that address either the first or the second task, there is no organizing framework that integrates work in the field and provides empirical evidence supporting this framework. Only in a few investigations the generative nature of conceptual combination that leads to synthesis of knowledge structures has been spelled out in a sound way. The goal of this paper is to identify and investigate mechanisms of theory formation in conceptual combination. In so doing the schema outlined above provides some methodological assistance by guiding the investigations to both a micro-level and a macro-level.

The paper is organized as follows: First, I am describing the type of conceptual combination that has been investigated in this work. Second, the role of theories in conceptual combination is discussed. Third, following the work of Stickl (1989) and Hobbs, Stickel, Appelt & Martin (1990), I give an outline of abduction, which is assumed to be the generative mechanism that drives theory formation in conceptual combination. While the work on abduction mentioned provides a sound foundation of processing conceptual combinations, there are some empirical questions relating to the generation and selection of hypotheses that are not addressed by this approach. Fourth, according to the two-step schema introduced above, I am presenting two experiments on these issues. The first experiment highlights mechanisms of linking modifier and head in conceptual combination. The structure of preferred theories is investigated in the second experiment. The final discussion places the results into the framework presented initially and considers open questions related to theory formation in conceptual combination.

Conceptual Combinations

The first part of a nominal or noun-noun compound is usually called the *modifier* and the second part is referred to as the *head*. There are various schemata for classifying interpretations of this type of compound, but the one most widely accepted schema seems to be the one introduced by Wisniewski (e.g., Wisniewski, 2000). He distinguishes three types of interpretations: In *relation-linking* interpretations, people explicitly use a relation to explain a compound (e.g., robin snake = a snake that eats robins). *Property* interpretations involve one or a few properties of the *modifier* that are applied to the *head* (e.g., robin snake = a snake that has a red underbelly). *Hybrid interpretations* are not precisely characterized since this category might apply to a conjunction of the constituents or a cross between them (robin canary = a bird that is half canary and half robin). The work on conceptual combination described in this paper is focusing on noun-noun compounds that have a relational interpretation.

The Role of Theories

The seminal paper of Murphy & Medin (1985) is often taken to be the beginning of a line of research that views concepts as condensed theories. In many investigations of conceptual combination that follow this approach, knowledge or theories have not been described very precisely. Still, ample evidence has been collected that background or domain knowledge feeds into conceptual combination (e.g., Hampton, 1997).

In the work presented here, theories may be defined on two levels: On a functional level, theories are conceived as knowledge structures subjects may use for description, explanation and prediction of phenomena of interest. On a representational level, I am adopting a schema for describing both the nominal compounds, background knowledge and for deriving thematic or compounding relations that has been suggested by Hobbs et al. (1990, p. 24f):

$$(\exists x, y)\, turpentine(y) \wedge jar(x) \wedge nn(y, x)$$

The three propositions of this logical form are meant to signify a juxtaposition of two nominals, and *nn* is a placeholder for the compounding relation to be found. The background theory might take the following logical form

$$(\forall y) liquid(y) \wedge etc_1(y) \supset turpentine(y)$$

which denotes that being liquid is among other attributes a feature of turpentine and

$$(\forall e_1, x, y) function(e_1 x) \wedge contain'(e_1, x, y) \wedge liquid(y) \wedge etc_2(e_1, x, y) \supset jar(x)$$

meaning that if the function of something (x) is – among other things – to contain liquid, then it may be a jar.[1]

Abduction in Conceptual Combination

The view on conceptual combination outlined in this work follows a rationale of inference called *abduction* that can be described as explanatory hypothesis generation (Stickel, 1989; Hobbs et al, 1990). More precisely, the proper place of (the generative part of) abduction in the schema described above is within the first task: By abductive inference hypotheses are generated on the basis of domain or background knowledge that provide a means for interface selection. Evaluation of the hypothesis is part of the second task.

Abduction is a mechanism used frequently in models of theory formation. Contrary to deductive reasoning there is no guarantee for correctness in abductive reasoning. Cast in a more concise formal lingo, abduction can be described as follows:

$\mathfrak{D}$ is a collection of data (facts, observations, givens);
(1.) $\mathcal{H}$ explains $\mathfrak{D}$ ($\mathcal{H}$ would, if true, imply $\mathfrak{D}$);
(2.) No other hypothesis explains $\mathfrak{D}$ as well as $\mathcal{H}$;
Therefore, $\mathcal{H}$ is correct.
(cf. Falkenhaimer, 1990, p. 160, numbers added).

Applied to the analysis of conceptual combination $\mathfrak{D}$ refers to a noun-noun juxtaposition. $\mathfrak{D}$ is really just a juxtaposition and does not provide any hints concerning its potential coherence or fitting together. However, it motivates processes that seek to find evidence in favor or against coherence in $\mathfrak{D}$ (cf. Thagard, 1997). $\mathcal{H}$ signifies one or many compounding relation(s). They slip into the role of hypotheses that have the potential of specifying in which way the concepts of $\mathfrak{D}$ cohere. Note that hypotheses are derived from domain or background theories. In our example introduced in the preceding section we may infer abductively

$$(\forall e_1 x, y) contain'(e_1, x, y) \supset nn(x, y)$$

meaning that the placeholder *nn* might be identified with the relation or hypothesis *contains*.

If there are more hypotheses that may explain $\mathfrak{D}$, the best of them is selected. Clearly the criteria of what "best" means in the field of conceptual combination are not specified in this fairly general definition.

Two things should be noted in the definition of abduction as provided by Falkenhainer (1990): First, abduction is a two-step process that bears strong commonalities to the two tasks in conceptual combination described above. Second, to find out whether or not the definition – and thus abduction – holds in conceptual combination, this definition needs to be applied to the field and also further specified. But what does "true" (1.) and what does "well" mean" (2.) in the definition above?

Both issues are essentially empirical questions. Concerning the first of them I am making the conjecture that the hypothesis $\mathcal{H}$ is said to be true iff the relation can be successfully instantiated by the concepts of $\mathfrak{D}$. Whether and to which degree instantiation is modified by similarity on the level of attributes is also an open issue. Concerning the second issue I assume that a hypothesis is said to explain $\mathfrak{D}$ well if it is parsimonious and sound, which is equivalent to the heuristic of Occam's razor.

Experiment 1: Constraints on the Micro-Level

Experiment 1 examines the effect of activation of thematic relations on the process of conceptual combination. Patterns of the compounding relations were varied as the independent variable. This variable was chosen for two reasons: First, by using this variable it could be investigated whether the *full listing hypothesis* or the *decomposition hypothesis* holds in conceptual combination. Second, by using this variable groups of items could be set up that differed in the degree of similarity. Hence, a comparison of different accounts to conceptual combination could be carried out. These are approaches that rely primarily on similarity (e.g., Wisniewski, 2000) vs. approaches in which compounding relations hold the key to conceptual combination (e.g., Gagné & Shoben, 1997). With regard to the schema introduced above, experiment 1 addressed the interface-selection task, viz., the mechanisms leading to the linkage between modifier an head.

Method

A semantic decision task was used to assess conceptual combination in nominal compounds. Subjects were instructed to read both prime and target and were requested to decide as quickly and as correctly as possible whether the target was a concept that refers to a material entity (e.g., rubberball).

Participants. The subjects were 39 students (18 male and 21 female) of Freiburg University who either participated for course credit or payment. The age of the subjects ranged between 18 and 29.

Materials and Procedure. The experimental stimuli were prime-target pairs. Both prime and target were common compounds that were based on simple German

[1] The primed predicate $contain'(e_1, x, y)$ together with its arguments signify that e_1 is the eventuality of *contain* being true for x and y.

nouns[2]. Compounds based on metaphors, names or associated words were excluded. Since novel compounds are known to elicit a variety of interpretations, I used common compounds that have a standard interpretation. In this way, fixation of the number of interpretations was achieved, and thus the effect of the independent variable, viz., the pattern of the compounding relation, could be investigated more precisely. Investigations of the effects of the independent variable led to the selection of 4 groups of items (cf. Table 1).

	CoI	CI	NCI	DI
Prime	lipstick	snowball	tennisball	summertime
Target	rubberball	rubberball	rubberball	speedlimit

Table 1: Groups of Items used in Experiment 1

18 *Control items (CoI)*, which were made of pairs of compounds each of which used a different thematic relation. Moreover, the words in each pair were different (e.g., tennisball - snowball - thematic relations: "x is made of y", "x is used for y"). All items used (both prime and target) were made up of concrete concepts (e.g., lipstick).
18 *Concordant items (CI)*, which were made of pairs of compounds both of which shared the same thematic relation. Moreover, the head concept was identical in prime and target (e.g., snowball - rubberball, common thematic relation: "x is made of y"). To achieve a balance between concrete and abstract relations, 9 of the items of CI used the relation "x is made of y", and 9 employed the relation "x is used for y". All CI used concepts (both prime and target) referring to concrete words.
18 *Non-concordant items (NCI)*, which were made of pairs of compounds each of which used a different thematic relation. Still, 9 target compounds used a concrete thematic relation ("x is part of y"), while 9 used an abstract thematic relation ("x is used for y"). The head concept was identical in prime and target (e.g., tennisball - snowball, thematic relations: "x is made of y", "x is used for y"). All NCI used concepts (both prime and target) referring to material entities.
18 *Distractor items (DI)*, which were made of pairs of compounds each of which used a different thematic relation. In contrast to items of all other groups all distractor items (both prime and target) used abstract concepts (e.g., speed record).

Note that prime and target of CI, NCI and CoI (each of which was presented together with the items from DI) were becoming increasingly dissimilar: In CI there was an identity of thematic relation and modifier, in NCI only the heads were overlapping. Finally, in CoI there was neither on the level of words nor on the level of the thematic or compounding relations any overlap. While all words in CI, NCI and CoI were concrete, all words in DI were abstract.

[2]Note that the experiment was carried out in German where all compounds are written as one word.

The items were used in a between subjects design with three groups. Subjects of each group was presented with the 36 Items of (CI & DI; NCI & DI, CoI & DI). Thus, in each group there was the same number of abstract and concrete targets (18:18). The SOA was 300 msec and the ISI was 100 msec (cf. Zwitserlood, 1994). Subjects worked first through a series of 24 training items that included a mixture of all types of items mentioned above. After that subjects were requested to decide as quickly and as correctly as possible whether the 36 items used were concrete or abstract words.

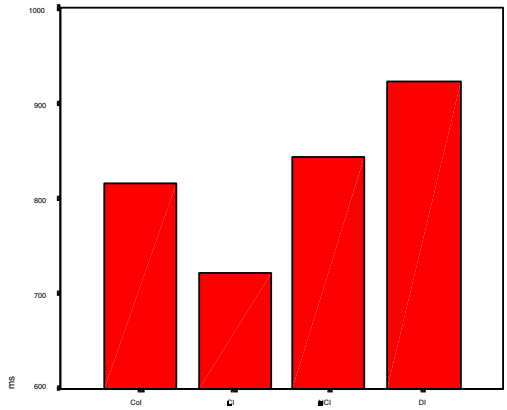

Figure 1: Results of Experiment 1

Results and Discussion

Fig. 1 presents an overall view of the results of experiment 1. Pairwise analyses of the results were carried out via Mann-Whitney-U-tests and via the Wilcoxon-test in the case of the dependent samples involved in the comparison of CI and DI. Scores of CI were significantly lower than the scores of the groups NCI (z=-7,37 , $p \leq .001$), CoI (z=-3,41 , $p \leq .001$), and DI (z=-6,45 , $p \leq .001$). Interestingly, the difference between scores of CoI and scores of NCI was not statistically reliable. Beyond that the difference does not point into the direction expected on the basis of a similarity approach (cf. Figure 1). This suggests that similarity (on the level of attributes) between heads of prime and target had no facilitating effect.

The results indicate two things: First, processing of the compounding thematic relation plays indeed an important role in conceptual combination. Throughout the investigation the thematic relation has never been expressed explicity. Given the fast mode of the task we may safely conclude that the compounding relation is processed unconsciously. This is especially striking since common compounds were used. These concepts are often believed to be processed as one unit without considering the constituents. This can be taken as a conservative test of the *decomposition hypothesis*, which was clearly better supported by the data than the *full listing hypothesis*.

Second, having addressed the more basic question whether the *decomposition hypothesis* or *full listing hy-*

pothesis gives a better account of the data, I will now turn to the question whether similarity (on the level of attributes) or relations hold the key for the interface-selection task. It is worth pointing out that NCI scored quite low although there was an identity of heads in both prime and target. If attributes had played at least a minor role, then the increasing similarity on the side of the stimuli (*sim* CI > NCI > CoI) would have induced corresponding effects on the side of the dependent variable (*rt* CI > NCI > CoI). However, this is not the case. Taken together, the data do not support the view that similarity (as specified on the level of attributes) provides the rationale of addressing the selection problem.

It is tempting to assume that by priming a particular (misfitting) relation in NCI, this relation may block or reduce the salience of the most suitable thematic roles of the constituents. Hence, the subject has to make an effort to retrieve a more appropriate relation from the domain knowledge. This may be due to a time-consuming derivation process. A possible model of this process is provided by the abductive rationale spelled out by Hobbs et al. (1990).

Experiment 2: Constraints on the Macro-Level

The goal of experiment 2 was to examine aspects of compound interpretation that affect its acceptance. With respect to the schema introduced above, experiment 2 addressed the interpretation selection task, viz., the choice between competing interpretations of a conceptual combination. If conceptual combination is indeed a form of theory formation, then features like "concise" and "plausible" often considered to be aspects of a good theory should also characterize an appropriate interpretation of a conceptual combination.

Method

In experiment 2 judgments of interpretations of novel compounds were elicited. The type of interpretation was used as the independent variable. The interpretations employed in the experiment had been generated and assessed in two preparation studies conducted before experiment 2 with independent samples of subjects.

Participants. 121 subjects (57 male, 64 female) between 16 and 42 years old participated in experiment 2.

Materials and Procedure. 4 × 20 pairs of novel compounds along with group specific interpretations were used in experiment 2. The material consisted of novel compounds since common compounds have a standard interpretation. Thus, a variety of different possible and in principle equally appropriate interpretations could not be generated on the basis of common compounds.

The interpretations investigated in experiment 2 had been set up in two preparation studies carried out with different subjects: First, in an in-between study a sample of subjects (20 subjects, 12 female, 8 male, between 18 and 41 years old) was requested to generate interpretations of 20 novel German compounds (e.g., "curtain hotel") according to 4 conditions: *detailed and creative* (dc), *detailed and plausible* (dp), *concise and creative* (cc), and *concise and plausible* (cp). Second, in a subsequent in-between rating study a new sample of subjects (32 subjects, 21 female, 11 male, between 18 and 47 years old) assessed each group of interpretations on a five-point scale according to its aptness or inaptness. For each of the 20 novel compounds that have been used, 4 interpretations with the highest aptness ratings were selected and were subsequently employed in experiment 2.

The final outcome of the two preparation studies were 80 pairs of conceptual combination + interpretation all of which were on a high level of aptness. The pool of 80 pairs of conceptual combination + interpretation was divided into 4 groups of 20 items. Each group consisted of an equal share of items from all 4 conditions (dc, dp, cc, cp). In experiment 2, subjects of each group were presented with 20 pairs of novel compounds + interpretations that should be assessed on a five point rating scale (1 excellent – 5 unappropriate) concerning their aptness as an explanation of the compound.

Results and Discussion

Fig. 2 presents an overall view of the results of experiment 2. Pairwise comparisons of the results were conducted via Mann-Whitney-U-Tests. Scores of cp turned out to be significantly lower than the score of the groups dc (z=-16,29 , p <.001), dp (z=-3,54 , p <.001), and cc (z=-18,05 , p <.001).

The results of experiment 2 show that criteria that are usually applied to sound theories also apply to interpretations of conceptual combinations. These results are consistent with the more general hypothesis of this paper that conceptual combination is a form of theory formation.

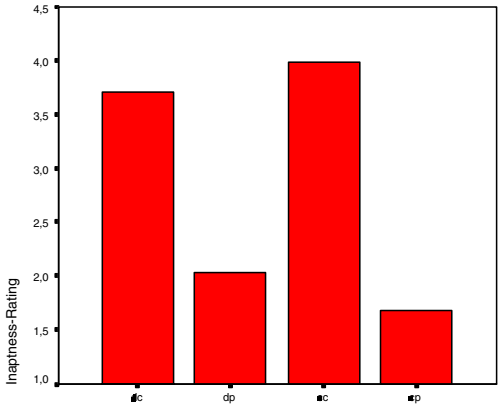

Figure 2: Results of Experiment 2

General Discussion

Research on conceptual combination can be characterized by two more general issues: First, empirical work in the field has mostly been conducted isolated from considerable formal work on conceptual combination. The

formal work on abduction outlined briefly in this paper provides valuable insights for conceptual combination, e.g., concerning knowledge representation and abduction. Second, within the camp of empirical researchers the two basic tasks in conceptual combination have usually not been distinguished properly. The work presented in this paper reacts to these problems both by setting up an account of conceptual combination as theory formation that integrates many aspects of the field and by providing empirical data that is consistent with this framework. Clearly, more empirical work is necessary that fleshes out the framework presented in this work and elucidate the role of domain or background knowledge which has also been found influencial in conceptual combination. In fact, work on abduction coming mostly from computational linguistics offers some guidance for knowledge representation (Hobbs et al., 1990, p. 24), which is almost absent in more psychological work on this topic. Taken together, both issues stress the role of abduction in conceptual combination. This pattern of reasoning might help to explain conceptual combination in terms of theory formation.

Viewing conceptual combination as an example of theory formation holds the promise of a crossfertilisation between two hitherto almost uncombined research tradition: Research on conceptual combination could became more aware than hitherto that the phenomenon under study is a generative process details of which can be captured in terms of explicit schemas of knowledge representation. On the other hand, work in theory formation that has been focusing on theory formation in the natural science (an excellent survey is given by Darden, 1997) could broaden this perspective and consider theory formation *en miniature* in conceptual combination. Investigations based on this research strategy could be fruitfully applied in psychology, anthropology and ethnology.

Acknowledgments

I like to thank Zachary Estes, Barbara Hemforth, Bipin Indurkhya, and Gerhard Strube for valuable comments to this paper, and I am grateful to Roman Kennke for the programming work put into this research project.

Combining Integral and Separable Subspaces

Mikael Johannesson (mikael.johannesson@ida.his.se)
Department of Computer Science, University of Skövde, Sweden and
Lund University Cognitive Science, Lund University, Lund, Sweden

Abstract

It is well known that pairs of dimensions that are processed holistically - *integral dimensions* - normally combine with a Euclidean metric, whereas pairs of dimensions that are processed analytically - *separable dimensions* - most often combine with a city-block metric. This paper extends earlier research regarding information integration in that it deals with complex stimuli consisting of both dimensional pairs previously identified as holistic, and dimensional pairs previously identified as analytical. The general pattern identified is that information integration can be more accurately described with a rule taking aspects of stimuli into consideration compared to a traditional rule. For example, it appears that combinations of analytical and holistic stimuli, are better described by treating the different subspaces individually and then combining these with addition, compared to any single Minkowskian rule, and much better compared to any of the Minkowskian rules traditionally used (i.e. the city-block-, the Euclidean or the dominance-metrics).

Introduction

Suppose we have objects that differ on several dimensions – how is (dis-) similarity of such objects related to (dis-) similarity on each of the dimensions? Since Attneave (1950) raised essentially this question, much research efforts have been focused on the applicability of different combination rules. The most commonly investigated rules, or metrics, for describing distances in a multidimensional space have been instances of the generalised Minkowski metric (Eq. 1).

$$(1)\quad d(i,j) = \left\{ \sum_{k=1}^{n} | x_{ik} - x_{jk} |^{r} \right\}^{1/r} \quad ; \; r \geq 1$$

where $d(i,j)$ is the distance between object i and j, x_{ik} refers to the position of object i on the kth axis and n is the number of constituting dimensions.

Three extreme cases can be identified: r = 1; *the city-block metric* - The distance is the sum of the absolute differences for each of the underlying dimensions; r = 2: *the Euclidean metric* - The distance corresponds to the square root of the sum of the squared differences for each of the underlying dimensions; and r = ∞ : *the dominance metric* - The distance between two objects is a function of the distance for the separate dimension that differ the most.

When it comes to cognitive modelling, the city-block and, especially, the Euclidean metrics are the most common. However, it is well established that some pairs of dimensions combine, with Garners (1974) terminology, to form *integral dimensions* and others to form *separable dimensions* (see e.g. Garner, 1974, 1977). An integral pair typically is processed as holistic, unanalysable, directly and effortlessly by subjects and that the constituent dimensions combine so as to conform to a Euclidean metric; pairs of hue, saturation or brightness of colour (see e.g. Hyman & Well, 1967; Kemler Nelson, 1993) and the auditory dimensions of pitch and loudness (Kemler Nelson, 1993) typically do this. The corresponding description for a separable pair is that the constituent dimensions are processed independently by subjects and that they combine so as to conform to a city-block metric, e.g. size and reflectance of squares (Attneave, 1950).

Now, the combination rules for integral and separable dimensions are well investigated for dimensional *pairs*. But, what about more complex combinations? How do we integrate information when both integral and separable pairs are involved? Adequate descriptions of information integration behaviour is not only important from a theoretical perspective, but also from a more practical and pragmatic machine learning perspective.

Simple parallelograms varying in saturation, brightness, height and tilt could serve as an example. Pairs of the dimensions of colour, i.e. of hue, brightness and saturation, are often used as prototypical examples of integral dimensions (see e.g. Hyman & Well, 1967; Kemler Nelson, 1993). Perception of variation in saturation and brightness on a single colour patch have in previous studies (e.g. Hyman & Well, 1967; 1968) been shown to be better described using the Euclidean compared to the city-block metric. The height- (size-) and tilt- dimensions of parallelograms is an example of separable dimensions (Tversky & Gati, 1982). Tversky and Gati found such pairs to be better described using the city-block metric compared to the Euclidean.

How, then, could subjects' phenomenological (dis-) similarity between parallelograms varying in height, tilt, saturation and brightness be described? With reference to the different metric properties of the underlying pairs of dimensions, it makes sense to divide the stimuli space into two separate subspaces - one describing the aspects of shape of the stimuli (i.e. height and tilt) - *the shape space* - and one the colour aspects (i.e. saturation and brightness) - *the colour space*. In this case it could be that two different metrics should be

applied: the city-block metric for the shape space and the Euclidean metric for the colour space. For combining the separate subspaces into a holistic measure, simple addition could be expected, with reference to that the pair of subspaces better fit the description of separability compared to integrality.

In the remainder of this paper, combination rules, such that the same Minkowski-r (r) applies to the whole stimuli space, will be referred to as *homogenous* rules. Metrics such that one r, say r_1, applies to one subspace, and one r, say r_2, applies to another, and that the holistic measure is obtained by combining the sub-metrics separably, will in the following be referred to as *heterogeneous* rules or metrics[1].

Now, how could we determine which of reasonable alternatives is the best when we want to describe (dis-) similarity judgements of stimuli varying in height, tilt, saturation and brightness?

General Method

The method used by Dunn (1983) in order to investigate the relationship between dimensional integrality and the combination rule used in a dissimilarity judgement task, will be adopted in this paper. However, it will be generalised in order to deal with stimuli with more than two underlying dimensions.

The basic idea is to divide the set of dissimilarity ratings into unidimensional and bidimensional ratings, reduce them to distances between points in a predefined dimensional space and then determine the r that best predicts the bidimensional dissimilarities from the unidimensional ones. In order to reduce ratings to distances correspondence, interdimensional additivity, intradimensional subtractivity and linearity must be assumed (Dunn, 1983; see also Johannesson, 2001a).

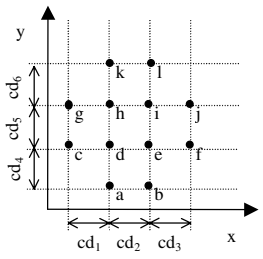

Figure 1: 12 stimuli and their component distances (cd1-cd6). (Based on Figure 1. in Dunn, 1983).

A first step is to decompose the unidimensional distances into component distances (see Figure 1 above). Further, under the assumption that the function relating dissimilarities to distances is linear, the dissimilarities between the stimuli in Figure 1 could, according to Dunn (1983), be expressed as

$$(2)\quad \delta(a,b) = \sum_{i=1}^{6} w_{iab} cd_i + A \;;w_{iab} = 0 \text{ or } 1$$

where $\delta(a,b)$ is the perceived dissimilarity between object a and b, w_{iab} refers to the weight of the component distance cd_i, and A is an additive constant.

Eq. 2 specifies a multiple regression equation in which the weights define a set of dummy variables, the component distances form the regression coefficients and A is the additive constant.

Determining the Spatial Metric

Performing a multiple regression analysis on unidimensional dissimilarities provides an estimate of the component distances and the additive constant. From these, it is straightforward to estimate any "Minkowski dissimilarity". In order to determine the "best" describing metric for a particular subject, Dunn (1983) compared the mean observed and the mean predicted bidimensional dissimilarity using a certain value of r: overestimation of r lead to underestimation of the observed mean, whereas underestimation of r lead to overestimation of the observed mean.

Methodology Adopted

The methodology outlined by Dunn will be adopted with the exceptions as outlined below. Since the present paper aims to investigate whether the machine learning community could gain from using different Minkowski metrics for different subspaces rather than a single metric applied to the whole space, the various tests suggested by Dunn are not central here.

Experiment I

Subjects

14 students at the University of Skövde participated for a reward of cinema tickets roughly worth £11 or $17.

Stimuli

The stimuli were parallelograms varying in height (h; 4, 5 or 6 units of length), tilt (t; 40, 50 or 60 degrees), saturation (s; 40, 60 or 80% of maximum saturation) and brightness (b; 40, 60 or 80% of maximum brightness). The width and the hue of the parallelograms were held constant (4 units of length and 240 degrees of the colour circle, respectively).

In order to not exhaust the subjects, 20% of the possible 3240 pairs (i.e. 648) where chosen randomly. The order of the selected pairs were randomised.

[1] There are few examples of true integral dimensions in the literature (Grau & Kemler Nelson, 1988). This fact does not undermine the possible practical importance of heterogenous models, since perception of many dimensional pairs fall between the endpoints of a continuum of dimensional separability (Smith & Kilroy, 1979; Smith, 1980).

Procedure

The experimental sessions were performed individually in a quiet room with drawn curtains.

Each subject was first asked whether she/he had normal colour vision or not[2], and was then asked to follow the instructions given on the screen.

The experiment consisted of several phases:

- *Instruction phase*: Subjects were informed that they should judge dissimilarity between coloured parallelograms using a 20-graded scale.
- *Stimulus presentation*: Diminished versions of all stimuli were presented simultaneously in a randomised layout.
- *Training phase*: Subjects made dissimilarity judgements for ten pairs of coloured parallelograms varying in the same dimensions as the real stimulus material. The levels did not coincide with the levels of the real material.
- *Instruction phase*: An instruction phase as above was repeated. This time subjects were also informed that the judgement sessions would be divided into six parts with breaks between.
- *Stimulus presentation*: Subjects were again presented with the complete stimulus material.
- *Judgement phase*: The 648 stimulus pairs were presented in the same random order for all subjects. The experiment took about 2 hours.

All subjects reported they had normal colour vision.

Results and analysis

Table 1 below presents the average component distances (see Figure 1 above) per dimension, and the coefficient of determination for the collapsed data.

Table 1: Average component distances and R^2.

Avg_h	Avg_t	Avg_s	Avg_b	R^2
4.160	2.907	1.214	1.214	0.762

The average component distances, which could be interpreted as the relative saliency of each dimension (Dunn, 1983), differ between dimensions. Especially, the saturation and brightness dimensions have somewhat shorter component distances (are less weighted) compared to height and tilt. A possible explanation for this unequal weighting is that subjects perceived the variation in height and tilt as larger compared to the variation for the integral pair of saturation and brightness.

The coefficient of determination is not very large, indicating that a linear model misses to account for a considerable proportion of the variance of the data.

Determining the Spatial Metric When there are just two underlying dimensions it is obvious that distances should be estimated and evaluated for stimuli differing in two dimensions. However, as the number of underlying dimensions increases, so does the number of possibilities. In the present case, when four underlying dimensions were used, stimuli pairs differing in two or more dimensions were analysed.

Justifying the Measure of Error In order to possibly improve the process of determining the spatial metric, two alternative measures of error for a particular r were contrasted. One was in line with Dunn's method: deviation of the absolute difference between the mean observed dissimilarity and the mean predicted/estimated dissimilarity from the mean observed dissimilarity - in the following referred to as DEV. The other, referred to as the mean squared error (MSE), is defined as

$$(3)\quad MSE = \left(\sum_{\substack{a,b \\ a \neq b}} \left(\delta(a,b) - \tilde{\delta}(a,b) \right)^2 \right) / N$$

where $\delta(a,b)$ is the perceived, $\tilde{\delta}(a,b)$ is the predicted/estimated - dissimilarity between object *a* and *b*, and *N* is the number of stimuli pairs.

For each of the homogenous rules: city-block, Euclidean and dominance, and all non-ordered combinations of heterogeneous rules, where the subspaces where formed by the city-block, Euclidean or dominance metric[3], the distances between all non-ordered combinations of stimuli were calculated from physical descriptions of the stimuli. By regarding the distances as fictive dissimilarities, and by estimating the dissimilarities as described above for different rules, the errors according to DEV and MSE were calculated. The same subset and physical descriptions as used in the present experiment were analysed. Further, the estimated distances were scaled into a discrete scale ranging from 1 to 20. Since the underlying rule was known in each case, the two alternative measures of error could be evaluated against each other.

For the homogeneous models, both DEV and MSE suggested the same - and correct - underlying model. For the heterogeneous models MSE suggested the correct model in all cases. The use of DEV, however, was clearly systematically ambiguous. In all cases when

[2] In a pilot experiment preceeding this subjects performed a colour test in order to find out if they could discriminate between the colours that were to be used. Since all subjects in the pilot experiment reported the colour test to be simple a simple question was judged to be enough.

[3] Note that the heterogenous rule where both subspaces are formed by the city-block metric exactly corresponds to the city-block homogenous rule.

the underlying model could be described *as metric A applies to subspace 1 and metric B applies to subspace 2*, **both** the correct model and the model such that *metric B applies to subspace 1 and metric A applies to subspace 2*, were suggested. The explanation is that that the sum of absolute deviations for the two models necessarily is the same for a balanced set of stimuli.

In summary, based on this analysis, MSE appear to be the better measure for the purposes of this paper.

Spatial Metric Candidates for describing the individual subjects' data were evaluated using MSE as the measure of error. In addition to the rules used when evaluating the two error measures above, i.e.

- the homogenous rules: city-block, Euclidean and dominance - in the following referred to as *Hom cit*, *Hom euc* and *Hom dom*, respectively,
- all non-ordered combinations of heterogeneous rules, where each of the subspaces were formed by the city-block, Euclidean or dominance metric - in the following referred to as *Het citeuc*, *Het citdom*, *Het euccit*, *Hit euceuc*, *Hit eucdom*, *Hit domcit*, *Hit domeuc* and *Hit domdom*, respectively,

errors were calculated for values of Minkowski-r ranging in small discrete steps from r = 1.0 to r = 50.0 applied to the whole stimuli space (the homogenous model giving the lowest error will be referred to as *Hom opt*), the shape subspace and the colour subspace respectively. The heterogeneous model where the separately optimised r for the two-dimensional shape space is applied to "shape" and the separately optimised r for the two-dimensional colour space is applied to "colour", will be referred to as *Het sepHT-sepSB*. Finally, the combination of r:s, one for the shape subspace and one for the colour subspace, when optimised simultaneously with a heterogeneous rule - will be referred to as *Het simHTsimSB*.

Table 2: Models, r:s and errors for average data.

	R	Err
Het simHTsimSB	1.55;2.25	2.146
Het sepHTsepSB	1.55;2.2	2.146
Het euceuc	2;2	2.339
Hom opt	1.2	2.481
Het eucdom	2;50	2.601
Het euccit	2;1	2.894
Het domeuc	50;2	3.838
Het domcit	50;1	3.905
Het citdom	1;50	3.948
Het citeuc	1;2	4.194
Het domdom	50;50	4.313
Hom cit	1	5.907
Hom euc	2	7.805
Hom dom	50	16.644

The candidate models evaluated and the errors for the collapsed data are presented in Table 2 above.

A heterogeneous model combining a rule between the city-block and the Euclidean metrics[4] for the shape space, and a rule roughly corresponding to the Euclidean metric for the colour space (*Het simHTsimSB* and *Het sepHTsepSB*), gave a lower error than the best of the homogenous models (*Hom opt*), which had a r = 1.2, i.e. halfway between the city-block and the Euclidean metrics. This was true irrespectively of if the r:s were optimised separately or simultaneously. The optimal heterogeneous Minkowski-r:s found were lower for the shape space compared to the colour space. However, the r:s found were slightly different from the levels identified by previous research when two-dimensional stimuli have been used. The values were somewhat higher compared to what has been identified for these spaces before. It may be the case that the r-value goes up when the dimensionality increases. This speculation makes sense considering that we have limitations in terms of how many dimensions we can process simultaneously, and that larger values of r corresponds to focusing more on the dimension where the stimuli-pair at hand differ the most.

The common homogenous Euclidean rule (*Hom euc*) gave a substantially worse error than both the best heterogeneous rule and the best homogenous rule. However, the somewhat unequal weightings of the dimensions defining the two subspaces (see above) probably causes the peculiarity that *Het euccit* produces an error lower than that for *Het citeuc*. The fact that there are differences in weighting indicate that there are differences in salience between dimensions.

In summary, a heterogeneous rule or model seems to describe the data better compared to a homogenous one.

Errors and r:s were calculated also for the heterogeneous rules combining the "odd", or counterintuitive, subspaces h/s and t/b on one hand and h/b and t/s on the other. The heterogeneous models with the lowest errors for the average data for each of the three subspace divisions are presented in Table 3.

Table 3: Different subspace divisions and their errors.

Subspace division	Model	Err
height/tilt; sat./bri.	Het simHTsimSB	2.146
height/sat.; tilt/bri.	Het simHSsimTB	3.030
height/bri.; tilt/sat.	Het simHBsimTS	2.861

The errors for the heterogeneous models for the "odd" subspace divisions are considerably larger compared to the error for the original division. For the

[4] Note, however, that the Minkowsky-r of a rule giving distances halfway between the city-block and the Euclidean metric is not the intuitive 1.5, but rather approximately 1.2.

individual data, the corresponding difference was true for 8 out of 12 cases with at least one r differing from 1.0. This difference indicate that the intuitive division into subspaces of shape and colour makes sense.

Experiment II

In Experiment II, the heterogeneous r:s found were larger than what has been found in earlier research. A reasonable question is if the element of non-separability together with the increased dimensionality causes such effects. A second experiment was conducted in order to investigate if integrality (non-separability) could be eliminated as an explanation or not. Contrary to Experiment I, the underlying dimensions in the present experiment are purely separable.

Subjects

12 students (the majority were undergraduates) at the University of Skövde participated for a reward of cinema tickets roughly worth £11 or $17.

Stimuli

The stimuli varied in four dimensions, height (h), tilt (t), width of a stripe parallel to the horizontal axes (st) and brightness (b) of a parallelogram. These dimensions differ from the ones used in Experiment I above in some crucial aspects. One is that they do not form intuitive subspaces. Another is that all possible pairs of dimensions match the description of separable dimensions.

Each dimension varied in three levels, h: (4, 5 or 6 units of length), t: (40, 50 or 60 degrees), st: (1, 2 or 3 units of width) and b: (40, 60 or 80% of maximum brightness). The width, hue and saturation were held constant (4 units of length, 240 degrees and 60% of maximum saturation, respectively).

The same pairs (w.r.t. the numbers of the stimuli), and order between pairs as in Experiment I were used.

Procedure

The experiment was conducted as Experiment I above.

Results

The average component distances for the collapsed data in Experiment II (Table 4 below), are not perfectly equal, especially the brightness dimension is weighted less compared to the others.

Table 4: Average component distances and R^2.

Avg_h	Avg_t	Avg_st	Avg_b	R^2
2.089	2.381	1.530	0.625	0.541

The coefficient of determination is very low, hence a general linear model does not apply well.

Spatial Metric The same candidate models as evaluated in Experiment I were evaluated. The resulting errors for the collapsed data are presented in Table 5.

Table 5: Models, r:s and errors for average data.

	r	Err
Het simHTsimSTB	1.1; 1	3.483
Hom opt	1	3.523
Hom cit	1	3.523
Het sepHTsepSTB	1.6; 1	4.010
Het citeuc	1; 2	4.213
Het euccit	2;1	4.434
Het citdom	1; 50	4.638
Het euceuc	2; 2	5.573
Het domcit	50; 1	5.885
Het eucdom	2; 50	6.185
Het domeuc	50; 2	7.234
Het domdom	50; 50	7.935
Hom euc	2	11.333
Hom dom	50	17.219

It is clear that the best rule, of the ones tested for, for describing the collapsed data in Experiment II is close to a city-block rule (*Het simHTsimSTB* (r=1.1;1), *Hom opt* (r=1) and *Hom cit*). It is not, in this special case, possible to view this as supporting either of homogenous or heterogeneous models since the city-block metric is the sum of the differences for the constituting dimensions. Therefore, there is no difference between a homogenous city-block rule and a heterogeneous rule where city-block rules are used within all subspaces.

As opposed to experiment I, the Minkowski-r values (for the best models) did not increase in magnitude with increased dimensionality.

The heterogeneous models with the lowest errors for the average data for each of the three subspace divisions are presented in Table 6. As, for the collapsed data, the optimal "heterogeneous" rule for the "original" subspace division was close to the city-block metric for both subspaces, this was necessarily the case also for the "odd" subspace divisions.

Table 6: Different subspace divisions and their errors.

Subspace division	Model	Err
height/tilt; str./bri.	Het simHTsimSTB	3.483
height/str.; tilt/bri.	Het simHSTsimTB	3.523
height/bri.; tilt/str.	Het simHBsimTST	3.523

General Discussion

The aim of this paper is to investigate and communicate the idea that division of features/dimensions of objects into separate subspaces - when applicable - possibly could increase descriptive power.

Experiment I involved pairs of dimensions previously found to be combined best by the city-block and the Euclidean metric, respectively. The Euclidean rule turned out to badly describe the data. Instead, a heterogeneous rule combining the two subspaces formed by the intuitive division, was found to provide the best description. The r:s for the two subspaces found in this experiment rhymes with previous research in that they really possess different metric properties and that the r for saturation/brightness was higher than for height/tilt. However, both r:s found were somewhat larger compared previous findings for the separate two-dimensional subspaces. The dimensions involved in Experiment I were all expected to be pairwise separable. Also in the four-dimensional case, the best describing metric turned out to be the city-block rule.

The idea presented received support in that the general pattern identified from the experiments is that phenomenological dissimilarity can be more accurately described with a heterogeneous rule taking aspects of the stimuli into consideration, compared to a homogenous Minkowski-metric.

There are a number of open questions. One relevant issue is how the subspaces themselves should be combined. In this paper, only one of many possible ways was investigated. Another question concerns the magnitudes of the r:s identified. Since the r:s estimated in Experiment II were not larger compared to what could be expected for pairwise combinations of the constituent dimensions, it is apparent that the increase in magnitude of r:s as found in Experiment I, is not generalisable to all complex stimuli. However, it is in the developmental literature well documented that the separability changes with experience (see e.g. Smith, 1980), with the direction from integrality to separability. This pattern also apply to short term learning (Johannesson, 2001b). A possible reason for the relatively large r:s in Experiment I could thus be that stimuli with contents of integrality are harder to "learn" than stimuli composed by separable dimensions. If so, the r:s could possibly stabilise at a lower magnitude for sufficiently experienced subjects. If not, it could simply be that the specific metric properties associated with integral/separable dimensions only are true in the context of single pairs of dimensions, i.e. depending on if they are combined or not. An interesting set of stimuli that could be used in order to explore this (and others) issue further is multimodal stimuli composed of the pairwise integral dimensions of pitch/loudness and hue/saturation.

The results presented clearly motivates further research on the idea that information integration could be described as a combination of distances within different subspaces. More research on if, how and when information integration behaviour can be described in terms of combinations of subspaces may shed light on how we interact with the inherently high-dimensional real world. For example, Edelman & Intrator (1997) discuss the necessity of low dimensionality for learning in perceptual tasks - known as 'the curse of dimensionality'. However, even if we always use low-dimensional representations internally, even for cognition, if these representations involve more than two dimensions, cognitive science have interesting problems to solve.

Abstract

Socio-cognitive complexity, as manifest in dynamic multi-party interactions, is central to many theories of hominid cognitive evolution. To assess the rudiments of these abilities in apes, we chose to study the triadic interaction known as "social tool use". In this scenario, one animal (the User) is said to interact with a second (the Tool) to in some way influence the behavior of a third (the Target). The "Machiavellian" model typically used to account for such behavior depends on folk theoretical descriptions of intentional manipulation and deception and has mired the field in unproductive attempts to define such mental states and justify their inference based on observable behavior. As an alternative, we conducted a distributed cognition analysis of these interactions among a group of seven bonobos (*Pan paniscus*) at the San Diego Wild Animal Park. Assuming that attentional behavior was critical, we gained insights from a wide range of research including human developmental, neurological, ethological, and comparative experimental work on social gaze in primates. This work lead us to perform a micro-analysis of 16 video segments (12 of social tools, 4 controls) in which we recorded all changes, at 1/6 second intervals, in relative trajectory, relative body and head orientation (open, peripheral, or closed to other animal) and, whenever possible, gaze. We also recorded the source, timing and duration of social interactions (groom, aggress, etc.) that occurred in those segments. In addition, data on patterns of association and social interaction collected over several years were used to establish long-term relationships such as rank and affiliation to situate and thus help interpret the micro-analysis. To facilitate cross-dimensional comparisons, the results of the micro-analysis were represented along time-lines (X axis = time) such that, for a given dyad and a given attentional dimension, each animal's proximity to physical or eye contact was indicated by the proximity of its line (along the positive or negative Y axes) to zero. Transitional probabilities for a change in any one of Animal A's dimensions being immediately followed by a change in any one of Animal B's dimensions ("triggering"), and for simultaneous changes ("syncs"), were computed for each dyad. Our results indicate that, while overt social behavior was directed by the User to the Tool, of the three dyads involved, the User/Target dyad were disproportionately responsive to one anothers' attentional behavior (while their counterparts in the control segments were not). Thus, this distributed approach has generated evidence that bonobos can and do monitor and respond to the attentional states of others, and that "social tool use" in these animals can best be characterized as a rudimentary capacity for multi-tasking.

Introduction

Studying Socio-Cognitive Complexity

Among the practices that set humans apart from other animals are the complex multi-party interactions in which we frequently engage. Comparative research suggests that the cognitive processes involved in such interactions are unusual in that they enable us to deal with a variety of dynamic social parameters simultaneously (e.g. Humphrey 1976). However, the elaborate collaborations (including conversation and other cultural activities) typical of our species present a daunting challenge to the evolutionary theorist concerned with their origins and course of development. By studying complex, polyadic interactions in our closest genetic relative, the ape, we hope to help identify rudiments shared by the less sophisticated system which, during hominid evolution, may have been subject to additional adaptive specialization.

"Social complexity" has been fairly well defined and documented in nonhuman primates. While in most social animals, power relations can be represented by a simple linear hierarchy and get played out in dyadic interactions, in many higher primates (monkeys and apes), rank and power are not necessarily equivalent (De Waal 1986). That is, for example, through triadic interactions such as coalitions or third party interventions, lower ranking animals can sometimes jointly gain access to resources over higher ranking individuals. Furthermore, the actions taken by a given participant have been shown to take into account not only that individual's own relationships to the others, but the relationship that exists between the others as well (e.g. de Waal & Van Hoof 1981; Cheney, Seyfarth & Silk 1995). For example, a subordinate macaque will

recruit aid against an opponent based more on the ally's rank relative to the opponent than on its own rank relationship with the ally (Silk 1999).

However, the concomitant models of the cognition involved are much less well developed. This is, in part, due to the difficulties inherent to studying social cognition. Gaining experimental control over the relevant variables in a social negotiation, for example, is extremely difficult and the relatively few attempts made with nonhuman primates have produced data that are ambiguous and controversial (see Heyes 1994; Povinelli 1994). Furthermore, the theoretical framework typically used to describe such interactions depends on "folk theoretic" accounts of "Machiavellian intelligence" (Byrne & Whiten 1988). That is, the animals involved are anthropomorphically portrayed as engaging in maneuvers designed to outwit, deceive, or otherwise strategically manipulate one another. This approach raises issues concerning complex, internal mental states such as intentionality, self-consciousness, theory of mind, etc. and has mired the field in attempts to define such states and justify their inference based on observable behavior.

In some respects, given our close genetic relationship, our largely-shared repertoire of gesture and expression, and our many brain similarities, such anthropomorphic descriptions of, especially, ape behavior may not be entirely unjustified. However, they constitute an unsatisfactory model of cognition for several reasons. For one, folk-theoretic accounts of mental behavior are arguably metaphorical, and their validity has been challenged even when applied to humans (Churchland 1981). Second, they may well reveal more about the 'storyteller' than about the players to whom they are applied, however consistent the tales that are generated. Third and most critically, it is unclear whether or not, as hypotheses, they are ultimately falsifiable. In any case, while fermenting much interesting discussion over the past decade or so, this approach has yet to yield much in the way of useful data.

An Alternative Approach

In this paper, we are proposing an alternative approach to the study of the cognitive complexity involved in primate negotiations. The distributed cognition approach (e.g. Lave 1988; Rogoff 1990; Resnick , Levine & Teasely 1991; Fogel 1993; Hutchins 1995) takes cognition as a co-constructed, real-time process that occurs not only whithin but also *between* individuals. (See also Vygotsky 1978; Wertsch 1985.) As a result, the observable group processes that occur during social discourse can themselves be taken as cognitive events. Through a detailed analysis of changes propagated across the "media" (Hutchins 1995) of such events, one can chart information flow, characterize task complexity, document developments in the roles of participants, etc. Thus, while not denying that internal mental states are involved, this model offers the advantage, especially as applied to nonhumans, of focusing on the cognition that is *apparent* in social interaction.

In particular, we have chosen to apply this model to the study of the triadic interaction known as "social tool use" (Kummer 1967; Jolly 1985; Goodall 1986) in the bonobo or pygmy chimpanzee. While no formal definition of "social tool" has been established in the primate literature, it is widely applied and commonly understood to involve one animal (the "User") interacting with a second (the "Tool") to in some way influence the behavior of a third (the "Target"). Such interactions are traditionally divided into five basic classes, all of which were included in our database. These include "recruitment" (User attempts to elicit aid from the Tool against the Target), "agonistic buffering" (User physically uses Tool as a shield or otherwise engages with it to diffuse a threat from the Target), "passport" (User positively interacts with Tool who has a special relationship to the Target, such as mother/offspring, to gain access to the Target), "incitement" (User positively interacts with Tool to incite investment from the Target) and "alibi" (User directs exaggerated attention at Tool to avoid responding to a solicitation from, or to disengage from interacting with, the Target).

While expressly avoiding attributing the implied mental states (manipulation, deceit, jealousy, etc.) to the animals involved, we explicitly acknowledge and even adopt these anthropomorphic terms for two reasons. One is that they are useful as 'shorthand' descriptions that readily communicate the essentials of the behavioral dynamics involved. The other is that it was on such an intuitive, anthropomorphic basis that we originally identified the incidents of social tool use from our videotapes of the bonobos' interactions. One goal of this study, then, is to discover, through a detailed analysis of the tapes, whether those intuitions have any basis in behavioral cues that are meaningful not only to us as observers but that also serve as salient, effective media in the animals' distributed cognition. It is from such an empirical base that we may build a stable comparative model of socio-cognitive complexity.

Methodological Challenges

Given that the distributed approach is still in its infancy, especially as applied to nonhumans (although for discussions see Cousi-Korbel & Fragazsy 1995; Strum, Forster & Hutchins 1997; Johnson, 2001) there are few

established protocols for research design and analysis beyond the essentials demanded by the theory. These essentials include using interactions (as opposed to the actions of individuals) as the units of analysis, charting change over time, and collecting observations at multiple time scales, including the historic and the micro-levels (see Hutchins 1995; Fischer & Granott 1995). The latter is generally done via detailed video analysis of particular interactions. The former is done using macro-level sampling techniques over the long-term, and is meant to provide background information (cultural constraints, social relationships, task exposure, etc.) that can help to "situate" and thus interpret the interactions. Beyond such guidelines, however, work in this emerging field faces several challenges in determining what to score, how to represent those data, and how to generate a meaningful interpretation of them.

Challenge I: What to score

For insights into what might be the most relevant parameters to document in the bonobos' behavior, we turned to the ethological traditions embraced by primatologists, the current experimental work by comparative psychologists, related neurological research, and the developmental study of "theory of mind' issues in human children. Interestingly, these approaches converge on some of the elements that they consider critical. For instance, in the developmental work, an emphasis has been placed on joint visual attention and, in general, on the social manipulation of attention, especially gaze (e.g. Baron-Cohen 1995; Moore & Dunham 1995). This has also become the focus of one of the few productive areas of comparative experimental work on social cognition. That is, for example, several primate species have recently been documented as being capable of "gaze following" (e.g. Anderson et al. 1996; Tomasello Call & Hare 1998; Peignot & Anderson 1999). However, with the notable exception of the chimpanzee (e.g. Povinelli & Eddy 1996; Itakura & Tanaka 1998), most respond to the direction of head orientation and seem incapable, even after extensive training, to respond to the eyes-only as a cue (although see Vick & Anderson 2000). Relevant physiological findings include an increase in cortico-steroids and other orienting responses to direct eye contact (e.g. Keating & Keating 1982; Perrett & Mistlin 1990), as well as cerebral cortex cells in monkeys that are sensitive to the direction of head orientation and/or gaze of another (Perrett et al 1985). Our subject, the bonobo, has not yet been tested on any of the above.

Ethologists, likewise, have long been tuned to the attentional behavior of their subjects (see Smith 1977; Alcock 1978). This can be traced to some simple structure/function relationships. For example, across the phyla, animals with forward-facing eyes (like primates) tend to move in the direction their gaze is oriented, making gaze direction a predictive signal for others. Similarly, body orientation (judged in primates by the orientation of the shoulders and degree of proneness) is also a cue as to one individual's readiness to engage with another. However, these measures are complicated by the fact that orienting toward another individual can also be a function of information-gathering. In fact, this dual role of attentional behavior - both sending and receiving information - is responsible for an inherent ambiguity that can be exploited by the likes of primates.

For example, a monkey that does not look directly at another who is threatening it, and thereby does not 'acknowledge' the threat, can sometimes effectively hold the aggressor at bay. Similarly, a subordinate not looking at a contested resource is much less likely to stimulate an overt conflict over it than another who openly displays its interest. In 1967, Chance described a more general relationship between primates' attentional behavior and rank, with subordinates looking to dominants more often than the reverse. This presumably serves to gather information about likely troop movement or other important group developments. Nevertheless, in most primates a direct stare is a threat and the avoidance of eye contact is common in most species (Kummer 1967).

Subject and Procedures

The subjects of this study were seven bonobos (*Pan paniscus*) living as a coherent social group since 1993 at the San Diego Zoo's Wild Animal Park. The group consists of four mature animals - one adult male, two adult females, and one female who went from adolescent to parturient adult over the course of the study. The group also includes three juveniles born, one to each of the females, in 1991, 1994 and 1996.

In response to the above-described research, we chose to score the following dimensions of the bonobos' activity. Historic data on association patterns (per inter-animal distances) and gross social interactions (such as groom, follow, food-sharing, aggress, etc.) were taken in instantaneous scan samples, at two minute intervals, in twenty minute sessions, for months to years preceding the video segments. These data were used to establish long-term rank and affiliative relationships, as well as to document more short-term developments like disputes or alliances, changes in reproductive status, etc.

Approximately fifty hours of videotape taken of the group since 1993 were reviewed by the authors and twelve incidents of 'social tool use' were identified. (Additional putative examples were also found, but

these did not meet practical criteria such as video quality sufficient to assess gaze, or all three animals being visible for at least 80% of the interaction.) These selections were based on the strength of a combined total of ten years of experience watching these animals. The control segments involved the same configuration of animals, from the same periods of time, engaged in the same gross interactions (e.g. a pair grooming in the vicinity of a third) as the test segments, but which did not, in the authors' estimation, involve social tool use.

For each segment, a User, Target and Tool (or their correspondents in the control segments) were identified and data collected on each dyad (User/Target, User/Tool and Target/Tool). The segments, which varied from 15 to 50 seconds long, were analyzed at intervals of 1/6 of a second (ten frames), which was determined as the shortest interval in which any relevant event (e.g. a glance) could take place, For each interval, the following states were recorded for each individual within each dyad: 1) Inter-animal distance, in fractional body widths, 2) Focus of gaze, whenever it could be determined, 3) Relative body orientation and 4) Relative head orientation, the latter two scored as OPEN, PERIPHERAL, or CLOSED. OPEN was defined as (body or head) oriented directly toward the dyad partner. PERIPHERAL was defined as the partner being positioned from about 20o to about 110o right or left of a sagittal plane between the animal's eyes. (This estimate is based on bonobo visual and cranial anatomy and is assumed to include the area in the animal's peripheral visual field. Ankel-Simons 1983) CLOSED was defined as the partner being behind and thus not within the animal's visual field. For any *change* in state across intervals, the individual responsible (i.e. whose movement resulted in the change) was scored as having shifted TO or FROM its partner. If an individual actively maintained a state (e.g. turned its head to track another's movements, thus actively maintaining an OPEN) this type of 'change' was scored as a KEEP. In an ongoing, time-locked narrative, we also recorded all social interactions (such as groom, play, sex, etc.) and individual tension/relaxation indicators (such as scratch, flinch, clap, playface, etc.).

Challenge II: How to represent

When continuous data are collected over multiple media simultaneously, representing the results in a comprehensible form poses another challenge. In general with such data, some sort of time-line charting the course of changes is commonly employed. But, for example, warranting the ordering of the Y axis values, or aligning the valences of such changes across multiple lines (so that, for instance, movement away from the X axis at time T along one dimension is augmented by movement away from the X axis, at the same time, along another dimension) demand a careful assessment of the media being studied. We again looked to behavioral and physiological data on primates to facilitate this assessment.

In our own earlier work with the bonobos, we found that 70% of all incidents of eye contact were followed by a decrease in inter-animal distance and/or direct interaction (of both positive and negative kinds). Bonobos are also unique among nonhuman primates in that they regularly engage in face-to-face sex, during which eye contact is typically made (Savage-Rumbaugh & Wilkerson 1978). In keeping with the above-described primate research, such data make it clear that eye contact should be treated as central in any representation of the bonobos' gaze relationships. That is, head and gaze states can be organized according to their 'proximity' (i.e. ease of transition) to eye contact. Similarly, body orientations and inter-animal distances can likewise be organized according to the accessibility they offer to (physical) contact.

As a result, we have chosen to represent these data in the following manner. For each medium (gaze, body orientation, etc.), each dyad is represented along a single X axis of Time, marked at 1/6 second intervals. One animal's behavioral values are represented along the positive Y axis and the other's along the negative Y axis. In both cases, the Y values farthest from 'contact' are farthest from the X axis, so that when the pair are far away from each other or oriented away from (CLOSED to) each other, their time-lines are far from the X axis. As each makes a move toward, or turns toward, the other, their lines draw closer, until when contact (physical or eye contact) occurs, the lines meet at the X axis. Using these multiple time-lines, we can then chart a "cognitive trajectory" for each dyad, as informative changes move across and between the media. Plus, since the various time lines are constructed according to similar criteria, we can collapse or blend them into a single (paired) line that depicts all the changes (i.e. all TO's, FROM's and KEEP's) in a given dyad's attentional access to one another. Such summary lines are also useful for examining *inter*-dyad relationships, facilitating the search for the constraints imposed not just by the activity of an individual's partner, but also by the joint activity of the other dyad.

Challenge III: Analysis

While we can reasonably assume that the media we are scoring are perceptually accessible to our subjects, we are primarily concerned with whether these media are *functionally salient*. More specifically, we are questioning whether the three dyads involved

differentially produce and respond to changes in each other's attentional behavior.

To address these questions, we will first compare the transitional probabilities (see Bakeman & Gottman 1997), across dyads, of any change in one partner's media being followed, in the next 1/6 second interval, by any change in the other partner's media. We will also compare the occurrence of partners' simultaneous changes and coordinated active maintenance (i.e. simultaneous KEEPs) across dyads. Thus, both synchrony ("SYNCS")and immediacy of reaction ("TRIGGERS") will be taken as measures of the sensitivity of our animals to the attentional behavior of others. In addition, by assessing patterns of change initiation (e.g. Animal A:TO, followed by Animal B:FROM) we aim to establish a motivational valence for these interactions, based on the basic assumption that organisms approach stimuli they consider desirable and avoid those they consider undesirable. Ethologists have long maintained that "approach/avoidance" conflicts provide a reasonable account of much inter-animal positioning as well as the thresholds for dynamic change. Finally, we will also examine our data for large-scale temporal patterns, both in specific state changes as well as along the more general TO/FROM/KEEP dimension.

Preliminary Results

Defining social tool use as: "One animal using another to manipulate or influence the behavior of a third", we asked two additional observers, familiar with the animals but blind to the cognitive model being tested, to judge whether or not the test and control segments met those criteria. These observers each disagreed only on a single different example. In interviews after the tests, the observers indicated that the User's behavior toward the Tool seemed "insincere", at times because of the abruptness of its termination but most often because of "furtive" looks directed by the User to the Target (although neither mentioned a co-sensitivity to attention between both User and Target - see below).

We are currently conducting the micro-analyses of the video segments. Preliminary results indicate that, in all 12 social tool examples, the User/Target dyad can be identified by their disproportionately high level of responsiveness to changes in one another's attentional behavior. That is, both more Triggering and more Syncs occur in the User/Target dyad than in either the User/Tool or the Target/Tool dyads. In contrast, in the control segments, the pair that was engaged in the primary interaction (i.e. that of the User and Tool in the corresponding social tool examples) show a tendency to be the most responsive to one another's attentional behavior. The additional level of attentional sensitivity between what would be the User and the Target does not appear in the control segments.

As expected, the cognitive trajectories of these interactions frequently jump across media (e.g. an approach by one animal triggers a look-away by another). The most intense (simultaneously multi-media) interactions occur in the User/Target dyad. The directionality of triggers (i.e. who initiates an exchange) often varies between and even within segments. In fact, it may be the case that a tendency to 'vacillate' in the direction of triggers is especially characteristic of the User/Target dyad. In addition, the Target appears more sensitive to attentional interactions between the User and Tool than either of them do to his interactions with the other.

At least two types of larger-scale patterns have thus far been identified. "Cascades" involve a sequence of triggers, often alternating in source animal, and culminating in some intense level of attentional coordination. In "Suspensions" a prolonged lack of response is maintained by one animal, who remains visually fixated on a particular point (its hand, the grass, etc.), until the partner removes itself from probable engagement (e.g. "closes"), at which point the first finally glances at the partner. Both patterns are most often seen between User and Target. Such interactions provide additional evidence for the functional salience of attentional behavior as well as for the motivational dynamics that characterize social tool use.

Discussion

In summary, we have chosen to conduct a distributed cognition analysis of the triadic primate interaction known as "social tool use". Through this work, we have been able to show that bonobos can and do monitor and respond to the attentional states, including eye gaze, of one another under natural social conditions. Furthermore, rather than relying on a folk-theoretic description of "social tool" that involves attributing humanlike mental states to the animals involved, we have been able to generate an operational definition of social tool. That is, social tool use can be said to occur when one animal (the User) directs some overt social behavior toward a second (the Tool) while keeping its attention primarily fixed on the attentional behavior of a third (the Target) who is likewise attuned to the first.

By examining these interactions in moment-to-moment detail, we can clearly see the co-constructed nature of the cognition involved and the level of complexity that the animals can jointly attain. It would be particularly interesting to do a similar analysis of humans engaged in such interactions, to compare the media, transitional patterns, and levels of sophistication involved. In addition, as a result of this analysis, we can

characterize the individual cognitive abilities of the bonobos not as involving intentionality, deception, or theory of mind, but as reflecting a rudimentary capacity for multi-tasking. Considered one of the most complex of primate behaviors, social tool use is rare even in apes, and thus may be viewed as lying at the limits of those animals' abilities. As such, it suggests that speculation on the critical changes in hominid cognitive evolution might do well to focus on traits that would enable the manipulation of one's own and other's attentional behavior and the capacity to engage in multiple social trajectories simultaneously.

Cascade Explains and Informs the Utility of Fading Examples to Problems

Abstract

Recent research demonstrates that people learn to solve problems more effectively when presented with a series of faded examples and problems, than when presented with completely worked out examples and completely unsolved problems alone. We propose an explanation for this effect, based on the Cascade model. Cascade was originally built to model the self-explanation effect, but it also accounts for other aspects of human learning and problem solving strategies. A relatively straightforward application of Cascade, without alteration, also explains why fading might be beneficial. This explanation provides further support for Cascade as an accurate model of human learning and problem solving, and it also augments the results on fading with specific insight into how, and when, example fading should be effective.

Introduction

There are a variety of research results characterizing factors that facilitate the human ability to learn how to solve problems. Among recent results, Renkl, Atkinson, and Maier (2000) report that people learn more effectively when presented with a set of "faded" examples and study problems than they do when presented with study examples alone (followed by completely unworked problems). Given this result, our interest is in identifying the cognitive mechanisms that explain why the effect exists. Additionally, if we understand the underlying mechanisms, they may provide extra insight into precisely how to create effective sets of study examples and problems. We have identified a potential set of explanatory mechanisms, which are precisely the mechanisms that define Cascade, an existing model of human learning in problem solving (VanLehn, Jones, & Chi, 1991; VanLehn & Jones, 1993a). The Cascade model suggests which study and learning mechanisms contribute to the fading effect, and provides a tool for pinpointing precisely which types of faded examples will be most effective.

Fading Examples

A common curriculum for teaching students to solve problems in a particular domain involves having the students first read some domain material, then study some completely worked out example problems, and finally solve problems that have not been worked out. Various studies explore why it is beneficial for students to study completely worked out examples (e.g., Chi et al., 1989; Pirolli & Anderson, 1985; Renkl, 1997, VanLehn, 1996). The technique of *fading examples* constitutes a particular variation on such a course of study. When fading, the teacher first presents a completely worked example and then follows this with a series of *nearly* completely worked examples. Each subsequent problem removes an explanatory step, forcing the students to solve that portion of the problem themselves. This gives more guidance than a regular problem, because the student still has the guidance of the rest of the worked out example, but it gives less guidance than a completely worked example.

Renkl et al. (2000) demonstrated that different particular methods of presentation can yield different levels of learning. Specifically, they showed that fading sometimes improves learning over other orders of presentation. In their initial study, they presented subjects with a completely worked example, followed by an example that omits the last step in the solution. This was then followed by an example that omits the second to last and last steps and finally one presentation of a completely unworked problem. They compared this situation to one in which students first studied a completely worked example, and then solved a completely unworked problem. The results of this study confirmed that the group of subjects exposed to faded examples learned more effectively than the other group, even though both groups had similar pre-test performances. A more thorough, but similar, experiment produced comparable results.

Renkl et al.'s study provides us with valuable information about potential ways to design study curricula. However, the research also leaves a few unanswered questions. Among these are *why* fading works as well as it does. In addition, it would be useful to know exactly what forms of fading will be effective. Is it always the case that examples should be faded from back to front? Or are there more formal methods we can use to design faded examples? Such questions can, and should, be answered in part by further

experimentation. However, we believe that an existing computer model of human learning in problem solving can also shed light on some of the answers. At worst, the model can help guide future experimentation. At best, the model makes specific predictions and recommendations about how to fade examples.

The Cascade Model

Before presenting Cascade's account of example fading, we will first provide an overview of Cascade's cognitive mechanisms, and how they contribute to explaining other experimental results on human problem solving and learning. Cascade was originally developed to explain the cognitive mechanisms involved in the *self-explanation effect* (Chi et al., 1989; Fergusson-Hessler & de Jong, 1990; Pirolli & Bielaczyc, 1989). Simplifying a bit, the effect shows that people learn more effectively by studying examples when they are careful to explain to themselves as many steps of the example as they can. Students who do not carefully explain worked out example steps do not perform as well on subsequent problems.

Cascade explains this effect as the interaction between two basic learning mechanisms (VanLehn et al., 1991; VanLehn & Jones, 1993b). The basic prediction of Cascade is somewhat intuitive: A student learns effectively when the student is able to identify and patch a specific gap in their knowledge. In Cascade, such knowledge acquisition can occur both while studying worked out examples and while solving problems. When studying an example, Cascade must self-explain each worked step. When the system finds a step it cannot explain, this signifies a knowledge gap. Because the example specifies what the answer is, Cascade can (given appropriate domain-general background knowledge) compensate for the gap by constructing an explanation for the answer. When Cascade successfully creates such an explanation, it learns a new piece of knowledge that it has some faith will work in future problems.

When solving problems, Cascade may also learn by exposing and patching knowledge gaps. However, during problem solving, the process is less constrained because the system does not know the correct answer ahead of time. If the system is missing knowledge, there are potentially a number of ways Cascade could go wrong in attempting to solve a problem. Thus, it is highly likely that the system may expose and attempt to patch a "false" knowledge gap. However, when the system explains examples, it also stores search-control knowledge, essentially remembering the subgoal structure of each example. Experiments with Cascade show that this search-control knowledge can be enough to guide the system into *real* knowledge gaps during problem solving. It can then successfully patch those gaps (VanLehn et al., 1991). Without the search-control knowledge provided by self-explaining examples, Cascade cannot distinguish between real knowledge gaps and otherwise unproductive dead-ends in the attempted problem solution.

Experiments with Cascade have focused mostly on problems involving Newtonian physics, due to the fact that the system's creators had access to physics problem protocol data from Chi et al. The experiments show that Cascade's interacting learning mechanisms account for the basic self-explanation effect, and are able to explain a variety of problem-solving and learning strategies on an aggregate and an individual basis (Jones & VanLehn, 1992; VanLehn et al., 1991; VanLehn & Jones, 1993c).

Because it plays into Cascade's account of example fading, it is worth describing part of the experimental methodology used in the previous Cascade work. The basic method for running experiments with Cascade involves three steps:

1. Configure the system's initial knowledge base, to reflect the hypothetical initial knowledge state of a human subject.
2. Force Cascade to explain exactly those pieces of a series of examples that correspond to observed self-explanations in the subject's protocol (by running it in "explain" mode only on those example pieces).
3. Run Cascade on a series of problems, recording answers, errors, and learning events, to compare with similar events in the encoded subject protocol.

This methodology makes explicit that Cascade does not model all the cognitive process in learning from examples and problem solving. For example, although Cascade can explain the results of self-explanation episodes, it currently has no way to predict which pieces of an example a student will choose to self-explain. However, for the cognitive processes that Cascade models, it does a good job of matching detailed protocol data (Jones & VanLehn, 1992). Thus, we will use the same basic formula to test Cascade's account of example fading.

A Potential Explanation for Fading

Given the background details of how Cascade studies examples and learns to solve problems, we can now sketch the theory behind how Cascade ought to be able to explain the fading effect reported by Renkl et al. It should be clear that, if the Cascade model is accurate, fading of examples can lead to improved learning only if it provides the students with more opportunities to patch their knowledge successfully.

However, it is certainly a valid question whether this is really an accurate characterization of the source of the benefit of example fading. According to Cascade, if a student completely self-explains an example, the student would successfully encounter and patch every potential knowledge gap relevant to that example. Thus, there would be absolutely no benefit to first self-

explaining the example and then combining self-explanation with regular problem solving on a similar subsequent example. The only way example fading could be effective (according to the Cascade model) is if it leads the student to patch a knowledge gap that it would not patch through example studying alone.

As we mentioned above, Cascade can be configured to emulate the self-explanation behavior of any individual subject (Jones & VanLehn, 1992), or to emulate aggregate self-explanation effects (VanLehn et al., 1991). However, it does not explain how or why a subject chooses to self-explain any particular piece of an example. Although an idealized version of Cascade can self-explain a worked example in its entirety, there was not a single subject in Chi et al.'s study who was so thorough in their self-explanation behavior.

Thus, the evidence and model suggest that completely worked examples are never (or at least seldom) as beneficial to students as they could be, because students never (or at least seldom) completely self-explain the examples. This in turn may cause the students to miss opportunities to learn from the examples. However, when a student is given a faded example, there should be some confidence that the student will focus their attention at least on the part of the example that they are requested to solve. Thus, a faded example is similar to a completely worked-out example with a special highlight that says "make sure you self-explain at least this portion of the example".

Our hypothesis is that there are no additional mechanisms required by Cascade to account for the example-fading effect. Rather, using Cascade's existing mechanisms, we hypothesize that example fading forces the student to pay thorough attention to particular portions of the example. Because this forcing is highly focused, the student has a good chance of successfully exposing and patching a knowledge gap (if the faded piece of the example relies on such missing knowledge).

When Cascade is forced to self-explain an individual "faded" portion of an example, we predict that Cascade will acquire new knowledge if that portion of the example exposes a knowledge gap. In such a case, Cascade will exhibit improved learning over normal example studying *if* Cascade was not originally forced to self-explain the same example portion. Due to the fact that we do not have such protocol data from Renkl et al., there is currently no empirical way to tell if this is an accurate characterization of when Renkl et al.'s subjects learned. However, it does provide a testable prediction. Before that experiment is run, however, we should first test the Cascade model to make sure our predictions about its behavior during example fading are accurate.

As an example, a first-year college physics text will often contain an example with a block suspended from a string and sitting on an inclined plane. The example will include some lines that, implicitly or explicitly, involve the inclination of the normal force exerted by the inclined plane on the block. It is not uncommon for a first-year college student never to have heard of normal force, much less to know its inclination. If the student self-explains the entire example, they will come across these portions, reach an impasse, and be forced to create some new understanding concerning normal force. If the student does not bother to self-explain the important parts of the example, they will happily go off and solve inclined plane problems without involving normal force at all (such episodes appear in Chi et al.'s protocol data). Consider taking the same example, but replacing one part of the work with the problem statement, "What is the inclination of the normal force?" This certainly draws the student's attention to normal force, and it explicitly requires the student to understand the concept, if the student is going to be able to finish the problem. In contrast, a student can very easily read a completely worked example without bothering to learn about normal force at all.

Experimental Design

We ran Cascade on Newtonian physics problems, because we already had a thorough task analysis and knowledge representation for the physics domain.

The basic approach involves first using Cascade as a knowledge analysis tool. We ran the system on all the examples and problems given to Chi et al.'s subjects, determining which examples and problems provided the first opportunity to learn a variety of pieces of knowledge. In addition, we used the model to determine which problems required the application of particular pieces of knowledge. This exercise allowed us to create a dependency chart for a number of different knowledge chunks. The chart basically tells us "if you force Cascade to learn this chunk from this example, then it ought to be able to solve this piece of this problem." Or in some more interesting cases, if you force Cascade to learn a particular chunk from an example, it provides the scaffolding for the student to learn *another* chunk in a subsequent problem.

Given this knowledge analysis, it allows us to create experimental runs that simulate effective example fading. The analysis tells us exactly where in each example each knowledge chunk can be learned. Thus, we can focus the system, telling it to explain exactly that portion of the example that will lead to the acquisition of the desired knowledge chunk. This corresponds to creating a focused "faded example", where we allow Cascade not to self-explain most of the example, but force it to self-explain exactly the correct piece. We can then run Cascade on the same example, but with an additional faded portion, so the system can learn a second chunk from the same example. As a control, we can force Cascade to self-explain example

pieces that do not cause any learning, and demonstrate that this has no beneficial effect on future problem solving. An additional control has Cascade "study" the examples without self-explaining the lines, in which case no useful learning occurs.

Results

As predicted, the experiments with Cascade were able to demonstrate improved learning with simulated fading of examples over normal processing of examples. The knowledge analysis showed where Cascade required, or did not require, particular pieces of knowledge to solve a problem. In some cases, the system could solve problems even without any example studying. In other cases, the model was unable to solve problems due to a particular lack of knowledge, even if the system had "studied" an appropriate example without actually self-explaining the key portion of the example. With simulated fading, the system was forced to self-explain the appropriate portions of the examples, and then could solve more problems. Even more, the knowledge analysis was able to tell us exactly which pieces of certain examples should be faded in order to allow the system to solve each particular problem.

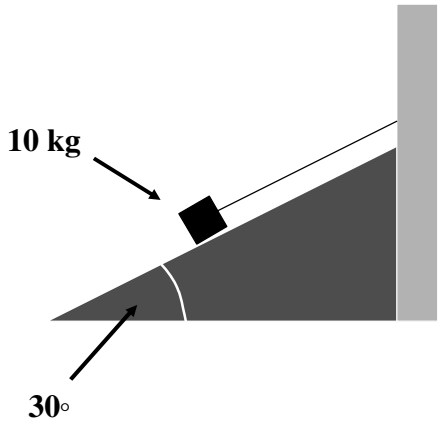

Figure 1: A typical inclined-plane problem. What is the tension in the string?

The experiments we report here concentrated on a thorough analysis of one particular sequence of examples and problems in the Chi et al. study. These examples and problems were all variations of inclined-plane problems (see Figure 1). Given Cascade's initial knowledge base, complete self-explanation of two inclined-plane examples and one "weights and pulleys" example provides the opportunity to expose and patch 12 knowledge gaps.

These opportunities appear in specific portions of the explanation traces for the examples. For example, Cascade can only learn about normal force from self-explaining the normal-force vector in the free-body diagram of the inclined-plane example. If Cascade fails to self-explain this portion of this example, it generates incorrect answers on any future problems that involve normal force. In fact, it usually generates the same incorrect answers as students who also fail to self-explain that portion of that example (Jones & VanLehn, 1992). A portion of the dependency table that covers this chunk appears in Table 1.

Table 1: Dependency chart for the normal-force chunk.

Chunk	`normal-force`
Learning opportunities	Example ixa, line 2 Example ixb, line 2
Used in problems	i1a, i1b, i2a, i2b, i3a, i3b, q5

In one experiment, we forced Cascade to learn about normal force by fading the normal-force portion of the example. Even if Cascade did not self-explain any other part of that example, it learned the normal-force chunk because we forced its attention there.

In each of our experiments, we deleted one of the 12 target rules from Cascade initial knowledge. We then compared Cascade's behavior without any self-explanation to Cascade's behavior when it is forced to self-explain only the portion of the examples that leads it to learn the deleted chunk. The results show that Cascade cannot solve all of the inclined-plane problems without acquiring all 12 of the target pieces of knowledge. It cannot solve *any* of the problems without learning at least some of the 12 chunks (although each of the problems only makes use of a subset of the 12 chunks). More importantly, the results tell us exactly which example portions will lead to success on which problems.

In some cases, Cascade is also able to learn new knowledge chunks during problem solving. In fact, it cannot solve some of the problems without also patching some knowledge gaps during the solution of that problem. The experiments also show that this learning is not always successful unless Cascade has first acquired all the knowledge it needs from the examples. Again, perhaps most informative is that the experiments tell us which pieces of the examples are most beneficial to fade. For example, Cascade cannot solve any problems correctly without first being forced to learn about normal force (as discussed above). But if Cascade is not forced (during example studying) to learn about the inclination of an inclined block's acceleration, it is able to learn that particular piece of knowledge (or at least compensate for it and get the right answer) during problem solving. It can only do this, however, if it has learned about the *existence* of normal force from one of the examples (or from prior experience).

In general, the experimental results confirm our contention that graded fading of examples can map to

improvement in Cascade, if we correspond fading with the forced self-explanation of portions of each example. These results demonstrate the basic dependencies we predicted. Thus, without any alteration to the underlying Cascade model, it is able to provide an explanation for the benefit of faded examples. The key assumption is that example fading serves primarily as a focus of attention, forcing the subject to study closely productive portions of each example. In the closing section, we discuss some implications of this assumption, as well as the possibility of further experiments that would identify more complex interactions between fading and learning.

Conclusions

We feel this work provides two basic contributions. First, it offers additional evidence that Cascade is an accurate model of (at least some of) the cognitive mechanisms involved in studying examples and learning to solve problems. In some ways, this may only be of interest to the designers of Cascade. However, more generally, it allows us to have more faith in using Cascade as a tool both to study human behavior, and perhaps as an aid for curriculum development. In this work, we were able to use Cascade not only as a cognitive model, but also as a knowledge analysis tool. It allowed us to perform a focused dependency analysis that would certainly be beneficial to an instructor creating examples and problems.

However, we should note that much of the hard work that made this analysis possible was performed years ago. We have the benefit of the detailed cognitive analysis of college physics that went into the original design of Cascade. To apply Cascade to any new domains would require a similar intensive effort. However, Cascade at least provides a framework and set of assumptions for creating such knowledge representations. Furthermore, it provides clear principles for where, and how, examples and problems will cause a student to learn target knowledge chunks, as well as which target knowledge chunks contribute to the solution of target test problems.

The second contribution is that we have enhanced our knowledge of how, and why, example fading proves beneficial in some circumstances. The Cascade model suggests that arbitrary fading of examples is not likely to be fruitful, in general. Rather, fading should be focused towards the pieces of examples that will enable learning of a teacher's target knowledge chunks.

Again, this conclusion depends on a key assumption that is integral to Cascade's candidacy as an accurate cognitive model. If Cascade is accurate, it must be the case that faded examples cause effective learning by forcing the student to encounter and overcome an impasse. This is a prediction that can easily be tested. Future experiments on fading should include detailed protocol analysis, and should look for evidence of impasses and learning events in the faded portions of the examples. Such data will confirm or disprove Cascade's account of fading.

It would be prudent to note that the account of fading presented here does not need to be the exclusive source of improved learning. As we mentioned in describing Cascade, the system relies on an interaction between a domain knowledge acquisition learning mechanism and a search-control knowledge learning mechanism. The experiment and explanation reported here relies almost exclusively on the knowledge acquisition mechanism. However, our knowledge of Cascade suggests that it would likely also predict at least some benefit to example fading from the learning of search control knowledge.

Even if a faded portion of an example does not force an impasse and learning event, if it forces some amount of problem solving, Cascade predicts that a student would acquire search control knowledge for the goals and subgoals addressed in the faded portion of the example. As with Cascade's model of the self-explanation effect, such search-control knowledge could benefit later learning, even if no knowledge chunks are learned during the solution of the faded example. However, we have not yet run an experiment along those lines. For now, we will leave that form of learning from a faded example to speculation, to be confirmed or rejected later. It would be most interesting to conduct such computational experiments in concert with similar detailed protocol studies of human subjects. The main point is that Cascade predicts the primary benefit of a faded example is that it forces the student to process parts of the example that they might otherwise ignore. Once a portion of the example is processed, all the cognitive mechanisms that Cascade posits can be brought to bear on learning.

Acknowledgements

This work would not have been possible without the original development of the Cascade system. That, in turn, would not have been possible without the efforts of Kurt VanLehn and Michelene T. H. Chi.

Abstract

Any viable model of serial reaction time (SRT) sequence learning needs to be able to capture the relative extents to which participants learn different SRT sub-sequences. However, previous attempts to empirically establish a relative pattern of this sort have failed to fully control for 'sequential-effects', or have not satisfactorily ruled-out the influence of speed-accuracy trade-off. In this paper it is shown that, when sequential-effects are controlled for in a two-choice SRT task, participants learn those sub-sequences that end in an alternation better than those that end in a repetition. It is further demonstrated that, at least for the parameters investigated, a buffer network, a Jordan network, an SRN, an augmented SRN, and an AARN are unable to account for this pattern.

Introduction

Since its introduction (Lewicki, Czyzewska & Hoffman, 1987; Nissen & Bullemer, 1987) the serial reaction time (SRT) task has proved a popular way to assay human sequence learning. In the most common version of this task a stimulus can appear in one of several locations on a computer screen, each of which has a corresponding response key. Whenever a stimulus appears, participants simply have to press the appropriate key as quickly and accurately as possible. Crucially, usually unknown to the participants, the order of locations in which the stimulus is presented follows a sequence, at least for the majority of the time.

Typically, participants' reaction times (RTs) on trials that are consistent with this sequence become significantly faster, either than their RTs on occasional inconsistent probe trials, or than the RTs of a control group that is only exposed to a (pseudo-)random ordering (e.g. Anastasopoulou & Harvey, 1999). This is taken to imply that the participants have learnt at least part of the sequence, and that they are using this information to prepare for the stimulus or response on the next trial.

The widespread use of this task makes it a priority to develop an adequate model of human SRT performance. A particularly stringent test of any candidate model is to capture the relative extents to which participants learn different parts (sub-sequences) of an SRT sequence. Unfortunately, however, nearly all of the patterns of sub-sequence learning that have been reported in the literature are potentially confounded by 'sequential-effects' (cf. Anastaspoulou & Harvey, 1999; Shanks & Johnstone, 1999).

'Sequential-effects' can be defined as the influence that the previous series of stimulus/response locations has on the participant's current response, in a choice-RT task in which the trial order is (pseudo-)random (e.g. Soetens, Boer & Hueting, 1985). To illustrate, in a two-choice task at a response-stimulus-interval (RSI) of 50ms, participants tend to respond faster when the stimulus appears in the same location as it did on the prior trial (Soetens et al., 1985).

Therefore, in order to more accurately assess SRT sequence learning, the performance of the sequence group and pseudo-random control group need to be compared on a 'test-phase' in which they are both exposed to the same order of trials; the assumption being that the two groups should manifest the same sequential-effects when responding to identical trial orders, allowing the difference between the groups to be used as an index of sequence learning.

However, the majority of previous SRT studies have failed to control for sequential effects in this manner (e.g. Nissen & Bullemer, 1987), calling into question the apparent patterns of sub-sequence learning they report.[2] Furthermore, the two previous studies that have adequately controlled for sequential effects, namely Anastasopoulou and Harvey (1999) and Shanks and Johnstone (1999), have not reported error data in sufficient detail to rule out the possibility that participants traded speed and accuracy between different sub-sequences.

Therefore it was necessary to carry out a new experiment in order to establish a relative pattern of SRT sub-sequence learning against which models of the SRT task could be tested.

Experiment

The experiment comprised a five session two-choice SRT task, with an Experimental Group that was trained on four sub-sequences and a Control Group that was exposed to a pseudo-random ordering for the same number of trials. To control for sequential effects, following training all

[1] Now at: University of Surrey, Department of Psychology (Clinical Psychology PsychD), Guildford, Surrey GU2 7XH, UK.

[2] Some authors have attempted to reduce the influence of sequential-effects by removing trials that they feel are particularly contaminated (e.g. Jimenez, Mendez & Cleeremans, 1996). However, it is not clear that this is sufficient.

participants were 'tested' on pseudo-random orderings, with the difference between the two groups being taken as an index of sequence learning.

Method

There is not the space to give full methodological details, but these will be provided in Jones and McLaren (in prep.).[3]

Participants, Stimuli and Apparatus The participants were 24 Cambridge University students and members of the public, whose ages ranged between 18 and 47. 16 were randomly assigned to the Experimental Group and 8 to the Control. This difference in numbers did not cause any reliable differences in variance between the groups; therefore the subsequent ANOVAs are valid. The experiment was run on a Macintosh LCIII, and the stimulus comprised a circle 1.9 cm in diameter which could appear 2.2 cm to the right or left of the centre of the screen. The two response keys were spatially compatible with these locations.

Trial Order The trials were batched into blocks of 120, and are described here in terms of Xs and Ys. The assignment of X and Y to right and left was counterbalanced across participants. As illustrated in Figure 1, the building blocks of the 'sequence-blocks' were four sub-sequences, each three trials long; specifically XXX, XYY, YYX and YXY. These sub-sequences conform to the rule 'if the first and second trials are the same then the third is an X, but if they differ it is a Y'. Sequence-blocks were constructed by concatenating 10 of each of these sub-sequences in a random order. Thus every third trial in a sequence-block was predictable on the basis of the previous two. Participants were not informed about the special status of third trials, and the RSI following third trials was the same as that following other trials.[4] It is also worth noting that when the properties of these sequence-blocks are considered on a trial-by-trial basis, then approximately two-thirds of the trials are consistent with the rule, and on average the four sub-sequences occur equally frequently. (This was confirmed by the Monte-Carlo method.)

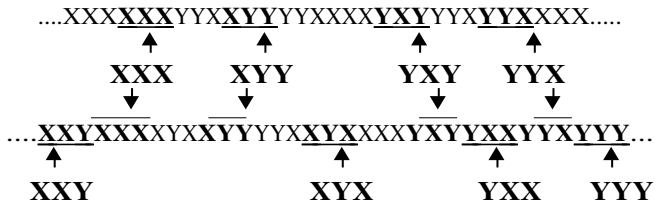

Figure 1: Examples of portions of a sequence-block (top) and a pseudo-random-block (bottom), with some of the constituent triplets highlighted.

[3] This paper will not include the simulation work presented here.

[4] The sequence-blocks were constructed so that the third trials had a special status because the original purpose of the experiment was to compare the pattern of sub-sequence learning between this incidental condition and one in which participants were told about the third trials (see Jones & McLaren, in prep.).

'Pseudo-random-blocks' comprised 5 of each of the sub-sequences (XXX, XYY, YYX and YXY) and 5 of each of the complementary triplets with alternate endings (XXY, XYX, YYY and YXX), randomly concatenated.

Design Each session comprised 20 blocks. The first 10 blocks of session one and the last 10 blocks of session five constituted the pre- and post-training 'test-phases', and were formed of pseudo-random-blocks for both groups. The 80 block 'training-phase' in between these comprised sequence-blocks for the Experimental Group and pseudo-random-blocks for the Control Group.

Procedure The procedure followed that described for the standard SRT task in the introduction, with the addition that participants were paid a performance bonus, designed to encourage them to be as fast and accurate as possible. The RSI was 500ms.

Results and Discussion

Due to space constraints, only those analyses most relevant to the subsequent modelling are reported here, but see Jones and McLaren (in prep.) for full details. Furthermore, only the RT results have been presented because the same trends were observed in the errors, ruling out speed-accuracy trade-off.

To assay sub-sequence learning, the data from the third trials of the first five blocks[5] of the post-training test-phase were divided up with respect to the identity of the previous two trials (i.e. XX, XY, YY and YX). They were then further divided on the basis of whether the third trial was consistent with the sub-sequence begun by the previous two trials (e.g. XXX) or inconsistent with it (e.g. XXY). For the Control Group consistency was a dummy variable, since they had never been trained on the sub-sequences.

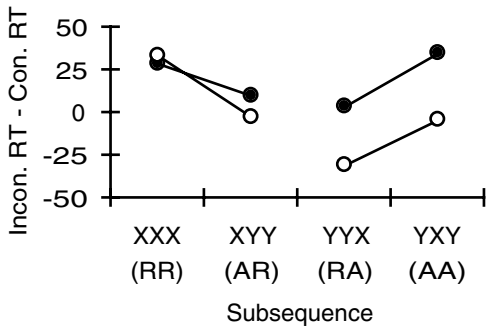

Figure 2: The mean difference scores from the third trials of the first half of the post-training test phase. Filled circles = Experimental Group. Open circles = Control Group.

A mean RT for each of the resulting eight trial types was calculated, on a per participant basis. To reduce variability, RTs were not taken from error trials or trials following an error. Then, for each sub-sequence, a difference score was constructed by subtracting the consistent RT from the inconsistent one. This measure was used because it subtracts

[5] An analysis of the learning curves suggested that extinction had set in by blocks 6-10 (see Jones & McLaren, in prep.).

out individual variability in baseline RT. The mean difference score for each sub-sequence, per group, are shown in Figure 2.

Following the convention adopted in the two-choice sequential effects literature (e.g. Soetens et al., 1985), the four sub-sequences were coded in terms of whether each trial was a repetition (R) or an alternation (A) of the previous trial (i.e. XXX=RR, XYY=AR, YYX=RA and YXY=AA). The difference scores were then analysed using an ANOVA with the factors: group (experimental vs. control), first position in the alternation-repetition sub-sequence code (A or R), and second position (A or R).

This demonstrated that the Experimental Group's difference scores were significantly larger those of the Control Group ($F(1,22)=31.77$, $p<.01$). This suggests that the participants in the Experimental Group learnt at least some of the sequential contingencies, because sequence learning should produce slower RTs on inconsistent trials and faster RTs on consistent trials, and thus a larger inconsistent minus consistent score.

The group X first-position (reading from left to right) interaction was not significant ($F<1$), nor was the group X first-position X second-position interaction ($F<1$). However, the group X second-position interaction was reliable ($F(1,22)=5.14$, $p<.05$). According to a simple effects analysis, this interaction arose because the Experimental Group's difference scores were significantly greater than Control for those sub-sequences that ended in an alternation ($F(1,22)=18.12$, $p<.01$) but not for those that ended in a repetition ($F(1,22)=0.17$, $p>.1$).

Thus it would appear that differential learning of the sub-sequences occurred, with participants only learning those sub-sequences that ended in an alternation within the time of the experiment.

Furthermore, this pattern would appear not to be contaminated by a floor effect, because if just the results from the inconsistent trials are analysed then the same trend is observed. (The expression of learning cannot be masked by RT being at floor on inconsistent trials because learning should slow responding on such trials.)

Finally, when data from all trials was included in the analysis, rather than just from the third trials, a similar pattern of sub-sequence learning was observed. Thus there was no evidence to suggest that the participants in the Experimental Group had learned about the special status of third trials (i.e. that they were always consistent during training). Rather, participants appear to have learnt the 2/3 contingencies that are present on a trial by trial basis (see method section).

In summary, in a two choice SRT task in which sequential effects are controlled for, it appears that people learn those sub-sequences that end in an alternation better than those that end in a repetition. But can the current neural network models of SRT sequence learning capture this pattern?

Modelling

To address this question, a variety of different neural network models of SRT sequence learning were presented with an exact analogue of the human task. These models all include some form of memory for previous trials. It is by associating a combination of the contents of this memory and a representation of the current trial with the identity of the next trial that they learn the sequential contingencies. As the models learn they become more accurate at predicting the next trial's identity, and consequently the mean squared error (MSE) of their prediction reduces.

Therefore, in the following simulations the MSE has been taken as an index of the models' RT to the stimulus that it is attempting to predict; the rationale being that a low MSE indicates that a model accurately expects the location of the next stimulus and so it should react more quickly to it when it occurs. While some authors transform the MSE using a decision rule or mechanism (cf. Cleeremans, 1993), this was avoided in order to prevent the properties of the models from potentially being obscured by the addition of an extra process.

In all the following simulations a localist code, with one unit for X and one for Y, was used to represent the input to the models and their predictions. The trial order was generated in exactly the same way as in the experiment, and for each type of model both an Experimental and Control Group were run. Finally, to assay sequence learning the models' MSEs from the first half of the post-training test-phase were analysed in the same way as the human data.

The different types of networks studied will now be considered in turn.

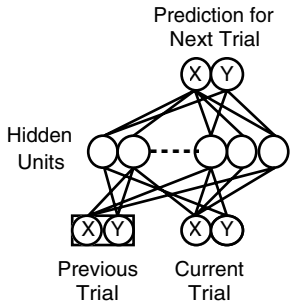

Figure 3: A buffer network.

The Buffer Network

The architecture of a buffer network is shown in Figure 3. In this model a memory is simply implemented by presenting as input to the network all the necessary elements of the sequence. Thus, the network's input comprises a representation of the current trial and a decayed (by half) representation of the previous trial. Trials prior to this are not included since the contingencies in the sequence-blocks are only depended upon the previous two trials. The architecture includes a layer of hidden units, because these enable it to learn non-linearly separable mappings (Rumelhart, Hinton & Williams, 1986), and the weights are updated using the backpropagation algorithm (Rumelhart, Hinton & Williams, 1986). For more details concerning buffer networks see Cleeremans (1993, pp. 141-143). (Note, a momentum term was not employed).

Thirty-two separate buffer networks, each with 4 hidden units, were run on an analogue of the experiment. Sixteen formed the Control Group and 16 the Experimental Group.

Each network 'subject' had a different set of randomly initialised weights. And, the learning rate was set to 0.8, since this value meant that the networks had learnt two of the four sub-sequences by the post-training test-phase, like the human participants had.

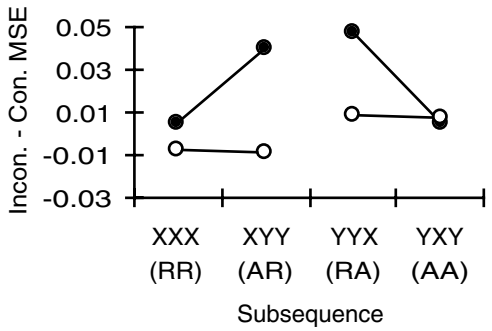

Figure 3: The Buffer networks' difference scores from the third trials of the first half of the post-training test phase. Filled circles = Experimental Group. Open circles = Control.

The mean post-training MSE difference scores are shown in Figure 3. The data were analysed using a group (2 levels) by sub-sequence (4 levels) ANOVA. This revealed that the Experimental Group's scores were significantly higher than Control ($F(1,30)=17.23$, $p<.01$), indicating that they had acquired some of the sequential contingencies. Moreover, there was evidence of differential sub-sequence learning (group X sub-sequence: epsilon corrected $F(2,57)=5.41$, $p<.05$); with a simple-effects analysis demonstrating that subjects had reliably learnt subsequences XYY/AR and YYX/RA (respectively $F(1,30)=22.05$, $p<.01$; $F(1,30)=5.84$, $p<.05$), marginally learnt XXX/RR ($F(1,30)=4.06$, $.1>p>.05$), and not learnt YYX/AA ($F(1,30)=0.24$, $p>.1$). The model made similar predictions with 20 hidden units.

However, these predictions differ from the pattern expressed by human participants (i.e. stronger learning of those sub-sequences that ended in an alternation). Therefore, the buffer network was unable to model the human data, at least with 4 or 20 hidden units.

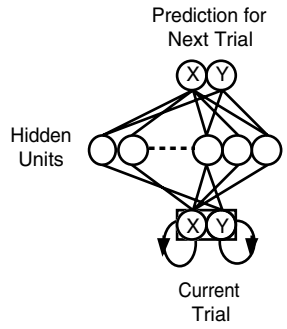

Figure 4: A Jordan network.

The Jordan Network

The architecture of a Jordan network (Jordan, 1986), modified to model the SRT task (Cleeremans, 1993, pp. 139-141), is illustrated in Figure 4. In this model the identity of previous trials are not explicitly represented on separate pools of input units. Rather, a memory of the sequence is implemented by adding to each input unit a self-recurrent connection of fixed weight, which is 0.5 in this case. As with the buffer network the variable weights are updated using the backpropagation algorithm.

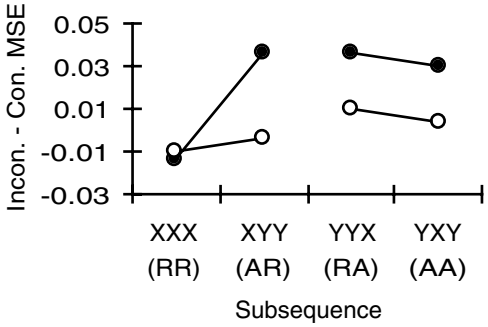

Figure 5: The Jordan networks' difference scores from the third trials of the first half of the post-training test phase.

To provide reliable results, 34 network subjects were run in both groups. Each network had 4 hidden units and a learning rate of 0.5. The results are shown in Figure 5. An ANOVA revealed reliable evidence of sequence learning ($F(1,66)=42.92$, $p<.01$) and of differential sub-sequence learning ($F(3,198)=17.28$, $p<.01$). A follow up simple-effects analysis demonstrated that the networks had learnt all the sub-sequences except XXX/RR (XXX/RR: $F(1,66)=1.47$, $p>.1$; XYY/AR: $F(1,66)=39.60$, $p<.01$; YYX/RA: $F(1,66)=20.23$, $p<.01$; YXY/AA: $F(1,66)=33.38$, $p<.01$). Therefore, with 4 hidden units, the Jordan network achieved a closer match to the human data than the buffer network, but it still was unable to capture the full detail of the pattern. When the number of hidden units was increased to 20, the networks' results were less similar to the human data.

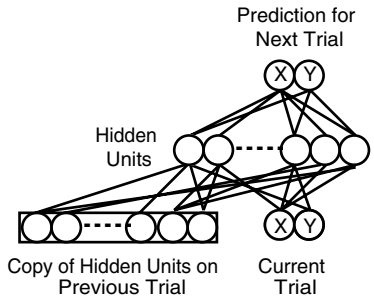

Figure 6: An SRN.

The Simple Recurrent Network (SRN)

Figure 6 illustrates the architecture of the SRN, which was developed by Elman (1990). In the SRN a memory of previous items in the sequence is implemented by providing

as additional input to the network its own hidden unit activations from the previous trial. As with the other models, the weights are updated by the backpropagation algorithm.

With 4 or 20 hidden units, and a range of large learning rates (0.5, 0.8, and 1.0), the SRN was incapable of reliably learning any of the sequential contingencies by the post-training test-phase ($p>.1$). However, when sixteen 40 hidden unit SRNs were run in each group (learning rate 0.5), an ANOVA revealed that reliable sequence learning did occur ($F(1,30)=13.41$, $p<.01$). For the means see Figure 7.

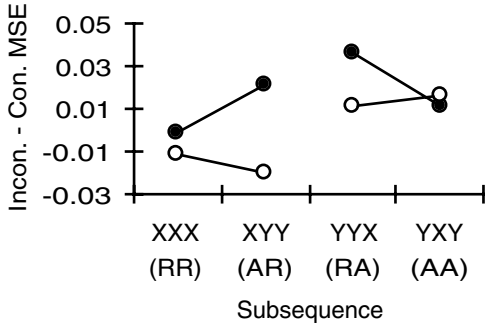

Figure 7: The SRNs' difference scores from the third trials of the first half of the post-training test phase.

Moreover, there was reliable evidence of differential sub-sequence learning ($F(3,90)=8.91$, $p<.01$), and according to a simple-effects analysis the network subjects had learnt all the sub-sequences except YXY/AA (XXX/RR: $F(1,30)=4.97$, $p<.05$; XYY/AR: $F(1,30)=13.82$, $p<.01$; YYX/RA: $F(1,30)=9.37$, $p<.01$; YXY/AA: $F(1,30)=1.59$, $p>.1$). However, this pattern deviates from the advantage for those sub-sequences that ended in an alternation seen in the experiment.

The Augmented SRN

In order to allow the SRN to capture a higher proportion of the variance in their SRT data, Cleeremans and McClelland (1991) made two modification to it, producing the Augmented SRN. First, to model the short term priming effect of previous learning episodes, weights and biases were divided into both a fast and slow component.

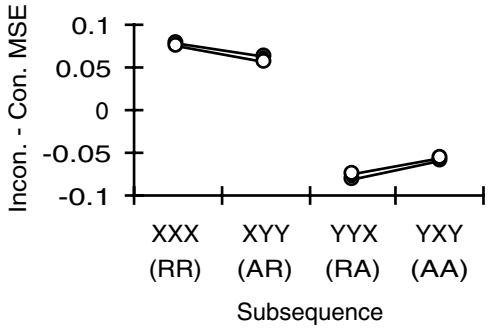

Figure 8: The Augmented SRNs' difference scores from the third trials of the first half of the post-training test phase.

Second, to capture response repetition effects the model's prediction of the next response was made dependent upon a decaying trace of previous responses as well as the SRN's output. For more details see Cleeremans and McClelland (1991).

To determine whether this model could capture the experimental results, 16 networks with 4 hidden units were run in each group. The learning rates were 1.3 and 1.0 for the fast and slow weights respectively. The other parameters were as described in Cleeremans and McClelland (1991). Given that the SRN's output activations are transformed in this model, the transformed activations were employed in the calculation of the MSE.

The results are shown Figure 8. While the trends may appear to be very small, an ANOVA did reveal that the networks had reliably learnt at least some of the contingencies ($F(1,30)=15.64$, $p<.01$) and that this learning varied across the sub-sequences ($F(3,90)=38.64$, $p<.01$). A subsequent simple-effects analysis demonstrated that XXX/RR and XYY/AR were learnt ($F(1,30)=28.17$ and 58.01, $p<.01$), while the Experimental Group's scores were significantly lower than Control for YYX/RA and YXY/AA ($F(1,30)=51.41$ and 11.63, $p<.01$). Thus the pattern of subsequence learning was the nearly opposite to that expressed by human subjects. Nor did increasing the number of hidden units to 20 substantially improve the situation.

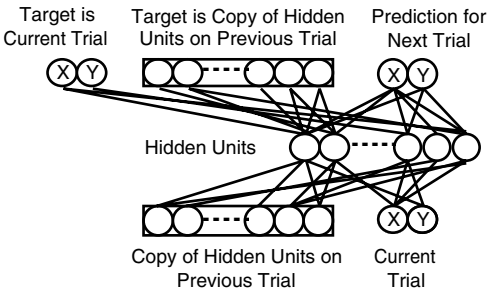

Figure 9: An AARN.

The Autoassociative Recurrent Network (AARN)

The AARN, which was developed by Maskara and Noetzel (1993), is shown in Figure 9. It differs from a standard SRN in that the network is taught not only to predict the next trial, but also to predict the pattern of activity across the input layer. This is implemented by including a extra pool of output units, with each of these units corresponding to a particular unit in the input layer. The target for one of these new output units is the activity of its corresponding input unit on the same trial.

Fifty AARNs, with four hidden units and a learning rate of 0.8, were run in each group. This large number of subjects was required to produce significant results. It is also worth noting that only the activations of the two output units that comprised the network's prediction for the next trial were included in the calculation of the MSE.

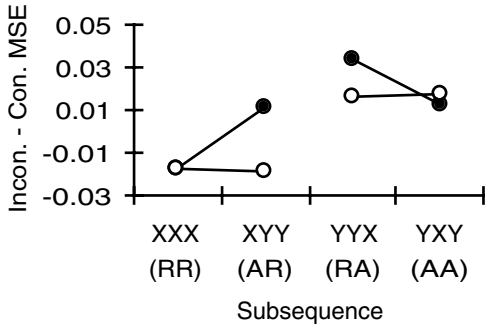

Figure 10: The AARNs' difference scores from the third trials of the first half of the post-training test phase.

The networks' mean MSE difference scores are shown in Figure 10. An ANOVA revealed that the Experimental Group had learnt at least some of the sequential contingencies ($F(1,98)=47.29$, $p<.01$) and that the sub-sequences had been learnt differentially ($F(3,294)=9.77$, $p<.01$). According to a simple effects analysis, subsequences XYY/AR and YYX/RA were learnt ($F(1,98)=39.81$ and 11.59, $p<.01$), while the remaining two were not ($F(1,98)=0.04$ and 1.37, $p>.1$). This pattern contrasted with the stronger learning of those sub-sequences that ended in an alternation observed in the human data. Furthermore, changing the number of hidden units to 20 did not improve the situation.

Dominey's Network

The ability of Dominey's (1995) model to capture the human data has also been examined. However, thus far we have been unable to find a set of parameters that enables the model to display any evidence of sequence learning on the task.

General Discussion

To summarise, previous attempts to establish a relative pattern of SRT sub-sequence learning are flawed because either they fail to control for sequential effects or do not present error data in sufficient detail. In a two-choice SRT task designed to overcome these flaws, it was found that people learn those sub-sequences that end in an alternation better than those that end in a repetition. Surprisingly, however, a buffer network, the Jordan network, the SRN, the augmented SRN and the AARN all appear unable to capture this result, at least with the parameters investigated.

A critic could argue that our human data might be beyond the scope of these models because it may reflect 'explicit' rather than 'implicit' learning. However, other work in our laboratory suggests that people show a different pattern when learning explicitly, namely they find XXX/RR the most salient sub-sequence. Therefore, it would seem that current neural network models of SRT sequence learning will probably at least need to be modified in order to accommodate the data presented here.

Abstract

This paper compares four models of the processes and representations in probability judgment. The models represent three principles that have been proposed in the literature: 1) the *representativeness heuristic* (interpreted as relative likelihood or prototype-similarity), 2) *cue-based relative frequency*, and 3) *similarity-graded probability*. An experiment examined if these models account for the probability judgments in a category learning task. The results indicated superior overall fit for similarity-graded probability throughout training. In the final block, all models except similarity-graded probability were refuted by data.

Introduction

Where do probability judgments come from? This question has been fiercely debated the last decades in research on judgment under uncertainty. In the late sixties the conclusion was that probability judgments are fairly accurate reflections of *extensional* properties of the environment such as frequencies (Peterson & Beach, 1967). This changed with the influential *heuristics and biases* program in the seventies and eighties, which emphasized that probability judgments are guided by *intensional* aspects like similarity (Kahneman, Slovic, & Tversky, 1982). The nineties saw a renewed interest in the idea that extensional properties are reflected in peoples' probability judgments as specified by the *ecological models* (Gigerenzer, Hoffrage, & Kleinbölting, 1991; Juslin, 1994). A third alternative combines intensional and extensional properties in an exemplar model to produce *similarity-graded probabilities* (Juslin & Persson, 2000).

Only rarely have these accounts been contrasted in studies that chart the processes and representations that underlie probability judgments. We compare four models of how people make probability judgments in a category learning task. The task involves assessment of the probability that a probe with feature pattern t belongs to one of two mutually exclusive categories, A or B. For example, a physician may assess the probability that a patient with symptom pattern t suffers from one of two diseases. The models represent three principles that have been proposed in the judgment literature: the *representativeness heuristic* (two versions), *cue-based relative frequency*, and *similarity-graded probability*. We present a category structure that allows us to contrast predictions derived from these hypotheses.

Representativeness Heuristic

According to the representativeness heuristic, people judge the probability that an object or event belongs to a category on the basis of the degree to which it is representative of the category, or reflects salient features of the process that generated it (Kahneman et al., 1982). The representativeness heuristic is routinely evoked post hoc to explain cognitive biases but has not been subjected to careful tests in inductive learning tasks.

A *relative-likelihood* interpretation of representativeness states that the probability judgment $p(A)$ that probe t belongs to A is made by comparing the likelihood of t in category A relative to its likelihood in categories A and B:

$$p(A) = \frac{.5d + f(t|A)}{d + f(t|A) + f(t|B)}, \qquad \text{Eq. 1}$$

where $f(t|A)$ and $f(t|B)$ are the *relative frequencies* of feature patterns identical to t in categories A and B, respectively. To allow for pre-asymptotic learning (Nosofsky, Kruschke, & McKinley, 1992) and response error in the use of the overt probability scale (Erev, Wallsten, & Budescu, 1994), all models in this paper are equipped with a free parameter d for dampening. The dampening effectively pulls the predictions towards .5 (e.g., an un-dampened prediction of 1 becomes somewhat less extreme as a result of d). Eq. 1 implies that the probability judgment that, say, a patient with symptom pattern t has disease A is a direct function of

the likelihood of these symptoms given disease *A*.[1]

A *prototype* interpretation of representativeness is that the probability judgments derive from the *similarities* $S(t|P_A)$ and $S(t|P_B)$ of *t* to the category prototypes P_A and P_B, respectively:

$$p(A) = \frac{.5d + S(t|P_A)}{d + S(t|P_A) + S(t|P_B)}, \qquad \text{Eq. 2}$$

where the similarity is computed by the multiplicative similarity rule of the context model (Medin & Schaffer, 1978),

$$S(t, y) = \prod_{j=1}^{D} d_j \ , \ d_j = \begin{cases} 1 \ if \ t_{.j} = y_{.j} \\ s \ if \ t_{.j} \neq y_{.j} \end{cases}, \qquad \text{Eq. 3}$$

where *y* is a prototype (as in Eq. 2 above) or an exemplar (as in Eq. 5 below). The value of d_j is 1 if the values on feature *j* match and *s* if they mismatch. *Similarity s* is a free parameter in the interval [0, 1] for the impact of mismatching features.

On this view, the probability judgment that a patient with symptom pattern *t* has disease *A* is a function of *t*'s similarity to the prototypical symptom pattern for disease *A*. The prototype is defined by the modal (i.e., most frequent) feature value in the category on each feature dimension. When the feature values are equally common, we selected the feature value that generated the more frequent overall pattern in the category.

Cue-Based Relative Frequency

The idea that probability judgments derive from cue-based relative frequency is represented by *Probabilistic Mental Model theory (PMM-theory;* Gigerenzer et al., 1991; see e.g., Juslin, 1994, for similar ideas). These ideas have been used to scaffold global predictions in studies of realism of confidence, but not been tested in studies of inductive learning.

In the current context, we interpret PMM-theory as suggesting that the probability judgment that probe *t* belongs to category *A* is a function of the cue value (α_1) of the single most valid cue that can be applied:

$$p(A) = \frac{.5d + F(A|\alpha_1 ***)}{d + F(A|\alpha_1 ***) + F(B|\alpha_1 ***)}, \qquad \text{Eq. 4}$$

where $F(A|\alpha_1***)$ and $F(B|\alpha_1***)$ are the *frequencies* of category *A* and *B* exemplars with cue value α_1, respectively, and the symbol "∗" denotes that the other cue values are discarded (there are four features in the experiment presented below). Eq. 3 represents the relative frequency of category *A* conditional on presence of cue value α_1. Thus, a subjective probability judgment is a reflection of the validity of the cue with the highest cue-validity that is present in the event or object being judged. This strategy is known as *Take The Best* (TTB) meaning that you rely on the cue with the highest validity (Gigerenzer, Todd, & the ABC Group, 1999).

Similarity-Graded Probability

A class of models that combines intensional and extensional aspects is exemplar models in categorization research. In exemplar models, decisions are made by comparing new objects with exemplars stored in memory. The *context model* (Medin & Schaffer, 1978) responds to both similarity (intensional property) and frequency (extensional property) in general, and to only one of these factors in predictable circumstances (Juslin & Persson, 2000). PROBEX (i.e., PROBabilities from EXemplars; Juslin & Persson, 2000) is a model of probability judgment based on the context model.

With PROBEX, probability judgments are made by comparisons between the probe *t* and retrieved exemplars x_i (i = 1…I). The exemplars are represented as vectors of *D* features (in the present experiment, *D*=4 and the features are binary). Continuing with the example of medical diagnosis, a patient with symptom pattern *t* leads to retrieval of stored exemplars of previous patients with similar symptoms and their diagnoses. The probability judgment is a weighted average of the outcome indices $c(x_i)$ for the exemplars, where $c(x_i)$=1 for exemplars in category *A* and $c(x_i)$=0 for exemplars in category *B*. The weights in the average are the respective probe-exemplar similarities $S(t|x_i)$:

$$p(A) = \frac{.5d + \sum_I S(t|x_i)c(x_i)}{d + \sum_I S(t|x_i)}, \qquad \text{Eq. 5}$$

where similarity is computed from Eq. 3. This hypothesis implies that if a new patient with symptom pattern *t* is similar to many exemplars x_i with diagnosis *A*, the probability that the new patient has disease *A* is high.

The complete version of PROBEX involves a sequential sampling of exemplars, but this aspect is ignored in the present application. This effectively reduces Eq. 5 to the original context model (Medin & Schaffer, 1978) with a dampening (see Nosofsky et al., 1992, for a similar formulation), but with one crucial difference: $p(A)$ does not refer to a predicted proportion of category *A* classifications, but to a prediction of a probability judgment.

With similarity parameter *s*=0, only exemplars with feature patterns identical to *t* affect the judgment and Eq. 5 emulates a "*picky frequentist*" (Juslin & Persson, 2000).[2] Ignoring the dampening *d*, Eq. 5 then computes

[1] "Direct function" means that the predicted probability judgments are a function of likelihoods alone, not likelihoods *and* prior probabilities, as implied by Bayes' theorem.

[2] This version of Eq. 5 is formally identical to Bayesian estimation of a probability with the Beta-distribution and parameters α and β equal to $.5d$.

the relative frequency of category *A* among exemplars with identical features. For $s>0$, Eq. 5 computes a *similarity-graded probability* that is both affected by the frequency of exemplars, and the probe-exemplar similarities. Note that, although PROBEX responds to similarity, it is not identical to the representativeness heuristic. For example, PROBEX (Eq. 5) cannot produce a conjunction fallacy, unless amended with auxiliary assumptions of some sort (Juslin & Persson, 2000). PROBEX has been fitted to people's probability judgments in a general knowledge task (Juslin & Persson, 2000) but not been tested in inductive learning tasks.

Category Structure and Predictions

The problem with contrasting these three hypotheses is that in most category structures, they generate highly correlated predictions. Table 1, however, provides one category structure that implies qualitatively distinct predictions for certain critical exemplars (Figure 1).

Table 1: The categories with the 20 x 3 exemplars.

X	C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}	C_{12}	Category		
1	1	1	1	1	3	3	3	3	5	5	5	5	A	A	A
2	1	1	1	1	3	3	3	3	5	5	5	5	A	A	A
3	1	1	1	1	3	3	3	3	5	5	5	5	A	A	A
4	1	1	1	1	3	3	3	3	5	5	5	5	A	A	B
5	1	1	1	1	3	3	3	3	5	5	5	5	A	B	B
6	1	0	0	0	3	2	2	2	5	5	5	4	A	A	A
7	1	0	0	0	3	2	2	2	4	4	4	4	A	A	B
8	1	0	0	0	3	2	2	2	4	5	4	4	A	A	B
9	0	0	0	0	3	2	2	2	4	4	4	4	A	A	B
10	0	0	0	0	3	2	2	2	4	5	4	4	A	A	B
11	1	1	0	0	3	2	2	2	4	4	4	4	B	A	B
12	1	1	0	0	3	2	2	2	4	4	5	4	B	A	B
13	0	1	0	0	3	2	2	2	4	4	4	4	B	A	B
14	0	1	0	0	3	2	2	2	4	4	5	4	B	A	B
15	0	1	0	0	3	2	2	2	4	4	4	4	B	A	B
16	0	0	1	1	3	2	2	2	4	4	4	5	B	A	B
17	0	0	1	1	3	2	2	2	4	4	4	4	B	A	B
18	0	0	1	1	2	3	3	3	4	4	4	4	B	B	B
19	0	0	1	1	2	3	3	3	4	4	4	4	B	B	B
20	0	0	1	1	2	3	3	3	4	4	4	4	B	B	B

The design involves 60 exemplars with four features each, organized into three substructures. The 20 exemplars in the first substructure have features C_1-C_4, the 20 in the second substructure have features C_5-C_8 and the last 20 have features C_9-C_{12}. The feature has two possible values (0 vs. 1, for C_1-C_4; 2 vs. 3 for C_5-C_8; 4 vs. 5 for C_9-C_{12}). The last three columns headed by "Category" specify whether the exemplar is in category *A* or *B*. The first column is for exemplars with features C_1-C_4, the second for exemplars with features C_5-C_8, and the third for exemplars with features C_9-C_{12}.

In the first part of the experiment, the 60 exemplars are presented with feedback about whether they belong to category *A* or *B*. In the second part, the participants are asked to estimate the probability that probes with certain feature patterns belong to category *A*. There are *fifteen distinctive feature patterns*, six for features C_1-C_4, three for features C_5-C_8, and six for features C_9-C_{12}. The participants estimate the probability of category *A* for all fifteen patterns. The critical patterns are 1111 for features C_1-C_4, 3333 for C_5-C_8 and 5555 for C_9-C_{12}. Across these, the models provide distinctly different predictions (see Figure 1).

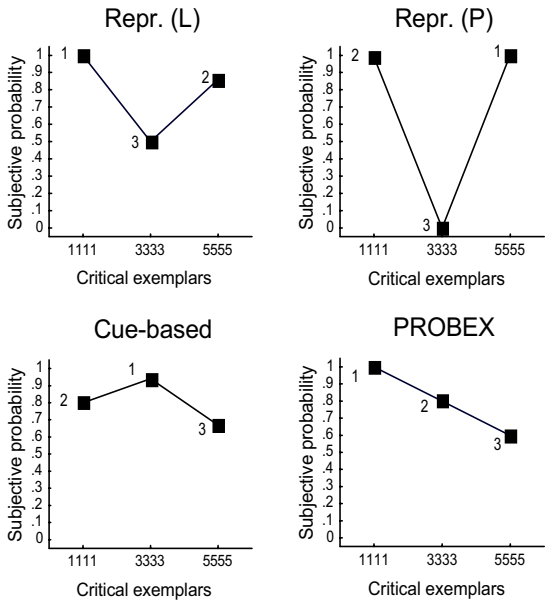

Figure 1: Predicted probability judgments. All predictions are derived with d=0. The predictions for representativeness with prototype similarity (P) are based on s=.1. The predictions for PROBEX are based s=0 (i.e., Picky frequentist).

For example, the predictions for feature pattern 3333 are derived as follows. The representativeness heuristic with a likelihood interpretation implies $p(A)$ = .25/(.25+.25) = .5: the probe is identical to 25% of the exemplars in category *A* and 25% of the exemplars in category *B*. In regard to a representativeness heuristic with prototype similarity, we note that the prototypes for category *A* and *B* in the second substructure (i.e., based on C_5-C_8) are 3222 and 2333, respectively. Ignoring the dampening *d*, Equation 2 implies the prediction $s^3/(s^3+s)$. The prototype for *A* differs on three features and the prototype for *B* on one feature. The prediction depends on the parameter *s*, but it will generally be low and always lower than .5. With cue-based relative frequency, $p(A)$ = 16/(16+1) = .94. Given the value of 3 for the most valid cue C_5, 16 of 17 exemplars belong to category *A*. According to the picky frequentist prediction by PROBEX (s=0), $p(A)$ = 4/5 = .8. Four out of five exemplars with identical feature patterns belong to

category *A*. At *s*>0, the prediction falls below .8. Predictions for the other two critical patterns are derived in the same way.

Note in Figure 1 that, depending on the model, the probability judgments for the three critical patterns have a different *rank order.* These predicted rank orders are *a priori* and not dependent on the parameters (i.e., *s* or *d*). By comparing the observed with the predicted rank order, we get a qualitative test of the models. In addition, we can evaluate the quantitative fit of the models to the judgments for all 15 feature patterns.

Method

Participants

Twenty-four undergraduate students (10 men and 14 women) in the age of 19 to 32 (average age = 23.3) participated. The participants where paid between 65-86 SEK depending on their performance. They received 30 SEK plus 1 SEK for each correct answer in the last learning block.

Apparatus and Materials

The experiment was carried out on a PC–compatible computer. In each of the four training blocks, the program first presented the 60 exemplars from Table 1. The task involved judgments for 60 companies, where 20 companies belonged to each of three countries (substructures). Each exemplar had four features that differed depending on the country. The features are presented in Table 2. The features and names of the countries were chosen to be as neutral as possible. In the test phase after each training block, the program presented each of the 15 distinct feature patterns twice.

Design and Procedure

A two-way within-subjects design was used. The independent variables were the number of training blocks (four blocks) and category substructure (three substructures). The dependent variable was the probability judgments. The specific assignment of concrete cue labels (see Table 2) to the abstract category structure (see Table 1) was varied and counterbalanced across the participants. Thus, each concrete label in Table 2 appeared equally often in each of the three substructures and equally often in the role of each of the abstract features denoted C_1 to C_{12} in Table 1.

The participants were to act as stockbrokers assigned to invest a large sum of money in three countries about which they knew nothing. They were told that it is usually enough to know four company features to know if the stock will rise or fall in the next twelve-months, but that the features differ between the countries.

Table 2: Twelve concrete features used in the experiment.

Features	Descriptions
1) Listed at the LAP / IPEK stock exchange?	
2) Less / more than 1000 employees?	
3) Commercials on television / the radio?	
4) Changed owner / merged in last three years?	
5) Less than / more than three years old?	
6) Give money to charity / sponsor sports team?	
7) Active in specific region / whole country?	
8) Co-operation with university / own research department?	
9) In state-financed SKATOS / TAPOS program?	
10) Primarily export-based / import-based?	
11) Affirmative action based on gender / ethnic background?	
12) Stock risen / fallen during the last 12-month?	

The participants were told that the first phase is a training session where they are presented with 60 companies, each described by four features that depend on the country. The features describe the companies as they were twelve months ago. They were to guess whether the stocks rose (*A*) or fell (*B*) in value in the last year. After each judgment, they received feedback on the actual development. The four features were presented on the screen. Below the question "Will the stock-value rise or fall during the next twelve month?" appeared. The participant answered s (short for the Swedish word for rise) or f (short for the Swedish word for fall). Thereafter, the correct answer appeared together with the company's four features.

In the test phase, the participants were told that they were to see a set of companies as they are today and judge the probability of an increase in their stock-value and that the markets are identical on all parameters today as they were one year ago. The feature patterns were presented in the same way as in the training phase, but with the question: "What is the probability that the stock of this company increases in value in the next 12 months?" They were told to answer in percentages and even up to 0, 10…100.

The test blocks consisted of two assessments of the 15 distinct feature patterns, one for rising stock-value (*A*) and one for falling stock-value (*B*). This allowed us to examine the additivity of the probability judgments (i.e., if the mean probability assigned to *A* and *B* for a feature pattern sum to 1). To get reliable data we recoded probability-*B* judgments into probability-*A* judgments by subtracting the probability-*B* judgments from 1. There was no feedback. The order of the probability judgments was counterbalanced within participants. The training and test blocks were repeated four times. The entire procedure took between one hour and fifteen minutes to two hours.

Results

Figure 2 presents mean probability judgments for the critical feature patterns in each of the four test blocks. The data for the third block shows a tendency to agree with the prediction by PROBEX. The fourth block exhibits clear agreement with the prediction by PROBEX. The confidence intervals for exemplars, 1111 and 5555 are clearly separated and the predicted decreasing trend is observed which refute all models except PROBEX.

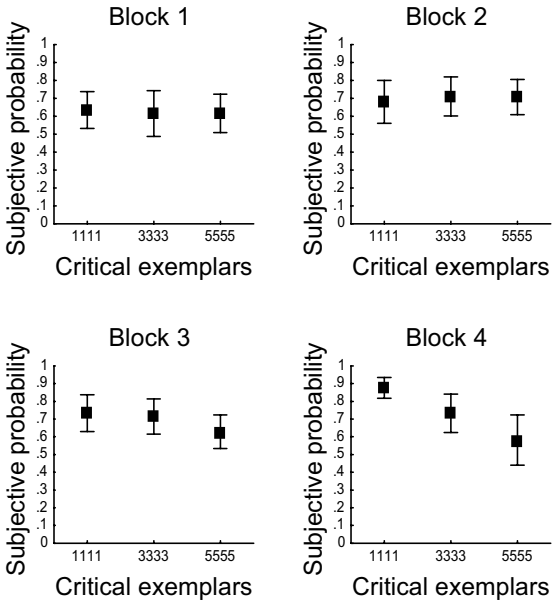

Figure 2: Means with 95% confidence intervals for the estimations of the critical exemplars for the four test blocks.

For the first two blocks, the data reveal no clear trend favoring any of the four models. One tentative interpretation of this result is that it reflects a mix of individual strategies in the early stages of training. To explore this more carefully, we fitted the four models to the data from all 15 distinct feature patterns. The probability judgments proved to be additive on average (i.e., the mean probability assigned to *A* and *B* for a feature pattern sum to 1).

The models were fitted to the mean probability judgments for each of the 15 distinct feature patterns with Root Mean Square Deviation (RMSD) as error function. This was done separately for each of the four test blocks. The model based on the representativeness heuristic as relative likelihood has one free parameter (*d*), representativeness heuristic as prototype similarity has two free parameters (*s* & *d*), cue-based relative frequency has one free parameter (*d*), and exemplar-based retrieval (PROBEX) has two free parameters (*s* & *d*). The results are summarized in Table 3.

Table 3 verifies that in the later stages of training, PROBEX provides a good fit to the data. Because the standard error of measurement is .05, the RMSDs for PROBEX (.054 & .058) come close to saturating the data. Considering all four blocks it is clear that cue-based relative frequency fits the judgments poorly in all blocks. Although the qualitative pattern in Figure 1 for blocks 1 and 2 does not accord with PROBEX, we find that it is the best fitting model throughout training. The models based on the representativeness heuristic exhibit moderate fit early in training, which successively deteriorates with training.

Table 3: Fit of the models as a function of test block in terms of RMSD and coefficients of determination r^2.

		Test Block			
Model	Index	1	2	3	4
Repr. (L)	RMSD	.087	.111	.105	.124
	r^2	.65	.69	.70	.73
Repr. (P)	RMSD	.094	.123	.124	.158
	r^2	.61	.62	.58	.55
Cue-based	RMSD	.139	.193	.188	.234
	r^2	.20	.21	.23	.22
PROBEX	RMSD	.060	.067	.054	.058
	r^2	.87	.92	.92	.95

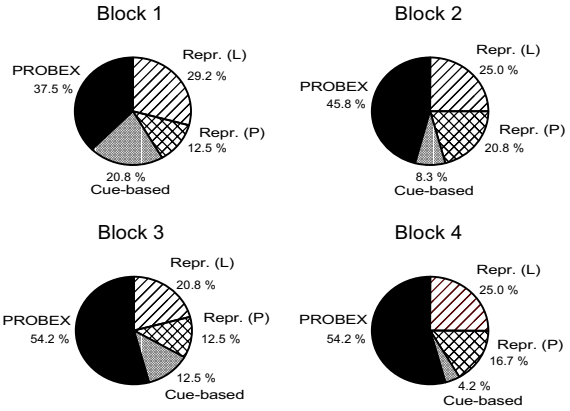

Figure 3: The percent of participants best described by each of the four models, in each of the four test blocks.

Finally, these conclusions were verified at the level of individual participants. The same model-fitting procedure was performed for each participant, with the exception that all models were fitted with one free parameter (*d*). In each block, the percentage of participants for which each model provided the best fit was ascertained. Figure 3 shows that PROBEX is the most frequent winner, although a minority of participants is

better fitted by representativeness as relative likelihood, mostly in the early test blocks.

Discussion

Research on subjective probability judgment has been characterized by a normative stance, where judgments are compared to norms from probability theory. Cognitive theory has primarily been evoked to provide post hoc explanations, as in most applications of the representativeness heuristic, or as scaffolds for more general predictions, as in the applications of cue-based relative frequency. The point of departure for our research is the need to make closer contact between cognitive theory and judgment research in controlled studies that allow us to support or refute core concepts in judgment research, such as the representativeness heuristic.

The results reported here provide clear support for the hypothesis of similarity-graded probability (Juslin & Persson, 2000). That an exemplar model is successful may not appear surprising considering the impressive performance of exemplar models in categorization studies (Nosofsky & Johansen, 2000). Yet, the results are at variance with crucial ideas in judgment research, like that of a representativeness heuristic (Kahneman et al., 1982) or cue-based relative frequency (Gigerenzer et al., 1991; Juslin, 1994).

The second to best fitting model was representativeness as relative likelihood, but this may be spurious as, the crucial feature patterns in Figure 1 aside, the predictions by the models tend to be correlated. However, the superiority of PROBEX is not a mere consequence of a greater inherent flexibility. To demonstrate this, we used the predictions for the last test block by representativeness as relative likelihood as fictive "true data" and added a normally distributed random error with a standard deviation of .05 to mimic measurement error. To this fictive data set, representativeness provided a superior fit (RMSD=.053, r^2=.97) as compared to PROBEX (RMSD=.096, r^2= .83). Thus, the better fit of PROBEX appears to reflect more than larger flexibility in the face of random error.

The best-fitting version of PROBEX (s=.21) in the last test block is not the Picky frequentist version identical to Bayesian estimation of the probability with a Beta-distribution (see Footnote 2). This suggests that, at least in regard to this more simplistic implementation of a Bayesian algorithm, PROBEX provides a better fit to data.

The main objection against the present study is perhaps that it is a single study involving one specific category structure. The category structure used here was guided by the aim of allowing qualitatively distinct predictions by the four models. This category structure may accidentally favor one model over another. Perhaps, a category structure more coherently organized around prototypes yields more support for representativeness as prototype similarity? Likewise, a more feature-rich category structure that posits more demand on information search may yield more support for cue-based relative frequency in the form of TTB (Gigerenzer et al., 1999). Only further research can tell. In any event, these hypotheses will have to count with a serious contestant in the form of PROBEX.

Abstract

Several studies have shown that similarity judgements involve a process of structural alignment akin to analogical mapping. Some research has shown that performing a similarity judgement task produces more relational responding in a subsequent cross-mapping task, suggesting that similarity necessarily uses structural alignment. However, other research has shown that this effect disappears when procedural/material manipulations fail to emphasise the relational aspects of similar scenes. The present study confirms the latter findings showing that if relational similarities are less prominent in a material set then subjects respond in an object-based rather than a relational way. Importantly, these results show that similarity processing does not by necessity make use of structural alignment but that the similarity processing adopted is pluralistic and depends on properties of the presented materials.

Introduction

A considerable body of recent research has shown that similarity comparisons can involve a process of structural alignment (see e.g., Goldstone, 1994; Goldstone & Medin, 1994; Goldstone, Medin & Gentner, 1991; Markman & Gentner 1993a, 1993b, 1997; Medin, Goldstone & Gentner, 1993). Representationally, this view characterises knowledge as structured hierarchies encoding objects, object attributes, relations between objects and relations between relations. Given these representations it is assumed that similarity comparisons involve the alignment of relational structure to find the most structurally consistent match between two systems of concepts, that satisfies the constraints of parallel connectivity (if two relations match, their arguments must match) and one-to-one mapping (that each item in one structure may only be mapped to one other item). Computationally, these ideas have been realised by a family of models that simulate analogical mapping (see e.g., Falkenhainer, Forbus & Gentner, 1989; Gentner, 1983, 1989; Holyoak & Thagard, 1989; Hummel & Holyoak, 1997; Keane, 1988, 1997; Keane & Brayshaw, 1988; Keane, Ledgeway & Duff, 1994; Veale & Keane, 1994, 1997, 1998). Indeed, structural alignment has been mooted as a unified account of a diverse range of phenomena including similarity, analogy, metaphor and concept combination (see Costello & Keane, 2000; Gentner, Holyoak & Kokinov, 2001; Keane & Costello, 2001).

Markman & Gentner (1993b) provided one of the key pieces of evidence supporting the role of structural alignment in similarity judgements. They used a one-shot mapping task in which subjects had to identify a cross-mapped object between two drawn scenes (see Appendix A). A cross-mapped object was defined as an object in one drawing that was perceptually similar to an object in a different relational role in the other drawing. So, for example, in the baseball scenes shown in Appendix A, the cross-mapped object would be the pitcher with the "C" on his uniform, because he is pitching in the upper scene and being pitched to in the other scene. Markman & Gentner have proposed that structural alignment is reflected in this task when subjects make relational responses (i.e., choosing the object in the same role) as opposed to object responses based on perceptual, feature similarity (i.e., choosing the perceptually similar object in a different role). The key manipulation asked participants to perform a similarity judgement task on the picture-pairs either before or after the mapping task. They found that

when participants made the similarity judgement *before* the mapping task they made more relational responses than when it was presented *after* the mapping task. Thus, the result strongly suggested that the similarity judgement task invoked a structural alignment process which then carried over to the mapping task increasing the proportion of relational responses (significantly, when an aesthetic-appreciation task was given before the mapping task no facilitation in relational responding was found).

Davenport & Keane (1999) queried these findings by pointing out that the materials and presentational procedure used may have contained unintended cues to promote relational responding. First, some of Markman & Gentner's materials had linguistic labels indicating the key relational similarity between the pictures (see e.g., the baseball pair in which "Pitch" is written). Second, the presentational procedure may have supported relational responding in that the all 8 stimuli presented were picture pairs with prominent relational similarities. Davenport & Keane found that when the linguistic cues were removed from the materials and the materials were mixed with fillers (involving simply object similarities) the similarity-judgement effect disappeared; that is, relational responding did not increase reliably when the similarity judgement task was made *before*, rather than *after* the mapping task. Significantly, Davenport & Keane also found that when the relational materials were blocked as a group and presented before the fillers there was increased relational responding relative to a condition in which the relational materials were randomly distributed among fillers in their order of presentation. This blocked-condition mimicked the presentational procedure used by Markman & Gentner. No reliable interaction was found between the ordering of the similarity judgement task (before or after mapping task) and the materials-order variable (blocked before or distributed among fillers). Hackett (2000) has subsequently replicated this materials order effect.

This pattern of results demands a very different account of similarity and mapping to that proposed by Markman & Gentner. First, it is no longer safe to assume that structural alignment is used in similarity judgements, as a matter of course, because relational responding does not follow prior similarity judgements. Second, it appears that relational responding is mainly dependent on the materials used and how they are presented. Specifically, the pattern of responding in the mapping task suggests that the *prominence of relational similarities* in the materials is the key variable affecting relational responding. This proposal best explains the evidence found:

- when linguistic cues are present that highlight key relational similarities then relational responding is seen (as in Markman & Gentner's original materials)
- when several materials are consecutively presented with relational similarities then relational responding results (as in Markman & Gentner's study and Davenport & Keane's blocked condition)
- when materials with clear object similarities are mixed up with these relational materials then relational responding decreases (as in Davenport & Keane's distributed condition)

So, structural alignment is really only used when the prominence of relational similarities in the materials appear to demand it, perhaps with the default style being processing based on attribute similarities.

If this account is true then any manipulation that reduces the prominence of relational similarities in the materials should reduce relational responding. For instance, if we take the materials that have previously produced relational responding and add in additional object similarities then, on balance, the relational similarities should be less prominent. Hence, we should see reduced relational responding for these modified materials. For example, consider picture-pair A in Appendix II; the top picture shows a woman kicking a football with goal posts and a sun behind her and the bottom picture shows her being kicked by a child with some blocks and a clock in the background. This picture pair is quite sparse, a sparseness that lends a greater prominence to the kicking relation shown. Compare picture-pair A with picture-pair B in Appendix II; the latter also shows two kicking episodes but the scenes are much richer with more similar objects in the top and bottom pictures (houses, the sun, goal posts, etc). Although, both picture pairs have the same kicking incident, the greater frequency of object similarities in the richer pair should, if our hypothesis is correct, reduce the occurrence of relational responding relative to the sparser pair.

The present study examines this sparse versus rich manipulation, where the richer pairs were essentially the same scenes with added matching objects. We also attempted a further replication of the similarity-judgement effect by giving different groups a similarity judgement task either before or after the mapping task. As such, we had a 2 x 2 between-subject design where the variables were task-order (similarity task before or after mapping task) and material-type (sparse or rich materials). Following Davenport & Keane, all conditions presented the materials in a distributed fashion with the target materials being randomly distributed with fillers. We made two predictions in the study. First, that the similarity judgement task would have no effect on relational responding, confirming Davenport & Keane's finding. Second, that the sparse materials would produce more relational responding than the rich materials, as the prominence of the relational

similarities is reduced in the latter by the greater frequency of object similarities.

Method

Subjects. Forty-eight undergraduate students at University College Dublin took part voluntarily in the experiment and were randomly assigned to one of the four between-subjects conditions.

Stimuli. The stimuli for this experiment consisted of 8 pairs of pictures depicting causal scenes with matching relational structure and 16 filler pairs. Each of these 8 pairs contained a cross-mapping as operationalized by Markman and Gentner (1993b) in which a pair of perceptually-similar objects were shown which played different roles in the matching relational structure of the two scenes (see Appendix B for an example). In all four conditions, the 8 relational pictures were designed so that the perceptually-similar target object was in approximately the same spatial position in the picture pairs (e.g., the woman in the soccer materials is in the same central position in both pictures). Two versions of the relational materials were prepared. The rich set was created by adding similar objects to both scenes of the original sparse pictures used by Davenport & Keane (see Appendix II for an example). In all other respects, the picture-pairs were the same (e.g., in the placing of the arrow indicating the to-be-mapped object).

Eight of the filler pairs depicted comparable scenarios without matching relational structure (e.g. two beach scenes, one with a man surfing another with a child is building a sand castle) and the other 8 pairs did not match in either scenario or relational structure (e.g. a scene of an artist and a scene of a man in a grocery store). The fillers were the same as those used by Davenport & Keane.

The stimuli were presented in booklet form with one pair on each page (one picture above the other). The stimuli for the mapping task had an arrow placed above an object in the top scene. For the 8 target pairs this was the cross-mapped object, otherwise it was an object which appeared in both scenes. The stimuli used for the similarity rating task had a scale with the numbers 1 through 9 at the bottom of the page. The words Low Similarity appeared under the 1 and the words High Similarity appeared under the 9.

Booklets in the all conditions had a completely randomised presentation of the 24 pairs for both the mapping and the similarity tasks.

Procedure. As in Gentner & Markman's study, the first page of the mapping section of the booklet instructed subjects to draw a line from the object under the arrow to the object in the bottom scene that "best went with that object". The first page of the similarity judgement section instructed subjects to rate the similarity of the two scenes by circling a number on the scale at the bottom of the page.

Subjects in the similarity-after conditions received a booklet with the mapping task followed by the similarity judgement task while subjects in the similarity-before condition received a booklet with the similarity judgement task first.

Subjects were tested in small groups of varying sizes and each experimental session took between 10 and 15 minutes.

Scoring. As in Gentner & Markman's study, participants' responses to the 8 target pairs in the mapping task were determined as an *object mapping* if a line was drawn from the cross-mapped object to a featurally-similar object in the bottom scene; a *relational mapping*, if a line was drawn to the object in the same relational role in the bottom scene; or a *spurious mapping* if a line was drawn to another, unrelated object. As in previous studies, spurious responses were removed prior to data analysis (5% of all responses made).

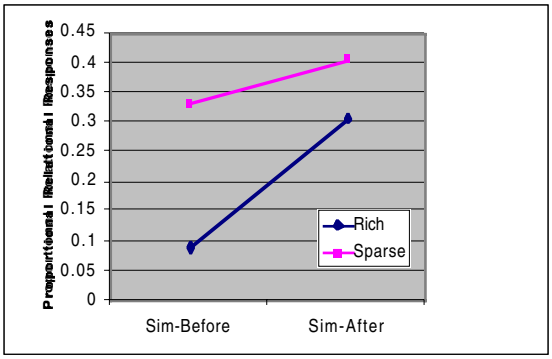

Figure 1: The Mean Proportion of Relational Responses in the Conditions of the Study

Results & Discussion

A two-way, between-subjects ANOVA found a reliable effect of material-type with a higher proportion of relational responding in the sparse conditions (M = .37) than in the rich conditions (M=0.19), though this difference is marginally reliable, $F(1,44) = 3.538$, p=.06, $MSError = 0.079$ (see Figure 1). Again, contrary to Markman and Gentner's predictions, no reliable effect was found for the task-order variable, $F(1,44) = 2.279$, $p > .10$. Indeed, the direction of the difference is in the opposite direction to that predicted; *less* relational responding occurs when the similarity judgement task is *before* as opposed to *after* the mapping task. Finally, there was no reliable interaction between task-order and material-type, $F(1,44) = 0.804$, $p > .10$.

General Discussion

There are two significant findings in this study. First, it replicates Davenport & Keane's finding that

relational responding is not influenced by a prior similarity judgement task; leaving open the question of whether similarity judgement involves structural alignment. Indeed, if we adopt the argument made by Markman & Gentner, we would be bound to conclude that structural alignment does not necessarily occur in similarity judgements. Second, and perhaps more surprisingly, it shows that structural alignment does not necessarily occur in the mapping task either. Rather, it appears that people sometimes respond on the basis of relational similarities and other times respond on the basis of object similarities. Furthermore, the key factor determining the mode of response lies in the nature of the materials themselves. When relational similarities are prominent in the given materials or across a set of consecutive materials then relational responding will result, but when these relational similarities are counter balanced by more object similarities in a given material or across a set of consecutive materials then object-based responding results.

Computationally, these findings present a number of challenges for models of similarity and analogy. They suggest that there are two distinct modes of processing for similarity judgement and mapping tasks. In one mode, relational correspondences are mainly used; this could be achieved by only computing relational matches (e.g., a type of selective attention to relations) or by computing both object and relational matches and then subsequently giving a greater weight to relational similarities. In the other mode, object attributes are mainly used: this could be achieved by only computing attribute matches (e.g., a type of selective attention to object features) or by computing both object and relational matches and then subsequently giving a greater weight to object similarities. Where you have two modes of processing there has to be a trigger for switching processing from one mode to the other. The empirical evidence suggests that this trigger is sensitive to the relative frequency of relational versus attribute similarities present in a stimulus pair and a set of stimulus pairs.

Do any current models have these sort of properties ? Goldstone's (1994) interactive activation model gave a greater weight to attribute matches during early stages of processing with relational matches emerging later on; this model deals with the finding that under time pressures people rely more on attribute similarity (Medin & Goldstone, 1994). However, it is not immediately clear whether it would predict less relational responding in the rich versus the sparse materials. Furthermore, this model would need to have a history of previous similarity judgements to model the effects of consecutive relational materials. Another model, the MAX model (Goldstone, Medin & Gentner, 1991) pools relational and attribute similarities separately, with relational or attribute responses being chosen based on the relative sizes of the two pools of similarities. This model might be able to deal with the relational prominence effect, as the rich materials might have a larger pool of attribute similarities relative to the sparse materials, leading to an object-based response. However, the MAX model does not have an account of the effects of consecutive materials as, again, it holds no history of previous similarity episodes. In short, no current model seems to be able to handle this evidence.

The current results leave open the question of whether similarities are selectively attended to with only a subset of all possible similarities being computed or whether all similarities are computed and then evaluated to decide on what response mode should be adopted. This is a key question to be settled by future empirical work. They also leave open the question of which mode of processing is the default mode or, in indeed, if there is a default mode. Attribute similarities seem to be computed more efficiently and easily (Goldstone & Medin, 1994). This mode of processing also has a laziness that is characteristic of human cognitive processing, when one considers people's mental sloth in making elaborative, bridging relational inferences.

However, there is one conclusion that is unavoidable given the current results: Namely, that comparison processes -– whether they be similarity or analogical processes – are pluralistic rather than monolitic (see Medin, Goldstone & Gentner, 1994; Keane & Costello, 2001). This conclusion should shift the focus of research to the key issue of what variables influence the mode of processing adopted in this pluralistic computational environment.

Abstract

Binding theory is the component of grammar that regulates the interpretation of noun phrases. Certain syntactic configurations involving picture noun phrases (PNPs) are problematic for the standard formulation of binding theory, which has prompted competing proposals for revisions of the theory. Some authors have proposed an account based on structural constraints, while others have argued that anaphors in PNPs are exempt from binding theory, but subject to pragmatic restrictions. In this paper, we present an experimental study that aims to resolve this dispute. The results show that structural factors govern the binding possibilities in PNPs, while pragmatic factors play only a limited role. However, the structural factors identified differ from the ones standardly assumed.

Introduction

Linguistic Intuitions The data on which linguists base their theories typically consist of grammaticality judgments, i.e., intuitive judgments of the well-formedness of utterances in a given language. When a linguist obtains a grammaticality judgment, he or she performs a small experiment on a native speaker; the resulting data are behavioral data in the same way as other measurements of linguistic performance (e.g., the reaction time data used in psycholinguistics). However, in contrast to experimental psychologists, linguists are generally not concerned with methodological issues, and typically none of the standard experimental controls are imposed in collecting data for linguistic theory. As Schütze's (1996) recent work on empirical issues in linguistics demonstrates, such methodological negligence can seriously compromise the data obtained. Schütze (1996) argues for a more reliable mode of data elicitation in linguistics, based on standard methods from experimental psychology.

Recently, Bard, Robertson, and Sorace (1996) and Cowart (1997) demonstrated how the experimental paradigm of magnitude estimation (ME) makes it possible to address problems such as the ones raised by Schütze. ME is an experimental technique standardly used in psychophysics to measure judgments of sensory stimuli (Stevens, 1975). It requires subjects to estimate the magnitude of physical stimuli by assigning numerical values proportional to the stimulus magnitude they perceive. Highly stable judgments can be achieved for a whole range of sensory modalities, such as brightness, loudness, or tactile stimulation. Bard et al. (1996) demonstrated that linguistic judgments can be elicited in the same way as judgments of sensory stimuli, and that ME can yield reliable and fine-grained measurements of linguistic intuitions.

The present paper applies the ME methodology to a longstanding dispute in linguistic theory, viz., the binding theoretic status of picture noun phrases (PNPs). Binding in PNPs has generated considerable interest in the literature, and has prompted a number of revisions of standard binding theory. However, there is considerable disagreement on both the relevant data (i.e., coreference judgments for PNPs) and on the theoretical conclusions to be drawn from these data. In this paper, we demonstrate how the use of experimentally elicited coreference judgments can resolve such theoretical disputes.

Binding Theory and Exempt Anaphors Binding theory (BT) is the component of grammar that regulates the interpretation of noun phrases (NPs). Three types of noun phrases are generally distinguished: (a) full NPs (e.g., *Hanna*, *the woman*, *every woman*), (b) pronouns (e.g., *he*, *her*), and (c) anaphors (e.g., *herself*, *each other*). The task of BT is to determine which noun phrases in a given syntactic domain can be *coreferential*, i.e., refer to the same individual. Coreference is normally indicated with subscripts:

(1) a. Hanna$_i$ admires *her$_i$/herself$_i$.
b. Hanna$_i$ thinks that Peter admires her$_i$/*herself$_i$.

In example (1a), the proper name *Hanna* and the pronoun *her* cannot refer to the same person, i.e., they cannot be coreferential (as indicated by the '*'). The pronoun cannot be *bound* by the proper name. In (1b), on the other hand, *Hanna* is a potential binder for *her*, i.e., coreference is possible. The possibilities for anaphor binding are exactly reversed; *Hanna* must bind (i.e., corefer with) *herself* in (1a), but cannot do so in (1b).

There are distinct structural conditions that determine the binding possibilities for the different kinds of NPs. Principle C of BT deals with the binding requirement for full NPs, and will not concern us here. Principle A captures the binding requirements for anaphors; in early formulations, it states that an anaphor has to be bound within a certain local domain (Chomsky, 1981). The local domain is defined using c-command, a structural notion defined on trees. Principle B, on the other hand, states that pronouns cannot be bound within the local domain. It follows that anaphors and pronouns are predicted to be in complementary distribution, i.e., anaphors can be bound where pronouns cannot be bound, and vice versa.

It was subsequently observed that this complementarity breaks down in certain structures. A case that has generated much theoretical discussion is PNPs, where anaphors and pronouns are equally acceptable:

(2) Hanna$_i$ found a picture of her$_i$/herself$_i$.

There is also the further complication that in PNPs with possessors (3) and in PNPs that are arguments of certain verbs (4) the complementarity between pronouns and anaphors seems to resurface:

(3) Peter$_i$ found Hanna$_j$'s picture of *her$_j$/herself$_j$.
(4) Hanna$_i$ took a picture of *her$_i$/herself$_i$.

Note that (4) is meant with the sense of *take* as in creating a photograph, not as in physically removing a picture. A number of authors have argued for a revised version of BT based on data such as (2), (3), and (4). Chomsky (1986) restates BT such that there is an asymmetry between pronouns and anaphors in certain contexts, including PNPs without possessors. For (4), Chomsky and Lasnik (1995) propose that there is a covert possessor. With these revisions, the predicted pattern of data is exactly as in (2)–(4). We will refer to this approach as the *structural account* of binding in PNPs.

Some more recent work, however, has proposed a *pragmatic* account of the PNP data in (2)–(4) (e.g., Kuno, 1987; Pollard & Sag, 1994; Reinhart & Reuland, 1993). These authors have observed that in certain configurations anaphors are *exempt* from BT. One such configuration is PNPs without possessors, as in (2) and (4). According to this view, the anaphor in (2) is not subject to Principle A, but is rather governed by pragmatic constraints, where relevant factors include referentiality, definiteness, and aspect. It is important to note that even the versions of BT that postulate exempt anaphors still maintain that Principle A holds of anaphors in PNPs when there is an overt possessor: although the anaphor in (2) is exempt, the anaphors in (3) and (4) are still subject to BT.

The present study attempts to clarify the empirical status of exempt anaphors. We present the results of an experiment that tests the influence of both structural and pragmatic factors on coreference in PNPs. This experiment uses the magnitude estimation (ME) paradigm to establish the coreference intuitions of linguistically naive subjects. (For other studies demonstrating the usefulness of experimental data in clarifying BT facts, see Cowart, 1997; Gordon & Hendrick, 1997.)

Before we discuss the results of this experiment, we present a control study designed to validate our experimental paradigm. To our knowledge, ME has never been applied to coreference judgments, hence we must show that its results are consistent with the theoretical literature and replicate previous experimental data.

Experiment 1: Control Study

The control study was designed as a replication of Experiment 3 of the study of coreference by Gordon and Hendrick (1997). It investigated basic effects of Principles A, B, and C of BT. Eight different binding configurations were tested, three of which occurred either with or without c-command (see Chomsky, 1981, for details on c-command). Table 1 lists the binding configuration tested by Gordon and Hendrick (1997). It also summarizes the predictions of standard BT for these configurations, and gives example stimuli.

Predictions

Our hypothesis is that ME generates valid coreference judgments. We therefore predict that the same significant effects as in Gordon and Hendrick's (1997) original study will be present, even though our replication used an ME task instead of the ordinal judgment task employed by Gordon and Hendrick (1997). Another difference is that we conduced our experiment over the World Wide Web, while the Gordon and Hendrick (1997) administered a conventional questionnaire. The web-based methodology entails differences in sampling and experimental procedure, which increases the need for a validation study.

Method

Subjects Fifteen participants were recruited over the Internet by postings to newsgroups and mailing lists. All participants were self-reported native speakers of English and naive to syntactic theory.

Materials Following Gordon and Hendrick (1997), the design contained one factor, viz., binding configuration (*Ana*) with eight levels. Three lexicalizations were used; one was the original lexicalization used by Gordon and Hendrick (1997), the other two were new lexicalizations, designed in analogy with the original one. This resulted in a set of 24 items (see Table 1 for sample stimuli).

Procedure The method used was ME as proposed by Stevens (1975) for psychophysics and extended to linguistic stimuli by Bard et al. (1996) and Cowart (1997).

Subjects first saw a set of instructions that explained the concept of numerical ME using line length. Subjects were instructed to make length estimates relative to the first line they would see, the reference line. They were told to give the reference line an arbitrary number, and then assign a number to each following line so that it represented how long the line was in proportion to the reference line. Several example lines and corresponding numerical estimates were provided to illustrate the concept of proportionality. Then subjects were told that linguistic acceptability could be judged in the same way as line length, and that this experiment required them to judge the acceptability of coreference. Following Gordon and Hendrick (1997), this was defined as follows: 'Your task is to judge how acceptable each sentence is by assigning a number to it. By acceptability we mean the following: Every sentence will contain two expressions in ALL CAPITALS. A sentence is acceptable if these two expressions can refer to the same person.' The task was illustrated by examples.

After reading the instructions, subjects took part in a training phase designed to familiarize them with the task. In the training phase, subjects were ask to use ME to judge the length of a set of lines. Then, a set of practice items (similar to the experimental items) were administered to familiarize subjects with applying ME to linguistic stimuli. Finally, subjects had to judge the experimental items. Each subject judged all 24 experimental stimuli and a set of 24 fillers, i.e., a total of 48 items.

The experiment was conducted over the web using WebExp 2.1 (Keller, Corley, Corley, Konieczny, & Todirascu, 1998), an interactive software package for web-based psycholinguistic experimentation. Keller and Alexopoulou (2001) present a detailed discussion of the safeguards that WebExp puts in place to ensure the authenticity and validity of the data collected, and also present a validation study comparing web-based and lab-based judgment data (for a WebExp validation study using sentence completion data, see Corley & Scheepers, in press).

Results

The data were normalized by dividing each numeric judgment by the modulus value that the subject had assigned to the reference sentence. This operation creates a common scale for all subjects. Then the data were transformed by taking the decadic logarithm. This transformation ensures that the judgments are normally distributed and is standard practice for ME data (Bard et al., 1996). All analyses and figures are based on normalized, log-transformed judgments.

The average judgments for the different conditions are graphed in Figure 1 for the original study and in Figure 2 for our replication. Visual inspection shows that the replication experiment produces the same acceptability pattern for each of the binding configurations.

This was confirmed by the statistical analyses. Gordon and Hendrick (1997) report a significant main effect of binding configuration (*Ana*), which was also present in our data ($F_1(7,98) = 17.561$, $p < 0005$; $F_2(7,14) = 295.262$, $p < 0005$). They also found that the acceptability of the name-anaphor configuration increased under c-command, which was replicated in our data ($F_1(1,14) = 17.057$, $p = .001$; $F_2(1,2) = 2389.474$, $p < 0005$). Another finding was that c-command significantly reduces the acceptability of coreference name-pronoun configurations. This effect was also present in the replica-

Table 1: Sample stimuli and predictions from Gordon and Hendrick (1997), Experiment 3

NP_1	NP_2	c-command	sample sentence	prediction
name	pronoun	no	(i) **Joan's** father respects **her**.	grammatical
pronoun	name	no	(ii) **Her** father respects **Joan**.	grammatical
name	name	no	(iii) **Joan's** father respects **Joan**.	grammatical
pronoun	anaphor	no	(iv) **Her** father respects **herself**.	ungrammatical
name	anaphor	no	(v) **Joan's** father respects **herself**.	ungrammatical
name	pronoun	yes	(vi) **Joan** respects **her**.	ungrammatical
pronoun	name	yes	(vii) **She** respects **Joan**.	ungrammatical
name	anaphor	yes	(viii) **Joan** respects **herself**.	grammatical

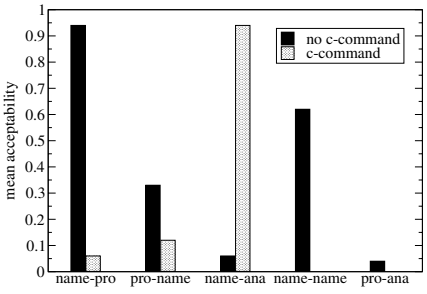

Figure 1: Original data from Gordon and Hendrick (1997), Experiment 3

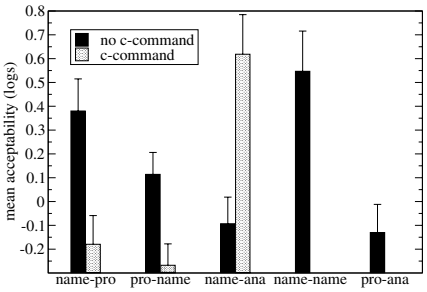

Figure 2: Replication of Gordon and Hendrick (1997), Experiment 3

tion ($F_1(1,14) = 21.818$, $p < .0005$; $F_2(1,2) = 315.306$, $p = .003$). An effect of c-command on the acceptability of pronoun-name configurations was also found both in the original data set and in our replication ($F_1(1,14) = 25.949$, $p < .0005$; $F_2(1,2) = 181.980$, $p = .005$).[1] Finally, a comparison of the name-pronoun and the name-name configurations showed that names are favored as antecedents ($F_1(1,14) = 13.770$, $p < .002$; $F_2(1,2) = 192.301$, $p = .005$), in line with what Gordon and Hendrick (1997) found.

To further compare the results of the original experiment and our validation study, we conducted a correlation analysis comparing the mean judgments for each cell in the experiment. A high correlation coefficient was obtained ($r_1 = .9198$, $p = .001$, $N = 8$). (No by-item correlation coefficient could be computed as Gordon and Hendrick (1997) fail to report by-item analyses.)

[1]Note that standard BT fails to predict the reduced acceptability of configuration (ii). A possible explanation might be that this configuration involves cataphoric reference (i.e., the pronoun refers forwards instead of backwards).

Discussion

In this study, we used ME to replicate a published experiment on coreference judgments that used a conventional ordinal scale (Gordon and Hendrick's (1997) Experiment 3). We obtained the same significant effects as in the original and a high correlation with the original data set, which amounts to a full replication of the original study.

This result indicates that the ME paradigm is suitable for investigating judgments of linguistic coreference, which are vital for testing claims from BT. Previous uses of ME were limited to grammaticality judgments (Bard et al., 1996; Cowart, 1997). The successful replication also reassures us that psycholinguistic data collected over the web yield results comparable to data generated by a conventional lab-based methodology, in line with previous findings by Keller and Alexopoulou (2001) and Corley and Scheepers (in press).

Finally, the present experiment allows us to establish a baseline for further experiments on linguistic coreference. It encompassed only clear-cut cases of coreference that are uncontroversial in the binding theoretical literature. It is important to establish the validity of our methodology for such clear-cut cases before moving to investigate more controversial issues such as binding in PNPs, where the theoretical and empirical claims in the syntactic literature differ widely. Binding in PNPs is the subject of the next experiment.

Experiment 2: Structural and Pragmatic Factors in Coreference

Based on the results from the control experiment, we carried out an experimental study investigating the factors that determine coreference in PNPs in English. The aim of this experiment was to provide reliable experimental data that settles the longstanding dispute about the binding theoretical status of PNPs. In particular, we tested the claim that PNPs are exempt from BT, and hence their coreference options are governed by pragmatic, rather than structural factors.

Structural Factors The current experiment tested the influence of structural factors on binding in PNPs by comparing the behavior of anaphors and pronouns in six configurations, listed in Table 2. Two structural factors were tested.

Firstly, the position of the binder, which can either be the subject of the matrix clause (as in configurations (i)–(iv) in Table 2), or the possessor of the PNP (as in configurations (v) and (vi) in Table 2). Secondly, the absence of a possessor (as in configurations (i) and (ii)), or its presence (as in configurations (iii)–(vi) in Table 2). The experiment contained three subdesigns, which tested the configurations (i) and (ii), (iii) and (iv), and (v) and (vi), respectively.

Table 2: Sample stimuli and predictions for Experiment 2

NP_1	NP_2	subject	possessor	sample sentence	prediction
name	pronoun	yes	no	(i) **Hanna** found a picture of **her**.	grammatical
name	anaphor	yes	no	(ii) **Hanna** found a picture of **herself**.	grammatical
name	pronoun	yes	yes	(iii) **Hanna** found Peter's picture of **her**.	grammatical
name	anaphor	yes	yes	(iv) **Hanna** found Peter's picture of **herself**.	ungrammatical
name	pronoun	no	yes	(v) Hanna found **Peter's** picture of **him**.	ungrammatical
name	anaphor	no	yes	(vi) Hanna found **Peter's** picture of **himself**.	grammatical

Pragmatic Factors The second aim of the present experiment was to investigate the influence of pragmatic factors on the coreference in PNPs. Such factors have received much attention in the theoretical literature. However, no quantitative studies have been conducted to determine to what extent these factors influence coreference, and how they interact with structural factors.

Three pragmatic factors were investigated. The first one is definiteness of the PNP. As an example of definiteness consider the minimal pair in (5): the PNP in (5a) is indefinite and the one in (5b) is definite.

(5) a. Hanna$_i$ found a picture of her$_i$/herself$_i$.
b. Hanna$_i$ found the picture of her$_i$/herself$_i$.

The second factor is the aspectual class of the matrix verb, illustrated in example (6): *find* and *lose* are examples of achievement verbs, while *take* and *destroy* are accomplishment verbs; *find* and *take* are [existence], i.e., they presuppose the existence of their object, while *lose* and *destroy* are [−existence], i.e., they do not carry this presupposition.

(6) a. Hanna$_i$ found a picture of her$_i$/herself$_i$.
b. Hanna$_i$ lost a picture of her$_i$/herself$_i$.
c. Hanna$_i$ took a picture of her$_i$/herself$_i$.
d. Hanna$_i$ destroyed a picture of her$_i$/herself$_i$.

Third, we tested the influence of the referentiality of the binder, as illustrated in (7):

(7) a. Hanna$_i$ found Peter's picture of her$_i$/herself$_i$.
b. The woman$_i$ found Peter's picture of her$_i$/herself$_i$.
c. Each woman$_i$ found Peter's picture of her$_i$/herself$_i$.

The pragmatic factors were included in the three subdesigns of the present experiment. The factors definiteness and verb class were included in the first subdesign, while referentiality was part of the second and third subdesign.

Predictions

Based on the theoretical literature (see Introduction), we predict that anaphors in PNPs are exempt from local binding (i.e., binding within the PNP), *unless* the PNP has a possessor, in which case the anaphor must be bound by the possessor (see examples (2) and (3)). We also predict that pronouns must be locally free from a possessor, if there is one. Table 2 lists the configurations and the associated predictions, together with example stimuli. Note that we expect that the relative acceptability of pronouns and anaphors is the same in configurations (i), (ii) and (iii). Configurations (iv) and (v) are predicted to be unacceptable, while (vi) is predicted to be acceptable. These constructions differ in terms of their syntactic structure (antecedent is the subject or the possessor; possessor is present or not). We expect to find no main effect of binding configuration for (i) versus (ii), but for pairs (iii)/(iv) and (v)/(vi) we expect binding configuration to have a significant main effect.

If the pragmatic approach to binding in PNPs is correct, then we also expect that the pragmatic factors verb class, definiteness, and referentiality have an effect on coreference. The underlying theoretical assumption is that coreference for exempt NPs is governed by pragmatics, rather than by structural principles. Hence we predict an interaction of binding configuration with verb class and definiteness in the first subexperiment, and an interaction of binding configuration with referentiality in the second and third subexperiment.

Method

Subjects Fifty-two native speakers of English volunteered to participate. All participants were naive to syntactic theory.

Materials The experimental materials included three subdesigns. The first subdesign investigated binding configurations (i) and (ii): name-pronoun and name-anaphor with the antecedent in the subject and without a possessor. The second subdesign compared binding configurations (iii) and (iv): name-pronoun and name-anaphor with the antecedent in the subject and a possessor in the PNP. The third subdesign dealt with configurations (v) and (vi): name-pronoun and name-anaphor with the antecedent as the possessor of the PNP.

This means that in each of the three subdesigns the factor binding configuration (*Ana*) had two levels: name-pronoun or name-anaphor. In the first subdesign, this factor was crossed with *Def* and *Verb*, representing the two pragmatic factors definiteness of the PNP and aspectual class of the main verb. *Def* had two levels (definite, indefinite, see (5)), *Verb* had three levels (achievement [existence], accomplishment [existence], accomplishment [−existence] (see (6a), (6c), (6d)). This yielded a total of $Ana \times Def \times Verb = 2 \times 2 \times 3 = 12$ cells for the first subdesign.

In the second and third subdesigns, the structural factor *Ana* was crossed with the pragmatic factor referentiality (*Ref*), which had three levels (proper name, definite NP, quantified NP, see (7)). The second and third subdesign therefore had $Ana \times Ref = 2 \times 3 = 6$ cells each.

All three subdesigns taken together had a total of 24 cells. Four lexicalizations were used for each of the cells, which resulted in a total of 96 stimuli. A set of 24 fillers was used, designed to cover the whole acceptability range.

Procedure The experimental procedure was the same as in Experiment 1. The stimulus set was divided into four subsets of 24 stimuli by placing the items in a Latin square. Each subject judged one of these subsets and 24 fillers, i.e., a total of 48 items.

Results

The data were preprocessed as in Experiment 1. Separate ANOVAs were conducted for each subexperiment.

Structural Factors In the first subexperiment (binding configurations (i) and (ii)), we found a large and highly significant main effect of *Ana* ($F_1(1,51) = 137.471$, $p < .0005$; $F_2(1,3) = 105.005$, $p = .002$). Anaphors (mean =

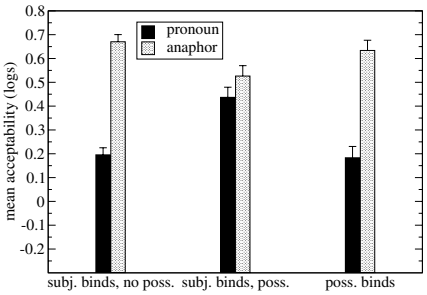

Figure 3: Structural effects on coreference judgments for binding in PNPs

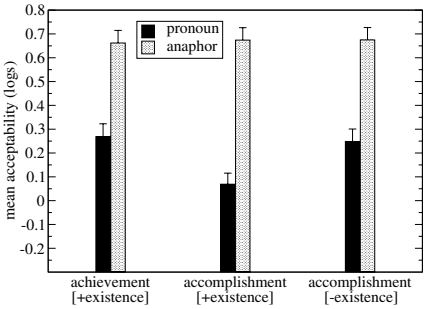

Figure 4: Effect of verb class on coreference judgments (subject binds, no possessor)

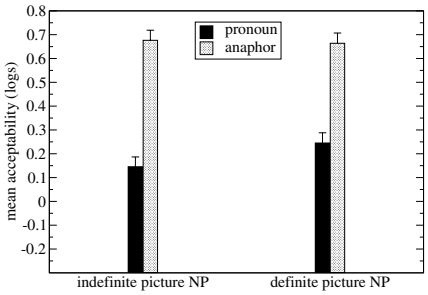

Figure 5: Effect of definiteness on coreference judgments (subject binds, no possessor)

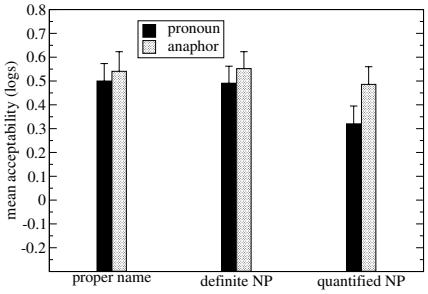

Figure 6: Effect of referentiality on coreference judgments (subject binds, possessor)

.6702) were more acceptable than pronouns (mean = .1954). In the second subexperiment (binding configurations (iii) and (iv)), *Ana* failed to reach significance: both anaphors (mean = .5262) and pronouns (mean = .4369) were equally acceptable. In the third subexperiment (binding configurations (v) and (vi)), again a main effect of *Ana* was present ($F_1(1,51) = 101.632$, $p < .0005$; $F_2(1,3) = 34.677$, $p = .010$). Anaphors (mean = .6338) were more acceptable than pronouns (mean = .1832). The coreference judgments for the six binding configurations (see Table 2) are graphed in Figure 3.

Pragmatic Factors The ANOVA for the first subexperiment also revealed a significant interaction of *Verb* and *Ana* ($F_1(2,102) = 11.275$, $p < .0005$; $F_2(2,6) = 6.193$, $p = .035$). This interaction is graphed in Figure 4, showing a decrease in the acceptability of pronouns for [existence] accomplishment verbs. An interaction of *Def* and *Ana* was also found, which however was significant by subjects only ($F_1(1,51) = 11.849$, $p = .001$; $F_2(1,3) = 2.168$, $p = .237$). Figure 5 shows that the acceptability of pronouns is increased for definite PNPs.

The ANOVA for the second subexperiment showed an interaction of *Ref* and *Ana*, significant by subjects only ($F_1(2,102) = 3.979$, $p = .049$; $F_2(2,6) = 2.745$, $p = .142$). This interaction is depicted in Figure 6, showing a decrease in the acceptability of pronouns if the antecedent is a quantified NP. No *Ref*/*Ana* interaction was present in the third subexperiment (see Figure 7).

Discussion

The theoretical predictions for the acceptability of the stimuli are listed in Table 2. Theory also predicts that anaphors are exempt from BT in configuration (i), and that structural factors should fail to have an influence on the acceptability of coreference for these structures. Contrary to this prediction, the present experiment revealed a significant influence of structural factors, although not in a way that any existing account predicts. Four major results were obtained.

In cases where the antecedent is in the subject and there is no possessor in the PNP (configurations (i) and (ii), see Table 2), structural and pragmatic binding theories alike predict that pronouns are fully acceptable and that pronouns and anaphors are equally acceptable. Our first and second major results are the falsification of both these predictions. Pronouns were significantly less acceptable than anaphors (see Figure 3). A comparison with standard cases of BT tested in Experiment 1 (see Figure 2) indicates that anaphors are fully acceptable in this configuration, while pronouns are of intermediate acceptability (but not fully unacceptable compared to, e.g., name-pronoun configurations with c-command).

Configurations (iii) and (iv), where the antecedent is in the subject, but there is a possessor, demonstrate our third major result. Here BT falsely predicts that anaphors

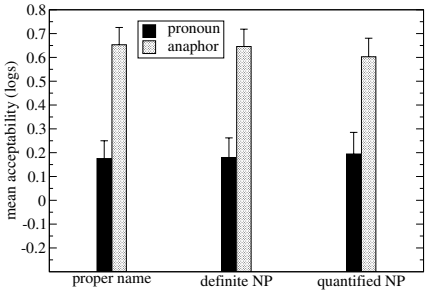

Figure 7: Effect of referentiality on coreference judgments (possessor binds)

are fully unacceptable. Note also that these anaphors are not exempt according to the pragmatic versions of BT, as there is a possessor. We found that pronouns and anaphors are both highly acceptable; no significant acceptability difference could be detected (see Figure 3). In other words, contrary to all that has been written in the syntactic literature, anaphors can be bound by the subject even in PNPs with possessors.

Our fourth result concerns the third structure we investigated (configurations (v) and (vi)), where the antecedent is the possessor in the PNP rather than the subject. We found the same behavior as in configurations (i) and (ii): the anaphors were fully acceptable in this configuration, while pronouns were significantly less acceptable, but not completely unacceptable compared to the configurations investigated in Experiment 1 (see Figure 2). The prediction for a PNP with a possessor is that a pronoun bound by the possessor is completely ungrammatical and that a pronoun bound by the subject is completely grammatical. This prediction was not supported by our results. We found that a pronoun bound by the possessor is as acceptable as a pronoun bound by a subject, but that both are only moderately acceptable.

We also investigated the influence of the pragmatic factors verb class, definiteness, and referentiality on coreference in PNPs. The underlying theoretical assumption is that coreference for exempt anaphors is governed by pragmatic factors, rather than by structural constraints. In binding configurations (i) and (ii), we found a significant effect of verb class: the acceptability of pronouns was reduced for [existence] accomplishment verbs (see Figure 4). This accords with intuitions reported in the literature (see Introduction, (4)). Furthermore, we found a significant effect of definiteness: pronouns are more acceptable with definite PNPs than with indefinite ones (see Figure 5). However, the verb class effect and the definiteness effect were weak and did not change the overall acceptability pattern, i.e., the preference for anaphors over pronouns.

In configurations (iii) and (iv), we found that the pragmatic factor referentiality has a significant effect on the acceptability of pronouns, which were less acceptable if the antecedent is a quantified NP, compared to cases where the antecedent is a name or a definite NP (see Figure 6). Again, this effect was weak and did not change the overall pattern, i.e., the fact that both pronouns and anaphors were highly acceptable in configurations (iii) and (iv). Finally, we failed to find any effect of referentiality in configurations (v) and (vi) (see Figure 7).

Conclusions

Experiment 1 was a control study that made a methodological contribution. The results showed that the experimental paradigm of magnitude estimation, previously only used for grammaticality judgment tasks, can be applied successfully to coreference judgments, which form the empirical basis of binding theory.

Building on this result, Experiment 2 used magnitude estimation to provide crucial data regarding binding in PNPs, which have been the subject of much research in the syntactic literature. The results provide an example of how experimentation can be used as a tool to settle debates in linguistic theory.

More specifically, Experiment 2 aimed to clarify the empirical status of exempt anaphors and provide data to distinguish between structural and pragmatic accounts of exempt anaphors. The results show that structural factors govern the binding possibilities in PNPs, while pragmatic factors play only a limited role. However, the structural factors identified differ from the ones standardly assumed. We found that (i) an anaphor can be bound from outside the PNP, even if there is a possessor in the PNP, (ii) anaphors and pronouns bound by the subject are equally acceptable when there is a possessor, (iii) pronouns are only moderately acceptable when there is no possessor, and (iv) pronouns bound by the possessor are also moderately acceptable.

Finding (i) is the most theoretically interesting one, and has recently been confirmed in an eye-tracking experiment (Runner, Sussman, & Tanenhaus, 2000). It falsifies a major prediction of all binding theories by showing that structural factors (subject/no subject, possessor/no possessor) fail to influence the binding of anaphors in PNPs. This means that the role of structural factors is even smaller than envisaged by proponents of pragmatic accounts. For pronouns, however, there is a structural effect, viz., they are more acceptably bound by the subject if there is a possessor NP.

In our view, the best way to understand this result is by making reference to the notion of predication (Pollard & Sag, 1994; Reinhart & Reuland, 1993). An anaphor must be bound by a dominating coargument of the predicate that selects for the anaphor, if there is one. For example, an anaphor that is in the object position of a matrix clause must be bound by the subject, because the subject position dominates the object position: both the subject and object are arguments of the same predicate, i.e., the predicate needs the subject and object to satisfy its syntactic and semantic requirements. But the possessor of a PNP is not an argument of the head, as the head does not require it (i.e., pictures do not *necessarily* have possessors). This observation correctly accounts for the full acceptability of anaphors in PNPs, with or without possessors, and the necessity for local binding when anaphors are in matrix argument positions (as in (1)).

We can also use the notion of predication to understand the pattern for [existence] accomplishment verbs, as in (4) *Hanna$_i$ took a picture of *her$_i$/herself$_i$*, without positing a covert possessor. It is possible that speaker-hearers treat expressions like *take a picture* as one predicate, in which case the anaphor or pronoun in such examples is actually a coargument of the subject and governed by Principle A or B, respectively. Runner (to appear) argues for just such an analysis of predicates like *take a picture* based on syntactic and semantic evidence.

Abstract

Three sources of difficulty for the nine-dot problem were hypothesized: 1) *turning on a non-dot point*, i.e., ending one line and beginning a new line in a space between dots; 2) *crossing lines*, i.e., drawing lines that intersect and cross; and 3) *picking up interior dots*, i.e., drawing lines that cross dots that are in the interior of the nine-dot and its variants. Training was designed to either facilitate or hinder participants in overcoming these difficulties. Participants were then tested on variants of the nine-dot problem. Results showed that participants in the facilitating training condition performed significantly better than the hindering or control group.

Constraints and Insights

Prior knowledge is the main resource that a problem solver can bring to bear on a problem. Prior knowledge produces unconscious biases that might influence perception and/or encoding of a problem. In general, prior knowledge can be helpful and productive when reasoning or solving a problem. However, when a problem solver faces a very unfamiliar or novel type of problem, there is no guarantee that prior knowledge will be relevant or helpful. The defining characteristic of so-called insight problems is that they activate seemingly relevant prior knowledge which is not, in fact, relevant or helpful (Ohlsson, 1984b, 1992; Wiley, 1998). To succeed, the problem solver must de-activate or relax the constraints imposed by the more or less automatically activated but unhelpful knowledge. To understand human performance on an insight problem, we should therefore try to identify the particular prior concepts, principles, skills or dispositions that constrain performance on that problem. Knoblich, Ohlsson, Haider, and Rhenius (1999) and Knoblich, Ohlsson, and Raney (1999) applied this perspective with considerable success to a class of match stick problems. In this paper, we apply it to the nine-dot problem and other connect-the-dots (CD) problems.

The nine-dot problem (Maier, 1930) requires that nine dots arranged in a square be connected by four straight lines drawn without lifting the pen from the paper and without retracing any lines (Figure 1). This task is ridiculously simple in the formal sense that there are only a few possible solutions to try, but ridiculously difficult in the psychological sense that the solution rate among college undergraduates who are given a few minutes to think about it is less than 5% (Lung & Dominowski, 1985; MacGregor, Ormerod, & Chronicle, 2001). The problem is surely of an unfamiliar type – when in everyday life do we ever draw lines to connect dots under certain constraints? – but what, exactly, are the sources of difficulty? Interestingly, seventy years of research (Maier, 1930) have not sufficed to answer this question.

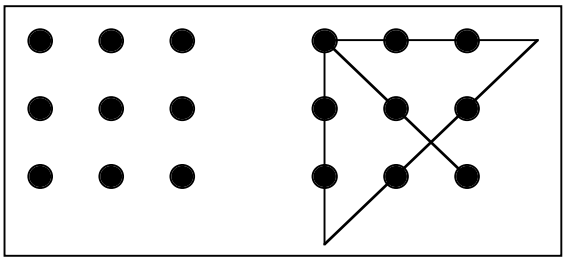

Figure 1: The nine-dot problem and its solution

The Gestalt psychologists introduced insight problems into cognitive psychology and explained their difficulty in terms of Gestalts, schemas that supposedly organize perceptual information (Ohlsson, 1984a). Consequently, they hypothesized that the nine-dot problem is difficult because people are so dominated by the perception of a square that the do not 'see' the possibility of extending lines outside the square formed by the dots (Scheerer, 1963). This hypothesis predicts that telling participants that they can draw lines outside the figure should facilitate the solution. Burnham and Davis (1969) and Weisberg and Alba (1981) tested this hypothesis, and found that the instruction only worked if combined with other hints that gave away part of the solution, e.g., telling the participants at which point to start or giving them the first line of the solution. A second prediction from the Gestalt hypothesis is that altering the shape of the problem and thus breaking up the square should also help. Both Burnham and Davis (1969) and Weisberg and Alba (1981) found facilitating effects of this manipulation. A third prediction from the Gestalt hypothesis is that giving people experience in extending lines outside the figure should help. Weisberg and Alba (1981) and Lung and Dominowski (1985) indeed found facilitating effects of such training.

Recently, MacGregor et al. (2001) and Chronicle, Ormerod, and MacGregor (in press) have proposed a

theory that attempts to predict quantitative differences in solution rates for different CD problems. Their explanation is based on four principles: (a) People always draw their next line so as to go through as many dots as possible. (b) People judge the value of a line as a function of how many dots it picks up in relation to how many dots are left and how many lines they have left to draw. (c) People look ahead 1, 2, 3 or at most 4 steps when deciding which line to draw next. (d) When lookahead indicates that every possible line from the current dot will end in a situation where the next line does not provide sufficient progress, they consider, with some probability, lines that go outside the figure formed by the dots.

This theory successfully predicts the differences in solution rates between different several different CD problems. It provides a more detailed description of why people get stuck than any previous theory – their lookahead is not deep enough to reveal that the solution path they are trying will dead end eventually – but the basic explanation for the difficulty is similar to that of previous theories: people consider lines within the shape formed by the dots before they consider lines that go outside the figure.

However, if this is true of variants of the nine-dot problems that do not form squares or any other 'good figure', then the Gestalt explanation for why people do not go outside the figure no longer holds. So what is the difficulty?

By analyzing pilot data and inspecting MacGregor et al.'s (2001) solution rates for the different nine-dot variants, we hypothesize that "hesitating to go outside the figure formed by the dots" is the wrong formulation of the constraint operating in this type of problem. Instead, we propose that *people are disposed to turn on a dot*, as opposed to turn on a point on the paper where there is no dot (a non-dot point). This constraint overlaps in meaning with the stay-within-the-figure constraint, so it explains the success of the training provided by Lung and Dominowski (1985). At the same time, this formulation is different enough to explain why telling people that they can go outside the figure does not help; they do not hesitate to extend lines outside the figure, but they do not want to turn on a non-dot point. As a secondary constraint, we hypothesize that people hesitate *to cross lines*, having a strong disposition towards thinking of the four lines they are supposed to draw as forming a closed outline. As a consequence, they do not see how *to pick up the dots in the interior of the figure*, an operation that requires crossing lines in many CD problems.

In the present study, we tested this hypothesis by both comparing problems that did and did not require turns on non-dot points and by attempting to facilitate the solution via training. As a novel methodological feature, we also tried to *hinder* the solution with training intended to *strengthen* the inappropriate constraints.

Method

Participants

Participants were 90 undergraduates (30 in each training group: facilitating, hindering, and no training) from UIC's Participant Pool. No demographic data were collected about the participants.

Materials

The training exercises were designed by the first author.

Facilitating Training The facilitating training was designed to eliminate the difficulties that participants were thought to face when solving the nine-dot problem. Twelve training exercises were designed, each with similar instructions to the nine-dot problem (Connect all of these dots using ___ straight lines without lifting your pen from the page and without retracing any lines). Each exercise required a different number of lines to connect the dots.

Six of the training exercises required participants to cross lines and pick up interior dots (Figure 2), and the other six could only be solved by turning on a non-dot point (Figure 3). Each training exercise was presented on its own page. The dots were filled circles that were .5 cm in diameter, and the centers of each dot were approximately 3.75 cm apart.

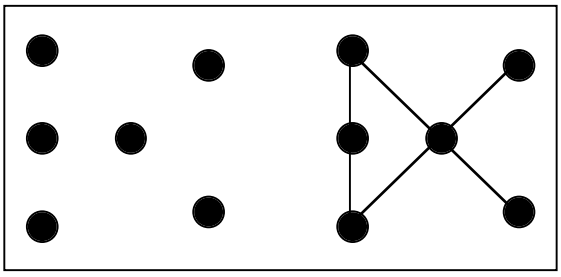

Figure 2: Facilitating Training Exercise and its Solution: Crossing Lines and Picking up Interior Dots

Hindering Training The hindering training consisted of 12 exercises that were solved by drawing lines that always turned on a dot and never crossed another line (Figure 4). As in the facilitating training, participants were instructed with similar directions to the nine-dot problem (Connect all of these dots using ___ straight lines without lifting your pen from the page and without retracing any lines). Again, each exercise required a different number of lines to connect the dots. The

hindering training was constructed just as the facilitating training, with the dots, or filled circles, being .5 cm in diameter and the centers of each dot being approximately 3.75 cm apart.

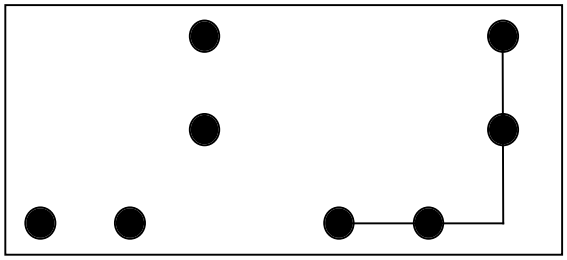

Figure 3: Facilitating Training Exercise and its Solution: Turning on a Non-Dot Point

Nine-Dot Variants The three insight and three non-insight versions of the nine-dot problem that were used had been designed by MacGregor et al. (2001). The insight problems required participants to turn on a non-dot point (Figure 5), while the non-insight problems were the insight problems with an added dot, which excused participants from having to turn on a non-dot point (Figure 6). Each problem was presented on its own page. The dots were filled circles that were 1 cm in diameter. The center of each dot was approximately 3.75 cm apart.

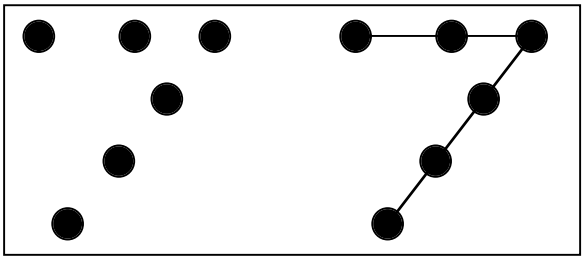

Figure 4: Hindering Training Exercise and its Solution

Procedure

Participants were seen in groups of 2-10. Each session lasted from 40 minutes to an hour. All test materials were contained in a booklet.

Training Phase Participants in both the facilitating and hindering training conditions were given the same directions for the training exercises. The instructions explained that they would be connecting dots using the number of lines specified on each page without lifting their pens from the page or retracing any lines. They were also told to start at the dot marked with a star for each group. The purpose of giving participants a set starting point was to make sure that there was a single solution for each training exercise.

Participants had one minute to work on each training exercise. Time was kept by the experimenter. Participants in the no training (control) group did not complete the training exercises and instead began with the problems.

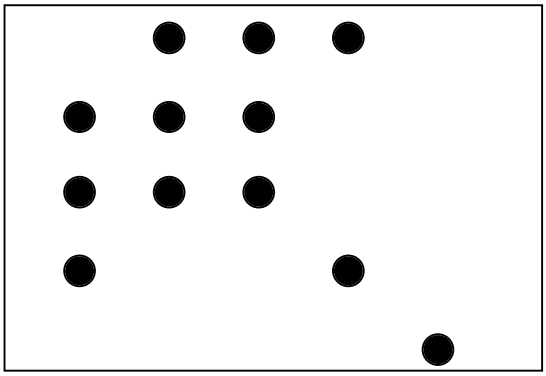

Figure 5: Nine-Dot Variant: Insight Version

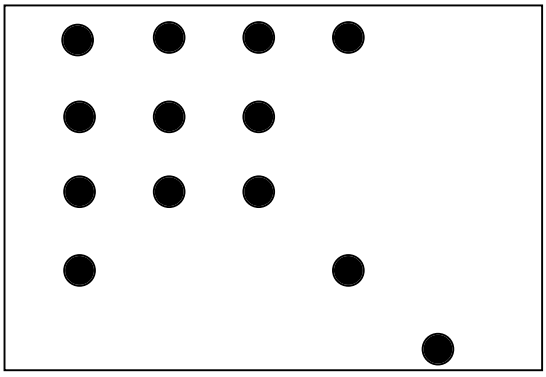

Figure 6: Nine-Dot Variant – Non-Insight Version

Problem-Solving Phase. After completing the training, participants began the problem-solving section of the booklet. Participants were instructed that they would have four minutes to connect all the dots in the figure using four straight lines without lifting their pens from the page and without retracing any lines. For each problem, there was a practice sheet followed by a second identical sheet with the problem on it. Participants were instructed to try the problem as many times as they wanted to on the practice sheet. When they thought they had come up with a solution, they were to record the time out of the four minutes that had passed, using a large clock at the front of the room.

The participants then were to turn the page and redraw their final solutions on the clean page.

The order of problems was the same for all participants. The first problem was an insight problem, the second was a non-insight problem, the third was an insight problem, and so on. Each insight problem was followed by its non-insight version. The first insight problem was of principal interest in comparing the effect of the training manipulations. The other problems were included to obtain baseline solving rates for various problem types, and to compare solving rates in the UIC participant population to the solving rates obtained by MacGregor et al. (2001).

Results

The results focus on the first insight problem (see Figure 5).

Group Analysis

A 3 x 2 chi-square analysis was conducted for the first insight problem. The independent variable was the type of training: facilitating, hindering, or no training. The dependent variable was whether or not a participant had solved the first insight problem. Nineteen participants (63%) in the facilitating group solved the first insight problem, eight (27%) in the hindering group solved, and 11 (37%) in the no training group solved. The chi-square was significant, $\chi^2(2, \underline{N} = 90) = 8.836$, $\underline{p} < .05$. Post-hoc comparisons showed significant differences between the facilitating group and the hindering group, $\chi^2(1, \underline{N} = 60) = 8.148$, $\underline{p} < .05$, and between the facilitating group and the no training group, $\chi^2(1, \underline{N} = 60) = 4.267$, $\underline{p} < .05$, but not between the hindering group and the no training group, $\chi^2(1, \underline{N} = 60) = .693$, $\underline{p} > .05$.

A between-groups analysis of variance (ANOVA) was conducted for the average amount of time it took participants in each group to solve the first insight problem. Participants in the facilitating group averaged 116 seconds to solve the first insight problem, the hindering group averaged 188 seconds, and the no training group averaged 185 seconds to solve. The ANOVA was significant, $\underline{F}(2,87) = 5.873$, $\underline{p} < .05$. Post-hoc Tukey tests revealed significant differences between the facilitating group and the hindering group ($\underline{p} < .05$) and the facilitating group and the no training group ($\underline{p} < .05$), but not between the hindering group and the no-training group ($\underline{p} > .05$).

Individual Differences Analysis

Although the facilitating group did better on the first insight problem than the other two groups, there was a large amount of variation in solving rate within the facilitating training group. Specifically, not all participants in the facilitating training group completed the training correctly. Participants in the facilitating group were split into two sub-groups based on whether or not they had completed the training correctly. In order to be classified as having completed the training correctly, a participant had to correctly complete over half (six) of the training exercises. If a participant did not correctly complete at least six of the training exercises, then he or she was put into the "did not complete training" group. In the "completed training" group, no participant got more than four training exercises incorrect. In the "did not complete training" group, one participant got six exercises wrong, and the others got seven or more exercises wrong.

There were a total of 19 participants in the "completed training" group, 17 (89%) of which solved the first insight problem, and 11 participants in the "did not complete training" group, two (18%) of which solved the first insight problem. A chi-square analysis comparing the performance of the two sub-groups on the first insight problem was significant, $\chi^2(1, \underline{N} = 30) = 15.248$, $\underline{p} < .05$.

Within each group, there were large differences in the amount of time needed to solve the first insight problem. Participants in the facilitating group who solved the first insight problem needed between 8 and 180 seconds to solve, with the majority of solvers requiring between eight and 109 seconds. The amount of time needed to solve ranged between 15 and 235 seconds in the hindering group, and between 20 and 195 seconds in the no training group.

Discussion

The results show that the problems that did not require turns on non-dot points were easier than those that did, and that the facilitating training improved performance on our CD problems, supporting the idea that the difficulties of the nine-dot problem and of CD problems generally might be some combination of a disposition towards turning on a dot and a disposition to think of the four lines they are supposed to draw as forming an outline and hence not crossing each other.

Contrary to expectation, the hindering training did not suppress the solution rate below that of a control group. There are several possible explanations. First, the solution rate was low enough so that attempting to suppress it further encountered a floor effect. Second, it is possible that the constraining dispositions were entrenched enough already so that attempting to entrench them yet further with a brief intervention did not succeed.

An interesting finding was that for the facilitating group, the degree to which participants completed the training determined their success in solving the first

insight problem. It is likely that only the participants in the facilitating group who fully completed the training were able to successfully transfer what they had learned during training to solving the insight problems. This finding shows that despite common difficulties for participants in solving CD problems, there exists individual variation in the degree to which participants can be guided to overcome these difficulties.

Where would people acquire the two central dispositions to want to turn on a dot and to draw outlines? The first disposition might stem from yet another Gestalt concept, the difference between figure and ground. The dots on the paper is the figure and the paper is the background and hence not part of what they are working on. The disposition to draw outlines might be grounded in how people draw when they try to make representational drawings; they trace the outline of the object they are trying to represent. Even if plausible sources can be identified for these two constraints, it remains to prove that they are operating in the nine-dot problem itself as well as in the altered versions we used in this study.

Another reason that people find the nine-dot and related CD problems difficult is that their prior experience in solving CD problems is based in children's connect-the-dot puzzles. This experience is irrelevant to the knowledge that is needed to solve the nine-dot problem. Prior knowledge creates unconscious biases that are not always helpful (cf. Ohlsson, 1984b, 1992; Wiley, 1998). The presentation of a problem can interact with prior knowledge, thus resulting in an incorrect and unhelpful encoding of the problem.

What is of most interest in studies on CD problems is to comprehend how people can get stuck on such trivial problems. To understand how the human mind works, we must understand unhelpful interactions between problems and prior knowledge, the impasses that result, and how people overcome those impasses by relaxing the inappropriate constraints. Insight problems are tools with which to study these processes.

Abstract

Progress in science is marked by the formation of theories that explain a body of observations. Contrary to this guiding philosophy, clinical psychologists have prescribed to an atheoretical system of diagnostic reasoning since 1980. We report two studies demonstrating that clinicians have not internalized atheoretical reasoning despite the system's widespread acceptance. The results show that clinicians' own theories about disorders significantly affect their diagnoses of hypothetical patients and memory for symptoms. Clinicians are cognitively driven to form and apply theories to observations despite decades of deliberate training, practice, and pressure to reason atheoretically.

Introduction

Philosophers of science have argued for decades that scientific progress is delineated not merely by the amassing of observations, but rather by the formation of broad principles that organize and explain these observations in a cohesive manner (Hempel, 1965). Evolutionary theory, for example, is regarded as a revolutionary advance in organismic biology in large part because it provides a deeper structure for a scientific taxonomy of living things, moving away from classification based on superficial features. Data are measured and considered within the larger structure of this overarching theory. Similarly, the human mind constantly seeks out underlying rules and principles that make sense of incoming data concerning the surrounding world. Adults (Murphy & Medin, 1985), children (Gelman, 2000; Keil, 1989), and even infants (Marcus, Vijayan, Rao, & Vishton, 1999) spontaneously extract and apply underlying organizing principles and abstract rules that go beyond surface features. In this way, the human mind forms categories and concepts based on its theories about the surrounding world (Carey, 1985).

Atheoretical versus theory-based reasoning

In contrast, the current *Diagnostic and Statistical Manual of Mental Disorders* (APA, 1994), prescribes an atheoretical approach to diagnosing mental disorders (Follette & Houts, 1996). Most mental disorders lack a single universally acknowledged pathogenesis, which in the past led to unreliability between clinicians in diagnosis. The *DSM-IV*'s (APA, 1994) widely acclaimed solution is to eliminate theory use altogether when making a diagnosis, incorporating instead checklists of symptoms compiled by a panel of experts. In doing so, it represents each disorder as a list of unrelated symptoms, ignoring the causal relations between symptoms that are a fundamental aspect of theory representations (Carey, 1985). For most disorders, the *DSM-IV* (APA, 1994) states that a subset of the list is sufficient for a diagnosis regardless of which combination of symptoms appears, thereby assuming that all symptoms in the list are equally central to the disorder. For example, any 2 of the following 5 symptoms warrant a diagnosis of schizophrenia, according to the *DSM-IV*: hallucinations, delusions, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms. Since eliminating any overt mention of an underlying theory for the taxonomy two decades ago (APA, 1980), the *DSM* system has become widely accepted in the U.S., forming the core of research, clinical assessment, diagnosis, and treatment in psychopathology. Research funding, journal titles, and health care reimbursements are all organized by, and dependent on, use of the categories defined by the *DSM-IV* (APA, 1994).

Has the *DSM* system succeeded in internalizing atheoretical reasoning in clinicians? An atheoretical approach would suggest that experienced clinicians, after years of emphasizing use of the *DSM* system, will come to embody its prescription of atheoretical reasoning (APA, 1994). In contrast, the theory-based approach would suggest that clinicians, despite such emphasis on the elimination of theory, are still influenced by their own idiosyncratic theories about disorders when reasoning about them (Medin, 1989).

The two approaches were differentiated by testing for the presence or absence of the causal status effect, a specific mechanism by which theory-based reasoning occurs (Ahn, 1998; Ahn, Kim, Lassaline, & Dennis,

2000). The causal status effect is said to occur when category features causally central to an individual's theory of that category are treated as more important in categorization than less causally central features. For instance, if symptom A causes symptom B in a clinician's theory, then A is more causally central than B, and A is thereby predicted to have greater diagnostic importance than B. To derive the causal centralities of individual symptoms imbedded in a complex theory, the following formula[1] can be used:

$$c_{i,t+1} = \Sigma_j \, d_{ij} \, c_{j,t} \quad (1)$$

where d_{ij} is a positive number that represents how strongly symptom j depends on symptom i, and $c_{j,t}$ is the conceptual centrality of feature j, at time t (Sloman, Love, & Ahn, 1998). This model states that the centrality of feature i is determined at each time step by summing across the centrality of every other feature multiplied by that feature's degree of dependence upon feature i. Thus, in the current studies we operationalized the theory-based view as a systematic effect of relational structures on conceptual representation and use.[2]

A theory-based view would further predict that any features relationally connected to other features would be treated as more important than isolated features in reasoning (Gentner, 1983). That is, if symptom A causes symptom B, but symptom C is isolated (it does not and is not caused by any other symptoms in a clinician's theory), C would be the least central symptom of the three.

Study 1

We measured expert and trainee clinical psychologists' causal theories in the first session. Then we examined whether the causal centralities of symptoms in their theories predict how important these symptoms are in diagnosis (in the first and second sessions), and how well they are remembered (in the second session).

Participants

Participants were 11 experienced clinical psychologists, and 10 clinical psychology graduate students. The experienced clinical psychologists had been in practice for a minimum of 15 years (ranging from 15 - 52 years with a median of 28 years). Ten were licensed psychologists with Ph.D.'s, and 1 was a board-certified psychiatrist with an M.D.

Session 1: Measurement of causal theories and conceptual centrality

We measured participants' individual causal theories for each of 5 disorders that were judged to be highly familiar by undergraduate students. The 5 disorders were Anorexia Nervosa, Antisocial Personality Disorder, Major Depressive Episode, Specific Phobia, and Schizophrenia.

In an initial disorder defining task, participants viewed a list of symptoms for each disorder. Symptoms included both the *DSM-IV* (APA, 1994) diagnostic criteria and the non-criterial, characteristic symptoms from the manual's disorder description. Participants were asked to define each disorder for themselves by adding new symptoms, crossing out symptoms, combining two or more symptoms, and / or dividing a single symptom into two or more symptoms.[3] All subsequent tasks in both sessions incorporated these individually tailored lists.

Participants' causal theories were then measured for each disorder. Participants received slips of paper, each bearing the name of a symptom. They were first asked to arrange the symptoms around the corresponding disorder name. Next, participants drew arrows between symptoms to indicate causal relations as they thought was appropriate. Finally, they rated the strength of each causal relation on a scale of 1-5 (1=very weak; 5=very strong). From these causal drawings, we determined the causal centrality of each symptom using Equation (1). Isolated features were always assigned the lowest causal centrality.

During this session, we also measured the conceptual centrality of each symptom to the disorder. Clinicians were asked, "how easily can you imagine a person with [disorder X] who does not have the symptom of [Y]?" for each symptom on a scale of 0-100 (0=very difficult to imagine; 100=very easy to imagine). The order of the two tasks, conceptual centrality and causal theory measurement, was counterbalanced between participants. The results demonstrated that conceptual

[1] Although other formulas are also consistent with the causal status effect, this formula showed the best fit in analyses of lay people's conceptual representations of common objects (e.g., apples and guitars; Sloman et al., 1998). Moreover, all of the analyses on causal centrality reported below are based on rank orders of causal centrality derived from this formula, and different formulas do not produce radically different rank orders.

[2] We do not intend to claim here that theory-based categorization is limited to the effect of relational structures. Categorization may also be affected by the content of relations, an issue that was not the focus of the current studies.

[3] For instance, a participant might choose to divide the single symptom "disturbed experience of body shape or denial of the problem" into separate symptoms ("disturbed experience of body shape;" "denial of the problem").

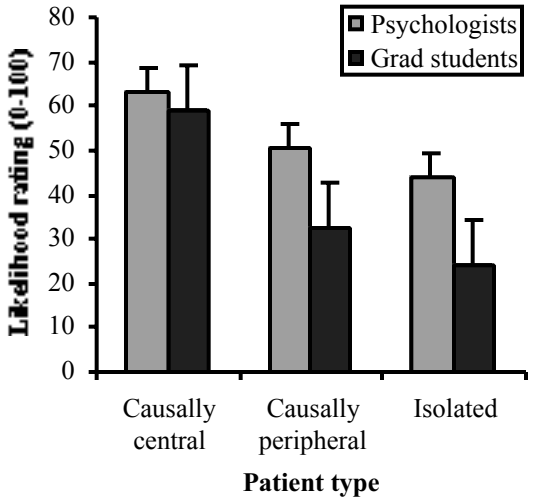

Figure 1. Clinical psychologists' and clinical graduate students' likelihood ratings of mental disorder category membership for hypothetical patients in Study 1. Error bars indicate standard errors.

centrality was positively correlated with causal centrality (as determined by Equation [1]) for 18 out of 20 participants,[4] such that the more causal a symptom was within each participant's theories, the more central the symptom was to that participant's concept of the disorder. The median overall correlation coefficients for clinical psychologists and graduate students were .41 (range: -.12 to .50) and .27 (range: .11 to .62), respectively.

Session 2: Hypothetical patient diagnosis and free recall of symptoms

Participants were brought back to the lab about 10 - 14 days after the first session. For the second session, we created a unique set of hypothetical patients for each participant based on that participant's own theories as reported in the causal centrality task. Two to three hypothetical patients were constructed for each of the 5 mental disorder categories. Each patient was composed of three symptoms that were either causally central or causally peripheral as determined by Equation (1), or isolated[5]. For example, causally central patients consisted of three symptoms causally central to the participant's theory of the disorder (i.e., they were thought to cause more symptoms more strongly than other symptoms did). Participants were told that these patients did not exhibit any other symptoms. The number of *DSM-IV* (APA, 1994) diagnostic criteria was equated over the types of patients. Therefore, according to strict *DSM-IV* (APA, 1994) criteria, each of the three different types of hypothetical patients should be equally likely to have the disorder in question.

We asked participants to rate the likelihood that each of these hypothetical patients actually had the associated disorder. Specifically, for each hypothetical patient, participants answered the question, "what is the likelihood, in your opinion, that a patient with the following characteristics has [disorder X]?" on a scale of 0-100 (0=very unlikely; 100=very likely).

Although the number of criterial symptoms according to the *DSM-IV* (APA, 1994) was equated across the three types of patients, participants judged patients with causally central symptoms (mean of 61.0) as nearly 20% more likely to have the disorder than patients with causally peripheral symptoms (mean of 42.0; $t = 4.5$, $p < .001$). Patients with isolated symptoms were judged as least likely to have the disorder (mean of 34.5; $t = 3.3$, $p = .003$). Figure 1 shows the results broken down by expert and trainee participant groups. There was neither a significant main effect of expertise nor any significant interaction involving expertise.

Approximately one hour after they completed the hypothetical patient diagnosis task, participants were asked to recall the symptoms of those hypothetical patients. Participants recalled significantly more causally central (67%) than causally peripheral (51%; $t = 2.9$, $p = .009$) or isolated (44%; $t = 2.7$, $p < .02$) symptoms.

Study 2

Study 2 expanded the generality of these findings using modified procedures. There were two principal changes. First, the causal centrality task was modified to measure participants' theories about all kinds of symptom-symptom relations, not restricting the measure to causal relations only. Second, another aspect of memory for symptoms was examined by using a recognition task instead of the recall task. These changes will be described in detail in the following sections.

Participants

Participants were another group of 14 experienced clinicians and 6 clinical psychology interns. The expert clinicians had been in practice for a minimum of 15 years (ranging from 17-43 years with a median of 26 years). All 14 expert clinicians were licensed psychologists; 13 had Ph.D.'s and 1 had an Ed.D.

[4] The data of one graduate student participant could not be included in this particular analysis because there was no variance among that participant's conceptual centrality responses within each disorder.

[5] Some participants left no symptoms isolated in their theory of a disorder. In these cases, a patient description composed of isolated symptoms could not be created.

Stimulus materials

The same 5 disorders in Study 1 were also utilized in this study. Unlike in Study 1, however, participants were provided with a list of "standard" symptoms. These symptoms were defined by the participants in Study 1. Namely, a symptom was dropped from the list of symptoms for Study 2 if it was dropped by over 50% of the experts and over 50% of the trainee participants in Study 1. Using these standard lists of symptoms allowed us to make direct comparisons between participants' theories, especially between those of experts and trainees.

Session 1: Measurement of relational theories and conceptual centrality

We measured participants' individual theories for each disorder using the same procedure as before, except that this time we asked participants to draw any kind of relations between symptoms they saw fit, not limiting the measure to causal relations. Participants rated the strength of each relation on a scale of 1-3 (1= weak; 2=moderate; 3=strong). They were asked to consider using, but not to limit themselves to, the following relations: "is a subset of," "is an example of," "precedes," "co-occurs with," "is a precondition for," "causes," "jointly cause," "affects," "determines the extent of," "increases," "decreases," "is a catalyst for," "is used as a defense against," "is a cure for." The relational centrality of each symptom was then determined using Equation (1). For instance, in applying the formula, "A is a precondition for B" and "A precedes B" are treated as "B depends on A." We used these relational centralities to further investigate clinicians' and clinical trainees' use of theories in reasoning with three modified measures of diagnostic importance and memory. During the first session, we also measured the diagnostic importance of each symptom to the disorder. Participants were asked, "how important is the symptom of [Y] in diagnosing a person with [disorder X]?" on a scale of 0-100 (0=very unimportant; 100=very important). As in Study 1, the order of the two tasks was counterbalanced between participants. The results demonstrated that diagnostic importance was positively correlated with relational centrality (as measured by Equation [1]) for 18 out of 20 participants (average r = .77, clinical psychologists; r = .66, interns). That is, the more symptoms depended on a symptom, the more central that symptom was to participants' concepts of the disorder. The median overall correlation coefficients for psychologists and graduate students were .25 (range: .02 to .61) and .44 (range: -.94 to .68), respectively.

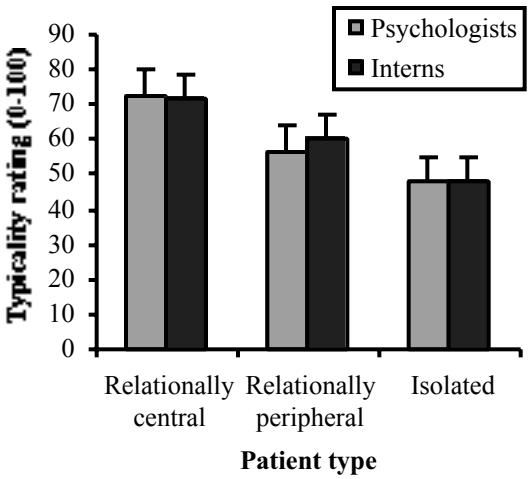

Figure 2. Clinical psychologists' and clinical psychology interns' typicality ratings for hypothetical patients in Study 2. Error bars indicate standard errors.

Session 2: Hypothetical patient typicality and recognition of symptoms

As in Study 1, we constructed 2 to 3 hypothetical patients for each of 5 mental disorder categories. Each patient consisted of a set of three symptoms that were either relationally central, relationally peripheral, or isolated, for each disorder and each participant. As in Study 1, a patient composed of isolated features was not included if a participant did not leave any symptoms isolated in their theory. Again, the number of criterial symptoms was equated between patients so that diagnoses based strictly on the *DSM-IV* (APA, 1994) would not differentiate them. Participants were asked to assess how typical hypothetical patients were of the disorder (following Cantor, Smith, French, & Mezzich, 1980). Specifically, participants answered the standard typicality rating question, "how well, in your opinion, does a patient with the following characteristics fit in the diagnostic category of [X]?" on a scale of 0-100 (0=very poorly; 100=very well) for each patient. Patients with relationally central symptoms (mean of 72.3) were judged as more typical of the disorder than patients with relationally peripheral symptoms (mean of 57.8; $t = 4.3$, $p < .001$), which in turn were judged as more typical than patients with isolated symptoms (mean of 47.9; $t = 2.7$, $p < .02$). Figure 2 shows the results broken down by experts and trainees. Neither a significant main effect of expertise nor an interaction effect involving expertise was found.

Following an approximately one-hour delay, participants received a standard recognition task (following Roediger & McDermott, 1995), in which they were asked to classify symptoms on a list as "old" or new" based on whether they had seen them earlier in the hypothetical patients task. The list included 30

relationally central and 30 relationally peripheral symptoms. Half of the symptoms in each group were old and half new. Consistent with previous findings showing an effect of schema on false recognition (Bower, Black, & Turner, 1979), participants were much more likely to falsely recognize new, relationally central symptoms as symptoms that they had seen before (23.3%) than new, relationally peripheral symptoms (13.2%; t = 3.0, p = .008). Participants showed greater sensitivity to relationally peripheral symptoms (d' = 2.62) than to relationally central symptoms (d' = 2.04; F[1, 18] = 2.43; p = .01). Thus, participants were less able to distinguish between presented and non-presented relationally central symptoms. False memory has generally been thought to be an issue for patients with psychological disorders or problems (Loftus & Ketcham, 1994). Interestingly, we found that therapists are biased to falsely remember having seen symptoms in their patients that are central to their personal theories about the disorder.

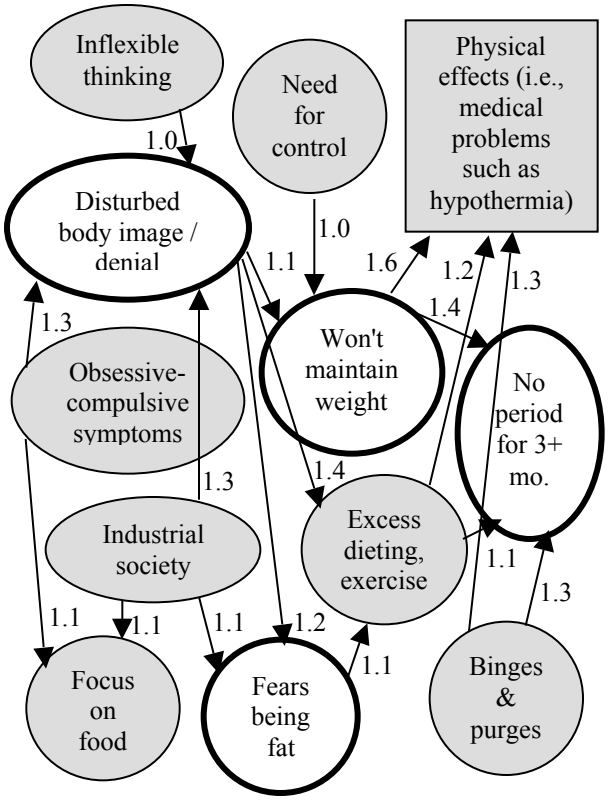

Figure 3. Participants' average relational theory of Anorexia Nervosa in Study 2. (Note: An arrow from A to B indicates that B depends on A [or A affects B]. The symptom descriptions in the figure were truncated and sometimes combined to keep the figure readable. Only dependency relations that received mean strength ratings greater than 1 on a 3-point scale are shown in the figure. Symptoms in white circles with boldface borders are *DSM-IV* (APA, 1994) diagnostic criteria. The *DSM-IV* implies that these are not weighted differently.)

Consensus on theories

Unlike in Study 1, all participants received the same set of symptoms, allowing a direct comparison of their theories. Participants' theories, as measured by relational centrality rank orders, were highly consistent with each other (Kendall's coefficients of concordance ranging from .34 to .59 across the 5 disorders, all p's < .0005). Because of this, we were able to construct an average dependency structure for each disorder, such as the one shown in Figure 3 for Anorexia Nervosa.

These average theories of experts generally agreed with those of lay people. For instance, the mean rank orders of diagnostic criteria symptoms for major depression obtained in an earlier study from undergraduate students (Kim & Ahn, 2001) were highly correlated with those obtained from clinicians and clinical trainees in Study 2 (r = .93, p < .001). We also developed hypothetical patient descriptions based on clinicians' and clinical trainees' averaged theories of the 5 disorders and gave them to 23 undergraduates. Relationally central patients (mean of 75.3) were judged to be more typical of a disorder than relationally peripheral patients (mean of 29.3; t = 12.44, p < .001).

Discussion

In sum, we found that symptoms playing a central role in clinicians' theories were considered to be more important in diagnosis, were more likely to be recalled later, and were more likely to be falsely recognized as having been present in patient descriptions. Despite the fact that the modern *DSM* system, which has become engrained into the conscious practice of clinical psychology, avoids the use of theory, clinicians prefer to base their reasoning on their own organizing theories. This was shown at a much more specific level of analysis than previous work documenting top-down effects of theory on reasoning (i.e., Chapman & Chapman, 1967; Wisniewski & Medin, 1994). Furthermore, in all six measures, there were no differences between levels of expertise, suggesting that years of training and long-term use of the modern *DSM* system do not diminish the effect of theory on reasoning.

Implications

When making formal *DSM* diagnoses using checklists, it is possible that clinicians may not be as strongly affected by their theories. However, the effect of theory-based conceptual representations found in the current studies may still pervade critical aspects of clinical work. As shown in our study, clinicians are

better at recalling symptoms central to their theories, and may be biased to falsely remember theory-central symptoms of patients they have already seen. These tendencies may influence clinicians' informal initial diagnoses, which may in turn markedly affect how clinicians subsequently perceive and interact with their patients. For instance, symptoms of mental disorders are often ambiguous, and clinicians may focus their attention on detecting symptoms central to their theories.

We also note that theory-based reasoning in itself is not a reasoning fallacy, provided that clinicians' theories are valid (Dawes, Faust, & Meehl, 1989). However, in the case of less well-known disorders such as personality disorders, experts may have more idiosyncratic theories. This, if true, may account in part for the notoriously low reliability between clinicians in diagnosing the personality disorders. We are currently conducting a study to examine this issue. In cases such as these, reliance on invalid theories may perhaps constitute a fallacy in clinical judgment.

In general, however, categorization based on valid theories conforms to the higher levels of taxonomy that scientists should strive for (Hempel, 1965). Indeed, symptoms that explain and cause other symptoms may be the most important ones to attend to and remember, because they may be the more useful predictors for prognosis and treatment. In the current study, we found clinicians' theories to be in general agreement with each other's and with lay people's theories, at least in disorders that are also familiar to lay people. This suggests that experts' theories of these socio-culturally familiar disorders are not highly idiosyncratic, but rather seem to be based on commonsense notions, and may therefore be worthy of careful consideration in revising the *DSM*.

Abstract

The effect of typicality of category exemplars on naming performance was investigated using a single subject experimental design across participants and behaviors in four patients with fluent aphasia. Participants received a semantic feature treatment to improve naming of either typical or atypical examples, while generalization was tested on the untrained examples of the category. The order of typicality and category trained was counterbalanced across the participants. Results indicated that patients trained on naming of atypical examples demonstrated generalization to naming of intermediate and typical examples. Patients trained on typical examples demonstrated no generalization to naming of intermediate or atypical examples. Implications for models of typicality and rehabilitation of aphasia are discussed.

Introduction

Aphasia is a language disorder that results from damage (such as stroke or head trauma) usually to the left hemisphere of the brain. Naming difficulty is the most common form of language deficit noted in individuals with aphasia. One widely accepted model of naming (Dell, 1986; Stemberger, 1985) suggests that activation of a word during naming involves two closely interacting levels, activation of the semantic representation as well as activation of the phonological form of the target word. Naming deficits can therefore arise from difficulty in activation at either of the two levels. Patients with naming deficits arising from an impairment in activating semantic representations often present with impairments in accessing appropriate semantic fields within categories (Goodglass & Baker, 1976).

Numerous studies on normal individuals have found typical examples of a category to be accessed faster and more accurately than atypical examples, an effect labeled the typicality effect (Rips, Shoben, & Smith, 1973; Rosch, 1975). Evidence for the typicality effect exists through typicality ratings (Rosch, 1975), response times on category verification tasks (Larochelle & Pineu, 1994), and category production frequency (Rosch, 1975). Little evidence, however, exists regarding representation of typicality in individuals with aphasia, although some investigations have noted deficits (Grober et al., 1980; Grossman, 1981). The interpretation of these deficits with reference to theoretical models of typicality however has not been addressed.

In a connectionist account of relearning in neural networks, it was found that a lesioned computer network retrained on atypical examples resulted in improvements on typical items as well (Plaut, 1996). Training typical items, however, only improved the performance of those items while performance of atypical words deteriorated during treatment. While Plaut's findings have not yet been tested in individuals with aphasia, the prospect of such generalization effects is especially significant for treatment of naming deficits, since most naming treatments have found little generalization to untrained items (McNeil et al., 1997; Pring et al., 1993).

The present experiment aimed to investigate the effects of exemplar typicality on naming performance in individuals with aphasia. Specifically, the purpose of the experiment was to train naming of a set of typical or atypical examples of a superordinate category, and examine generalization to untrained examples of the category. The present experiment was motivated by prototypical/family resemblance models of typicality (Hampton, 1979; Rosch & Mervis, 1975). According to these models, on a multidimensional scaling of a category (e.g., bird) based on similarity of items, typical examples (e.g., robin, sparrow) are found to have more features similar amongst them and with the category prototype, and therefore are represented closer to the center of the semantic space. In contrast,

atypical items (e.g., penquin, ostrich) have fewer features that are similar amongst them and the prototype, and are at the periphery of this semantic space. We hypothesized that training aphasic individuals to produce atypical examples from a category would result in generalization to more typical examples of the category. If indeed atypical examples are at the periphery of the category, then strengthening access to these examples by emphasizing the variation of semantic features across the category would strengthen the overall semantic category. Conversely, typical examples were hypothesized to represent little or no variation within the category. Therefore, training typical examples was predicted to improve only items at the center of the category, with no improvements expected for atypical examples.

Methods

Participants

Four individuals, ranging in age from 63-75 years, and presenting with aphasia resulting from a cebrebrovascular accident to the left hemisphere were selected for the experiment. All four patients presented with fluent aphasia, characterized by fluent circumlocutory speech, mild auditory comprehension deficits and severe naming difficulties. Based on standardized language testing, the locus of naming deficit was attributable to impairments in accessing the semantic representation of the target, and/or in accessing its phonological form.

Stimuli

Norms for typicality of category exemplars were developed prior to initiation of the experiment. One group of 20 normal young and elderly subjects constructed as many examples as possible for ten categories, while another group of 20 normal young and elderly subjects rated the typicality of these examples on a 7-point scale. Examples for each category were then divided into three groups, typical, intermediate and atypical, based on their average z scores. Based on several selection criteria, which included frequency, distinctiveness, number of syllables, unambiguity regarding category membership, two categories (birds and vegetables) with 24 examples each were selected for treatment. Each set of 24 items included a subset of eight typical and eight atypical items. The remaining eight in each set were determined to be intermediate in terms of typicality. For each of the selected examples, corresponding color photos printed on 4 x 6 inch cards were selected. In addition to the experimental photos, stimuli from three different superordinate categories (fruit, animal and musical instrument) were selected to serve as distracters for treatment.

Once the two categories and their 24 examples were selected, semantic features for each category were developed. For each category, a minimum of 20 features belonging to the category that were either physical, functional, characteristic or contextual attributes were selected. Additionally, a minimum of 20 distracter features to be used during the yes/no question tasks (see treatment), using the same four attribute types not belonging to the target category were developed. At least 10 features that were applicable to all examples in the category were selected (e.g., bird: has a beak, lays eggs), while obscure features (e.g., asian food for vegetable), and features that were salient only for a single example (e.g., hoots for owl, drills holes for wood pecker) were eliminated. Generally, features that were applicable to two or more items in the category were selected. Distracter features belonging to the categories sport, transportation, animal, insect, flower and weapon were selected using the same criteria as the target category features.

Design

A single subject experimental design with multiple baselines across behaviors and participants (Connell & Thompson, 1986) was employed. In such an experimental design, effects of treatment are assessed at regular intervals for each patient separately. In the present study, as treatment was extended to atypical or typical members of a superordinate category, generalization to the remaining examples was examined. The emergent naming patterns provided information regarding the re-organization and representation of semantic categories.

Prior to application of treatment, during the baseline phase, naming of all 48 examples of two categories (N = 24) was tested. Picture naming was then trained using selected examples of one superordinate category, with the order of categories and exemplar typicality counterbalanced across participants. During treatment, naming of all 24 examples in the category were assessed every second treatment session. These naming probes constituted the dependent variable in the study and naming accuracy over time was assessed. See table 1 for order of treatment for the four patients.

Criteria for acquisition of naming of trained items was 7/8 items named correctly on two consecutive naming probes. Generalization to naming of untrained examples was considered to have occurred when a 40% change over baseline levels was noted for untrained examples. If generalization to naming of untrained items was observed, treatment was shifted to the second category. If generalization to naming of untrained items was not observed, treatment was shifted to the next group (i.e., intermediate) within the same category.

Table 1: Order of treatment for the four participants

	P1	P2	P3	P4
Order of treatment				
1.	Birds 1.Typical 2. Inter 3.Atypical	Birds 1 Atypical 2. Inter 3.Typical	Vegetables 1.Typical 2. Inter 3.Atypical	Vegetables 1.Atypical 2. Inter 3.Typical
2.	Vegetables 1.Typical 2. Inter 3.Atypical	Vegetables 1.Atypical 2. Inter 3.Typical	Birds 1.Typical 2. Inter 3.Atypical	Birds 1.Atypical 2. Inter 3.Typical

Treatment

For each participant, one subset of items within a category (typical, intermediate or atypical) was trained at a time. In each treatment session, participants practiced the following steps for each of the eight examples of a subset: a) naming the picture, 2) sorting pictures of the target category (N=24) with three distracter categories (N=36), 3) identifying 6 semantic attributes applicable to the target example from a set of 35 features of the superordinate category, 4) answering 15 yes/no questions regarding the presence or absence of a set of semantic features about the target example. Distracters on this task included semantic features from the target category not applicable to the target, and features from unrelated superordinate categories.

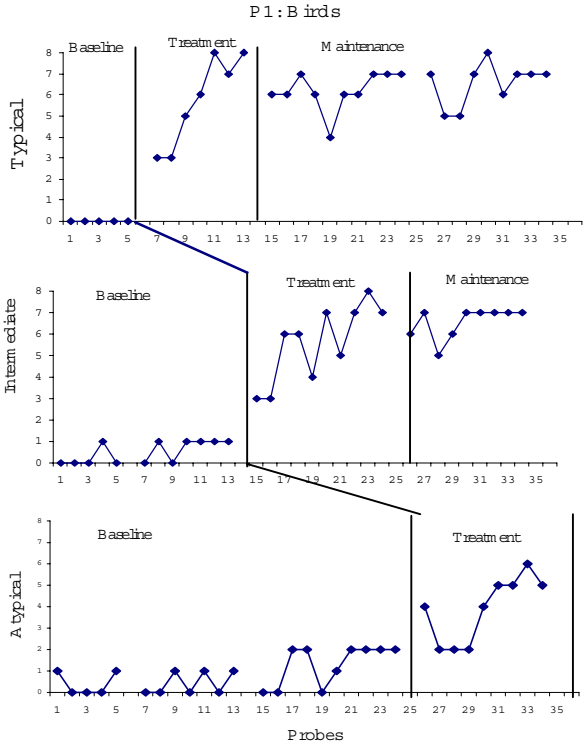

Figure 1. Naming accuracy on typical, intermediate and atypical items for the category birds for Participant 1

Results

Participant 1 Following five baseline sessions, treatment was initiated on typical items on the category birds. While naming of typical items improved to criterion (7/8 for two consecutive sessions), generalization to naming of intermediate or atypical examples was not observed. Treatment then was shifted to intermediate examples, following which improvement was observed on those items with no changes noted for atypical examples. Once criterion was achieved for intermediate examples, treatment was finally shifted to atypical examples and improvement was noted for the trained atypical items (see Figure 1). Administration of probes at phases denoting change of treatment set revealed no changes in items of vegetables.

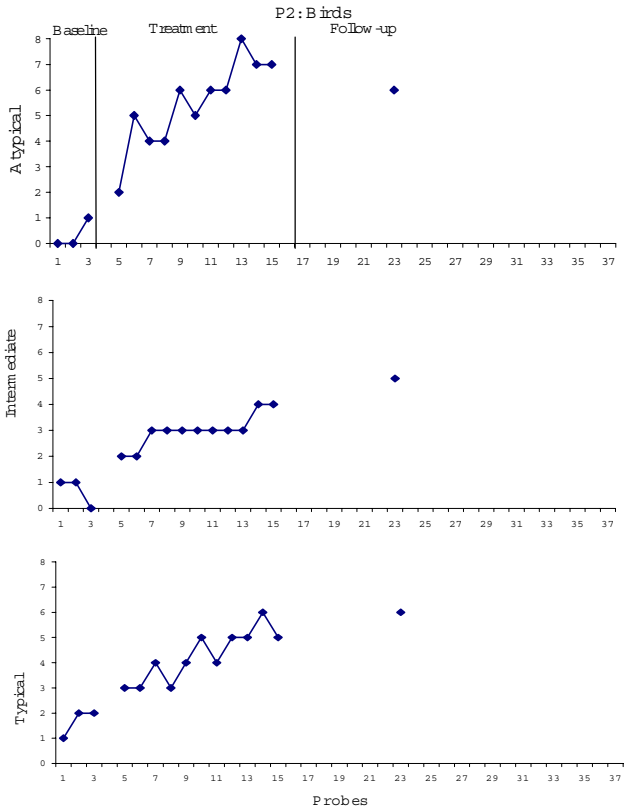

Figure 2. Naming accuracy on typical, intermediate and atypical items for the category birds for Participant 2

Participant 2 Following three baseline sessions, treatment was initiated for atypical examples of birds. Performance on naming of atypical examples improved to criterion (7/8 for two consecutive sessions), while generalization to naming of intermediate and atypical examples was noted (see Figure 2). Treatment then was shifted to vegetables. Following two baseline sessions, treatment was initiated on atypical examples of vegetables. Acquisition of atypical items for vegetables

was observed, and once again, generalization was noted for intermediate and typical examples, denoting replication within the participant across categories. Follow up probes administered within six weeks of completion of treatment indicated maintenance levels comparable to treatment levels.

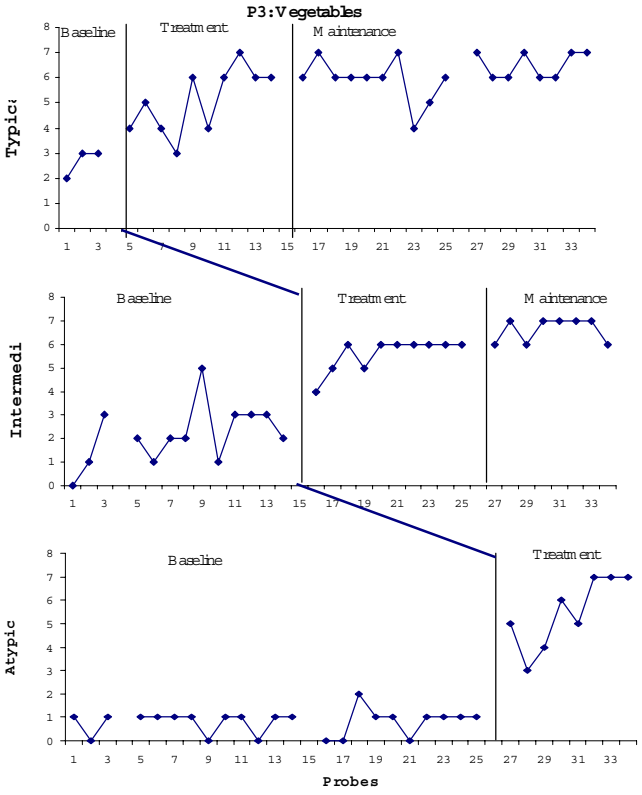

Figure 3. Naming accuracy on typical, intermediate and atypical items for the category vegetables for Participant 3

Participant 3 Following three baseline sessions, treatment was initiated on typical examples of vegetables. While an acquisition curve for typical items was discernible, criterion of 7/8 accuracy for typical examples was not achieved after 20 treatment sessions. Treatment was then shifted to intermediate examples, once again acquisition of trained items was noted but criterion was not achieved. Finally, treatment was shifted to atypical examples. Performance on those items reached criterion, while performance on typical and intermediate items was maintained (see Figure 3). Administration of probes at phase change revealed no changes in items of birds. For both participant 1 and participant 3, due to the extended duration, treatment was discontinued after completion of the first category.

Participant 4 Following five baseline sessions, treatment was initiated for atypical examples for vegetables. Performance on naming of atypical examples improved to criterion, with generalization noted on intermediate and atypical examples (see Figure 4) Treatment then was shifted to birds. Following two baseline sessions, treatment was initiated on atypical examples of birds. Acquisition of atypical items for birds was observed, while once again, generalization was noted for intermediate and typical example, once again providing a replication within participant across categories. Follow up probes administered within six weeks of completion of treatment indicated maintenance levels comparable to treatment levels.

Discussion

The present experiment demonstrates that training atypical examples of a category and their semantic features results in generalization to naming of intermediate and typical examples of the category. This finding was observed in Participants 2 and 4 across two categories even when the order of categories was counterbalanced across the two participants. Training typical examples and their semantic features, however, did not result in generalization to the intermediate and atypical examples, as observed in Participant 1 and 3.

These findings suggest that because atypical examples are dissimilar to one another and to the category prototype, these examples collectively convey

more information in terms of semantic features about the variation that can occur within the category than do typical examples. Heightening access to featural information relevant to semantic categories, therefore facilitate access to more typical items within a category. While it has been demonstrated that greater coverage of a category's features can lead to stronger inductive generalizations (Sloman, 1993), current models of typicality do not explain the treatment effects observed in the present experiment. For instance, findings of the present experiment cannot be explained by the two-stage feature comparison model (Smith, Shoben, & Rips, 1974), since this model only explains category membership and not exemplar access.

Similarly, prototype/family resemblance models (Hampton, 1979; Rosch & Mervis, 1975) suggest that categories are represented by a set of weighted semantic features as a function of typicality, but do not explicitly state the relation between these summary feature representations and the phonological representations of specific examples. Moreover, prototype models do not specify how the various examples in a category are connected to each other, an element crucial to the explanation of the present experiment.

Exemplar models (e.g., Heit & Barsalou, 1996) come closest to explaining the results of the present experiment in that typical and atypical examples are represented as specific instances in the category that have been previously encountered. Therefore, it can be assumed that these specific representations are associated with their phonological representations. However, if examples of a category are represented as abstractions of specific instances, the exemplar models do not explain why training semantic features of atypical examples would result in improvements in naming of typical examples.

In summary, although all models of typicality explain possible differences in the representation of typical and atypical examples, they do not predict why training semantic features of atypical examples would improve phonological access of not just atypical examples but of intermediate and typical examples as well. More importantly, these models do not predict why training semantic features of typical examples would result in no improvement in the phonological access of intermediate and atypical examples. Even Plaut's connectionist model (1996), which motivates the present experiment, does not explain the mechanism involved in accessing improved phonological forms. This model describes a reading via meaning task with four layers, orthographic input layer, intermediate layer, a semantic layer and clean up layer. To generate semantic features, the prototype represents a set of semantic features (or binary values) with a high probability of becoming active. Typical examples share most of their features with the prototype, while atypical examples share few features with the prototype. Therefore, while this model provides an explicit account on the extent of difference between typical, atypical examples and the prototype, the nature of these features (whether defining or characteristic), and the nature of the examples (whether summary representations or specific instances) are also unclear.

Any explanation for the present experiment should therefore account for the following: (a) effects of treatment on improvements in semantic feature representation, (b) influence of strengthened semantic representations on access to phonological forms, (c) selective strengthening of connections between atypical and typical phonological representations (and not the other way around). A combination of interactive activation models (Dell, 1986; Stemberger, 1985) and prototype models of typicality provide such an explanation. Two levels of representation are hypothesized, semantic and phonological, and the connections between the semantic and phonological levels are bi-directional and excitatory while connections within each level are inhibitory. Within the semantic level, each example of a category (e.g., bird) is a summary representation of weighted semantic features, which interfaces with the lexical representation of the example. Items that are typical exert greater lateral inhibition on other examples within the category, due to their similarity with the category prototype. Less typical items exert less lateral inhibition on corresponding examples. This is because less typical items are dissimilar from the category prototype and illustrate the variation of semantic features that can exist (e.g., cannot fly, lives near water). Training semantic features of atypical examples strengthens their corresponding lexical representation and by the nature of the weak lateral inhibition, strengthens the representations of intermediate and typical examples as well. These strengthened semantic representations exert an excitatory influence on their corresponding phonological representations, which are raised above a resting threshold level. It is hypothesized that items directly trained receive a greater unit of activation to cross the resting threshold than untrained items.

Training typical examples on the other hand, only strengthens the semantic representations of the typical examples, and since these features convey no information about the variation of semantic features that can occur in the category, they have no influence on the semantic representations of intermediate and atypical examples. Therefore, the lateral inhibition exerted by the semantic representations of typical examples on intermediate and atypical examples does not reduce following treatment. Consequently, only the strengthened typical representations can successfully raise their corresponding phonological representations

above the resting threshold. The unchanged semantic representations for intermediate and atypical examples, can exert no excitatory influence on their corresponding phonological representations, and therefore have to be trained directly in treatment to be named successfully. These hypotheses are currently being tested using a connectionist network simulation.

Finally, results of the present experiment have significant implications for rehabilitation in aphasia. These results, although counter-intuitive to traditional treatment approaches, suggest that training naming of atypical examples is a more efficient method of improving naming items within a category than training typical items. Interestingly, training more complex items which encompass variables relevant to simpler items have been demonstrated in other language domains. Training complex syntactic structures results in generalization to simpler ones in agrammatic aphasic patients (Thompson, Ballard & Shapiro, 1998; Thompson et al., 1997) and training complex phonological forms results in improvements to simpler forms in children with phonological deficits (Gierut et al., 1996, 1999). These results also provide important insights into the mechanisms of relearning in patients with brain damage. In these individuals, it is assumed that language organization is fractionated following brain damage. The goal of language treatment is then to compensate and maximize the use of spared functions. The results of the present experiment suggest that relearning of category structure and corresponding phonological representations can be re-established in a more efficient way than previously thought.

Abstract

Statistical probability theory posits that we learn about regularly-occurring events in the perceptual environment by determining the likelihood of each event's occurrence (Aslin, Saffran, & Newport, 1998). The current study investigates infants' ability to extract properties of repetitive visual events and represent predictable combinations of visual elements. Using a novelty-preference paradigm, 2-, 5-, and 8-month-old infants were habituated to a continuous stream of colored shapes that were presented in a statistically predictable pattern, and then tested alternatively on the same sequence and a randomly-ordered sequence. The randomly-ordered sequence differed from the originally presented sequence only in between-shape transitional probabilities. At each age, infants demonstrated a significant novelty preference for the random sequence. In conjunction with Marcus, Vijayan, Rao, and Vishton (1999) and Saffran, Aslin, and Newport's (1996) work looking at statistical learning in language with 7- and 8-month-olds, these results can be taken as preliminary evidence of a domain general learning mechanism.

Introduction

One of the fundamental questions asked by developmental psychologists concerns how infants learn so much in so little time, with apparently very little explicit instruction. Research suggests that, as adults, we are remarkably good at implicit learning (e.g., see Stadler & Frensch, 1998 for a review of the implicit learning literature). Implicit learning can be defined as non-conscious facilitation of task performance due to information acquired during previous exposure. Given the robust nature of implicit learning skills in adults, it is perhaps a reasonable assumption that these skills play some role in early learning. The research on implicit learning in children suggests that they too show implicit sequence learning to the same degree as adults (Meulemans, Van der Linden, & Perruchet, 1998; Thomas, 1998). In other words, children showed increased reaction time in a task that contained a predictable sequence, and, like adults, did not have explicit knowledge of this sequence. There were no reports in the literature, however, with participants younger than 3 years of age until recent studies of statistical learning, a form of implicit learning based on statistical regularities in the perceptual environment.

Saffran, Aslin, and Newport (1996) and Alsin, Saffran, and Newport (1998) presented evidence that 8-month-old infants determine the statistical probability of neighboring speech sounds based on a 2-minute exposure. Infants heard four three-syllable "words" composed of 12 unique syllables (e.g., *tupiro*, *golabu*, *dapiku*, and *tilado*), presented in a continuous stream in random order (e.g., *dapikutupirotiladogolabutupiro ...*). Between-word spaces were removed, as were all other cues to word boundaries (e.g., rhythm, intonation, and stress). Thus, the only cues to word boundaries were the transitional probabilities between syllable pairs. For example, the transitional probability of *tu-pi* in this corpus is 1.00, because *pi* always follows *tu* within the word *tupiro*, whereas the probability of *ro-go* is .33, because *golabu* is one of three words that can follow *tupiro*.

After exposure, Saffran et al. (1996) presented infants with both familiar words from the corpus and "nonwords." Nonwords were created by combining the last syllable of one word with the first two syllables of a second word (e.g., *rogola* and *butupi*). Infants showed greater interest in the nonwords than in the words. On the logic that infants often exhibit a post-familiarization novelty preference (Bornstein, 1985), these results suggest that they detected the difference between words and nonwords. This outcome is necessarily based on learning of the transitional probabilities defining the stimuli.

This finding is consistent with a powerful statistical learning mechanism that supports language acquisition, and gives rise to questions concerning the generality of such mechanisms. It is possible, for example, that other kinds of knowledge are gained during infancy by learning statistical regularities in the environment. Indeed, Saffran, Johnson, Aslin, and Newport (1999) presented evidence that both adults and 8-month-old infants can perform the same statistics when presented with "words" consisting of non-linguistic tone sequences. These data suggest that statistical learning is not just a linguistic mechanism, allowing us to parse words from noise. If this is the case, then perhaps statistical learning is a mechanism that bolsters all sorts of learning in many different domains. Perhaps statistical learning is a domain general mechanism.

Following from this hypothesis the next logical step is to look at statistical learning in a non-auditory domain. The visual domain provides a lot of opportunities for patterns to present themselves, and the current study tested infants' ability to pick out statistical regularities in a stream of visual events. The data present evidence that 2-, 5-, and 8-month-old infants are able to extract properties of repetitive visual events in a way that allows them to represent a predictable combination of visual elements. Results from this series of studies showed that at each age, infants demonstrated a significant novelty preference for a visual sequence that differed from the originally presented sequence only in between-stimulus transitional probabilities.

Method

Participants

A total of 48 infants participated in this study: 16 infants at 2 months of age ($\underline{M}$ = 1.95 months), 16 infants at 5 months of age ($\underline{M}$ = 5.10 months) and 16 infants at 8 months of age ($\underline{M}$ = 7.99 months). Infants were recruited through a database of infants in the Ithaca, NY area. Informed consent was obtained from all parents, and the infants received a small toy or T-shirt as thanks for participation. All infants were full term and healthy. In addition to the 48 infants included in data analyses an additional 16 infants were tested but were not useable. Eight of these infants were 2-month-olds who either fell asleep during testing or were so fussy that looking times could not be judged correctly. In the 5- and 8-month-old group, data from one infant was not included due to equipment failure; the remaining seven infants were not included because they were so fussy that testing had to be terminated prior to the presentation of test trials.

Stimuli and Apparatus

Stimuli consisted of six looming colored-shapes (pink diamond, red octagon, yellow circle, blue cross, turquoise square, and green triangle) presented on a 53 cm computer monitor. The six colored-shapes were vector shapes that loomed from 2.35˚ to 14.59˚ of visual angle. Each stimulus loomed from 4 cm (2.35˚ visual angle) to 24 cm (14.59˚) in 1000 ms. There was no pause between stimulus presentations. The stimuli appeared in a continuous stream of randomly-ordered pairs (e.g., Pair 1: turquoise square followed by blue cross; Pair 2: yellow circle followed by pink diamond, Pair 3: green triangle followed by red octagon), with only transitional probabilities defining between-stimulus boundaries (see Figure 1 for an example of one shape sequence). The transitional probability within pairs was 1.0 and between pairs was 0.33 (see Figure 2 for an example of the transitions). In other words, for an individual infant, the pairs were always the same, but the order of the pairs within the sequence was random (e.g., turquoise square, blue cross, yellow circle, pink diamond, green triangle, red octagon, yellow circle, pink diamond, green triangle, red octagon, turquoise square, blue cross, turquoise square, blue cross….)

Procedure

Infants were tested individually and sat on a parent's lap 93 cm from the television monitor. The parent was instructed not to pay attention to their baby or to watch the screen. Infants were first shown the original stimulus sequence until looking declined according to a preset habituation criterion, determined by a sliding window algorithm that calculated over the course of a block of four trials when the infant's looking time had decreased by 50% from baseline. After habituation, the infants viewed six test displays alternating between familiar sequences, composed of the same three colored shape pairs, and novel sequences, produced by random recombinations of the same colored-shapes. The only difference, therefore, between the familiar and the novel sequences was that in the familiar sequences the first member of a colored shape pair predicted the second member, whereas in the novel sequences the colored shapes had no predictive value. There were six test trials in total (three familiar, and three novel). Test trials were counterbalanced across infants so that half the infants saw a familiar trial first and half the infants saw a novel trial first. The actual structure of the pairs was randomized across infants, so that it was very unlikely that any two infants saw the exact same pair sequence.

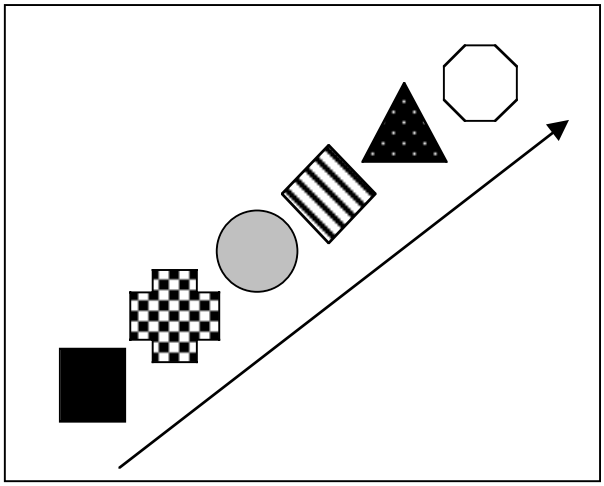

Figure 1: Example of a Shape Sequence (the actual shapes had unique colors, not black and white patterns).

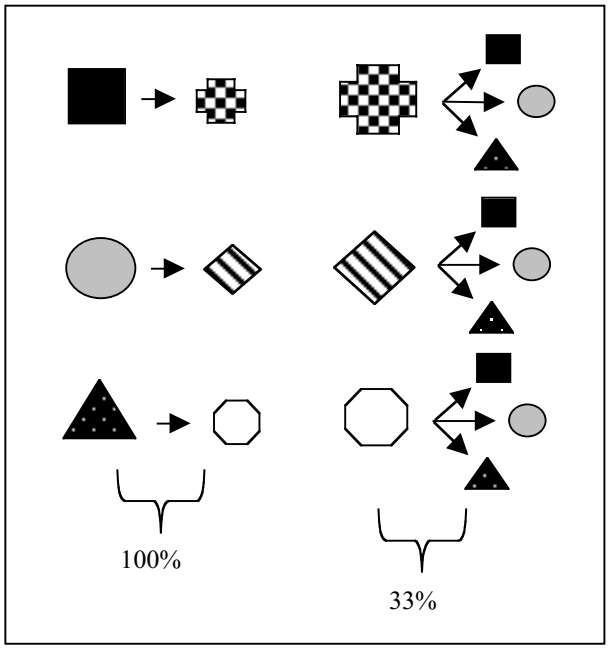

Figure 2: Example of the transitional probabilities between shapes.

Results

We hypothesized that infants would look longer at the novel sequences, if they were able to extract the visual statistical regularities available in the habituation stimuli.

The dependent measure was looking time at the familiar vs. the novel sequences. Looking time data in some cells were positively skewed (i.e., there were a few extremely long looking times); therefore, all data were log-transformed prior to analysis. A 3 (age group: 2-, 5-, or 8-month-olds) x 2 (test display: habituated vs. random sequence) ANOVA yielded a significant main effect of age, $F(2, 45) = 26.19$, $p < 001$, the result of longer looking overall by the youngest infants (see Table 1). As was predicted, there was a reliable main effect of test display, $F(1, 45) = 17.89$, $p < .001$, the result of longer looking at the random test display (see Table 1). Planned comparisons showed that at each age infants looked longer at the random test display than at the familiar test display (at 2 months of age, $F(1, 45) = 5.47$, $p = .024$; at 5 months of age, , $F(1, 45) = 6.68$, $p = .013$; at 8 months of age, $F(1, 45) = 5.77$, $p= .02$; see Figure 3).

Table 1: Mean looking time in sec per test display according to age group.

Age Group	Familiar Sequence	Novel Sequence
2 months	23.67	32.95
5 months	8.10	11.39
8 months	6.07	9.28

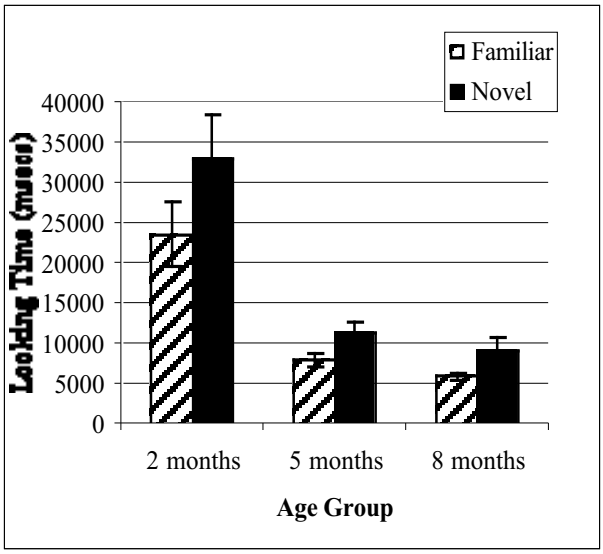

Figure 3: Infants' Looking Time to Familiar and Novel Patterns

Discussion

These results reveal that even very young infants are capable of picking up on statistical regularities in the visual environment. Moreover, they are discriminating between two visual sequences that differ *only* in these statistical probabilities. The sequences offered no cues as to the pairings: there were no pauses between stimulus presentations, the presentations were the same length, and the colored-shapes were not salient objects. Yet, each age group showed significantly longer

looking time to the novel sequences. This evidence that statistical learning is evident in young infants, in the visual domain, lends support to the hypothesis that this could be an early developing mechanism that supports learning across domains.

It is, of course, worth noting that this is only the first step in addressing the ways in which learning develops. We have yet to determine exactly how infants are encoding the information. Is it pure statistics? Are babies taking note of co-occurrences of events and stimuli, and judging the probabilities of those co-occurrences or are they abstracting these statistics into higher-order rules? Research on language learning has suggested that developmental constraints on learning actually provide the necessary prerequisites for later complex learning (Elman, 1993; Newport, 1988, 1990). Our research offers the same suggestion; early learning in the visual domain starts with the acquisition of the simplest patterns, and over development more complex patterns are acquired. This domain general learning could provide the beginnings of domain specific learning: as learning becomes more complex, the types of learning differentiate according to domain

As adults, we are brilliant implicit learners, and this learning has very little decay and requires very little effort. As infants, all we do is look, listen and touch; we absorb information from the environment and quickly pick up on the causal relationships we experience around us. For example, it does not take an infant very long to figure out that crying creates a desired effect, that of a parent's presence, and that the presence of a parent tends to predict food or comfort. This type of associative learning seems natural and adaptive. But, what if all initial learning is associative, and not dependent on a conditioned reward/punishment outcome. Note that the point here is to focus on initial learning, not to suggest that all learning develops in the same way. Perhaps the associations are all that is needed to elicit a type of implicit learning. Admittedly, the associations that are relevant and salient and do produce pleasant or unpleasant end results might be learned faster and remembered longer. We do not think that the infants we tested are going to predict the arrival of a turquoise square every time they see a yellow circle, for example, but it is interesting to observe that the associations were there at least long enough for the babies to notice a difference when the turquoise square did not predict a yellow circle. What is most interesting about the statistical learning process is not that it may be domain general but that it seems to work in situations that do not have reward/punishment end results, and therefore, seems capable of supporting a great deal of initial knowledge acquisition.

Acknowledgments

The authors would like to thank the many parents and infants for their participation, and all the members of the Cornell Baby Lab for help with infant recruitment. As well, we would like to thank Richard Aslin for many helpful comments. The research was supported by NSF grant BCS-9910779.

Abstract

We know that misinformation presented in interrogating questions or in advertising produces blendings, that even imagining a possible episode might produce blending as well, however, we do not know whether reasoning and problem solving can produce the same effect. On the other hand, models of analogy-making assume "perfect memory" for old episodes. The AMBR model of analogical problem solving has mechanisms for interaction between memory and reasoning which explain partial memory and memory distortions and has predicted blending effects which are due to the reasoning process. Such predictions have no parallel in any other model we know of. There has been no experimental support for these predictions so far. The current paper describes an experiment explicitly designed to test these predictions. It consists of three sessions: 1) solving three problems, 2) solving two more target problems by analogy with some of the problems in the first session, and 3) reproduction of the three problems in the first session. The results demonstrate that the degree of blending in the recalled stories depends on the target problem solved in the second session.

Motivation

There is a considerable amount of research demonstrating various types of memory distortions, such as schematisation, blending, and false memory illusions (Bartlett, 1932; Loftus, 1977; Loftus, 1979; Loftus, Feldman, & Dashiell, 1995; Loftus, Miller, & Burns, 1978; Loftus & Palmer, 1974; Moscovitch, 1995; Neisser, 1998; Nystrom & McClelland, 1992; Reinitz, Lammers, & Cochran, 1992; Schacter, 1995). These findings, however, have been established in "pure memory tasks" conditions. Very rarely researchers have tried to integrate memory tasks with other kinds of cognitive tasks in order to explore whether there will be interactions between them. Thus for example, we know that misinformation presented in interrogating questions or in advertising produces blendings, that even imagining a possible episode might produce blending as well, however, we do not know whether reasoning and problem solving can produce the same effect.

At the theoretical end these findings are typically explained by the constructive nature of human memory, however, very few models exist that lay out the specific memory mechanisms that could explain the memory distortion effects. The key concept has always been the postulation of distributed representations of some type in human memory. These include Hintzman's (1988) multi-trace model, Metcalfe's (1990) CHARM model, and McClelland's (1995) PDP-type of model. The last two models explicitly deal with memory blending effects.

On the other hand, models of human analogical reasoning which necessarily include a memory component (since they have to explain how analogous episodes are retrieved) simply ignore both the experimental findings about memory distortions and the theoretical ideas about the constructive nature of human memory. They typically assume "perfect" memory for past episodes and even some kind of nice organization of memory that would allow the retrieval of the relevant episode (Forbus, Gentner, & Law, 1995; Hummel & Holyoak, 1997; Kolodner, 1984; Thagard, Holyoak, Nelson, & Gochfeld, 1990; Warton, Holyoak, & Lange, 1996). All these models assume centralized representation of episodes which means that episodes are either retrieved as a whole (and than mapped onto the target problem description) or they fail to be retrieved. No blending of episodes may occur, no false memories can arise, no partial retrieval can happen. Surprisingly, this is true even for the LISA model (Hummel & Holyoak, 1997) which is based on distributed representations, since the representations are truly distributed only in working memory, but the episode representation in LTM is highly centralized, although distributed in some sense (in the same sense in which the representation is distributed in the model described in the current paper). A list of all units representing a single episode is assumed and if the episode wins the competition between episodes then all it corresponding units are switched from dormant to active state.

The main motivation for recent developments in the AMBR model of analogical problem solving (Kokinov, 1998; Kokinov & Petrov, 2000, 2001; Petrov & Kokinov,

1998, 1999) was to propose mechanisms for interaction between memory and reasoning which will allow for explaining memory distortions and blendings among other things. AMBR has predicted blending effects which are due to the reasoning process. Such predictions have no parallel in any other model we know of. However, we do not know of any experimental support for them either. That is why an experiment was designed to test these predictions. The current paper describes this experiment and its outcomes.

AMBR Model and its Predictions

The AMBR model of analogical problem solving was introduced in (Kokinov, 1988) and then further developed over the years (Kokinov, 1994a, Kokinov, 1998, Kokinov & Petrov, 2001). It is based on a general cognitive architecture called DUAL (Kokinov, 1994b,c) which relies on emergent computations produced by a society of micro-agents (Minsky, 1986; Hofstadter, 1995). The latest developments (Kokinov, 1998, Kokinov & Petrov, 2000, 2001; Petrov & Kokinov, 1998, 1999) are directed towards building a more psychologically plausible memory for episodes and thus allowing for memory distortions to take place. Moreover, a prediction is made that the reasoning process during the analogical problem solving may itself produce memory distortions.

Episode Representation

Episode representation in AMBR is highly decentralized, which means that each episode is represented by a large coalition of micro-agents each of them representing some aspect of the situation. We may call this representation "distributed at a higher level" by analogy to the connectionist representations which are distributed over a set of simple features. In reasoning, and in analogy-making in particular, the relations are even more important than single features and therefore they have to be explicitly represented. The agents here are more complex than the connectionist units (Kokinov, 1994a, b, c) and roughly speaking they represent a whole proposition (such as "there is a coffee pot", "the coffee-pot is made of metal", "the coffee-pot is on the plate", "the plate is hot", "the water is in the coffee-pot", "proposition 1 causes proposition 2", etc.). Thus the episode is represented by a set of such propositions (by a coalition of the corresponding micro-agents), but there is nowhere in memory a list of all propositions (all micro-agents) involved in a given episode. That is why we call this representation decentralized. There is one agent which refers to the unique point in time and space – when and where the event has happened, and all agents from a given coalition have links directed to it. In this way the system can differentiate among propositions belonging to different episodes, however, there are no links from this agent to the agents in the coalition, i.e. it does not know any of the members of the coalition. Therefore this agent cannot contribute to the retrieval or construction process.

Each agent has a level of activation that changes dynamically. The activation level determines the degree to which the information contained in that agent is available and the degree to which this agent participates in the computational process (Kokinov, 1994b,c, Petrov & Kokinov, 1999). Working memory is considered to be the active part of long term memory, i.e. the set of all active agents at a given moment. There is a process of spreading activation as well as a process of decay which guarantees that an agent that do not receive activation will soon quit WM.

Episode "Retrieval" or "Construction"

Episode "retrieval" corresponds to the process of activation of the agents representing various aspects of the event and bringing them into WM. This means that typically the recall is only partial since there is no way to guarantee the activation of all members of a coalition. Some coalitions will be stronger (having stronger links between the agents) and therefore the corresponding episode will tend to be reproduced more fully, other coalitions are weaker and only few aspects of the episode are reproduced.

However, many agents belonging to other coalitions will also turn out to be activated – agents representing some general knowledge (concepts, facts, rules, etc.), agents representing aspects of other episodes. Thus the set of agents happened to be in WM will produce a description of the episode which is partial, but also containing intrusions from general knowledge and other episodes. Intrusions from other episodes are in fact blendings between two or more episodes. In fact, the representation of an old episode is not just retrieved from LTM, but is actively constructed in WM. The process of spreading activation is an automatic one but it depends on the current state of WM, the goals of the system and its input from perception. Thus the reasoning process, which runs in parallel to the memory process, interferes with this process of episode construction and in fact even guides it to a certain extend.

Mapping Guidance in Episode Construction

In the context of analogical problem solving the construction of the old "retrieved" episode is guided by the mapping process between this episode and the current target problem. The mapping process in AMBR does not start after the old episode is retrieved as in all other models of analogy-making, but runs in parallel to it. This makes it possible the already established partial mapping to guide the episode construction in such a way that the old episode is reconstructed in directions which allow better alignment between base and target. For example, the intrusions from general knowledge and from other episodes will be not arbitrary, but will correspond to elements of the target description which do not have corresponding elements in the base description (they are either missing in the encoding of the episode or are simply not activated at the moment). The precise mechanisms for this episode extension are described elsewhere (Kokinov & Petrov, 2000). A simulation experiment with AMBR has demonstrated that

the parallel run of reasoning and "retrieval" in this model yields the retrieval of structurally similar episodes that would otherwise be not retrieved (Petrov & Kokinov, 1998).

AMBR's Prediction

AMBR's prediction relevant to the current paper is that intrusions from other episodes will happen more often if the currently constructed representation of the most active episode is missing elements which are important for the mapping process with the target problem. This emphasizes not any missing element, but elements which are crucial for the mapping. This is in contrast to a model that is very similar in flavor (Nystrom & McClelland, 1992; McClelland, 1995) which, however, is not sensitive to the structure but fills in any missing information. The latter model explains data from a memory experiment on sentence recall and is not intended to explore the relation between memory and reasoning. Structure might be unimportant in this case. In contrast, AMBR makes stronger predictions about the relevance and structural consistency of the intruded elements.

In this case the analogy-making process itself produces blending under certain conditions. Therefore the more partial the mapping between the target and the base problem is the more intrusions will occur and thus higher degree of blending between episodes will be observed. This is the prediction tested in the following experiment.

Experiment

The main idea of the experiment is the following one. Ask the participants to solve several base problems and as a side effect to hold them in their long-term memory. Half of the participants will then solve one target problem and the other half another target problem. After that we will ask the participants to retell us the base problems as accurate and complete as possible. We will measure the degree of blending between the problems and expect that it will depend on which target problem has been solved.

Method

Design

The experiment consists of three sessions:

- Session 1: solving three base problems (A, B, C);
- Session 2: solving one of two target problems (T1 – partially analogous to A and partially analogous to B, or T2 – partially analogous to B and partially analogous to C);
- Session 3: recalling the problems from session 1.

The whole trick is that target problem T1 partially maps to both A and B, while target problem T2 partially maps to both B and C. That is, in order to solve problem T1 one needs to make a double analogy (with A and B) and use two different principles which are provided in A and B respectively. This requires that A and B are both partially "retrieved" in WM and partially mapped to T1. We may describe this situation as blending the two episodes A and B and constructing a new "old" episode AB that is then remembered. Thus later on in session 3 we would expect that participants who solved problem T1 will tend to blend episodes A and B. Reversibly, participants who solved target problem T2 in the second session will tend to produce more blends of B and C in session 3.

Thus we use a between group design. The independent variable is the type of target problem solved in session 2 and its relation to the base problems. The dependent variables have to measure the blending occurring in the retold stories in session 3. We use two types of measures:

- a binary variable – "yes/no" expert judgments of blended memories;
- degree of blending (a value between 0 and 1) – measured as the degree of mixture between statements related to each of the base problems A, B, and C.

Material

The problems used in the experiment both in session 1 and in session 2 have been designed to fulfill several criteria:

- they should be solved by some general principles that can then be applied to another problem;
- if the principles used for solving the base problems A, B, and C in session 1 are called PA, PB, and PC respectively, then the target problems in session 2 should be solved by a combination of two principles (T1 by PA and PB, and T2 by PB and PC).

In *problem A* we used a criminal story about an attempt to come in for money of a wrong person who actually killed the legatee and dressed and acted like her. She imitated successfully even the gestures of the dead relative, including her habit to arch her right eyebrow when asking questions. She practiced these gestures for a long period of time in front of a mirror. Finally, however, she was recognized as a fake legatee. The question is how she was recognized. And the correct solution relies on principle PA: "Left and right are reversed in an mirror image". Thus, the lady arched her wrong eyebrow.

Problem B was an expanded version of the radiation problem. The principle underlying the correct solution was PB: the convergence of several weaker X-rays in one point form a stronger X-ray.

Problem C involved baking 3 flat loafs in a small baking tin which can hold only 2 loafs. The question was what is the minimal time period required to bake the 3 loafs turning each of them on both sides. And the principle underlying the correct solution was PC which outlines a turning schema: you first bake one side of two loafs, then you turn one of them and replace the second loaf with the third one, and finally you bake the remaining sides of the second and the third loafs.

All three problems were told as folk tales with some superficial similarities in the plot (having kings, princesses, wise man, etc.), still they were quite different.

Target problem T1 was about a five-headed dragon that has to be killed, but he can be killed only if at the very same moment his 2nd head from the left to right is cut off and his heart is destroyed by a strong laser beam. However, there were several obstacles: you cannot look at the eyes of the

dragon directly because you will become blind, and also there were only 3 weak laser beams available. Thus the participants had to apply principle PA and to cut off the 2nd right head (instead of the 2nd left one) staying backwards and looking at the dragon into a mirror and principle PB to use a converging configuration of three weak laser beams.

Target problem T2 involved killing another dragon where again his heart should be destroyed by a strong laser beam and you have only three small ones, however, here the dragon was behind a moat full of lava which could be passed only by using three magic stones. The obstacle is that you can use each stone only once to step on each of its two sides. The solution involved principle PB from above, and principle PC used in problem C – the particular scheme of turning the stones and loafs respectively.

Procedure

During the first session the participants were told that they will undergo a series of experiments on human thinking and they will have to solve various problems. The problems were given one by one without an explicit time restriction. After the participants produced a written solution the experimenter read it aloud and if this was not the targeted solution she encouraged them to find an alternative solution, if this did not help a hint was given, and finally if the target solution was not found it was provided by the experimenter. The aim was all participants in session 1 to solve the base problems correctly and to acquire the basic principles PA, PB, and PC.

The second session followed after a period of 3 to 7 days. During this second session the group was split and half of the subjects solved problem T1, and the other half – T2. The second session was run again individually and the thinking aloud method was used, the speech of the participants was recorded. No hints were provided here.

The third session followed immediately after the second session. During this session the participants were asked to retell as accurate and complete as possible the problems from the first session. The stories were reproduced orally and tape-recorded.

Participants

48 undergraduate students participated in the experiment, but only 33 went through all sessions. 16 were female and 17 – male.

Results and Discussion

The records were transcribed and the protocols of the third session were used as the main data set. Each story was segmented into short phrases which express independent and understandable statements. The texts of the problems A, B, and C were also segmented into separate statements and their appearance in the body of the protocol was encoded. For example, we separated the text of problem C into 22 statements – C1-C22 and whenever a phrase (or its semantic equivalent) occurred in the narration of the subject the corresponding Ck was inserted in the protocol encoding.

Quite often when reproducing one of the problems participants inserted statements from one of the other two problems. This was exactly what we were counting. Thus for measuring the AB blending (blending between problem A and B) we counted how many As and how many Bs we have in the reproduction. The degree of blending was calculated as the ratio: number of As over number of Bs (when the As are less than the Bs), or reverse – number of Bs over number of As (when the As are more than the Bs). To put it differently we measured the percentage of intrusions in the text arising from another problem. Thus if the number of As or Bs are zero than no blending has occurred (degree of blending is 0), and when the number of As and Bs are equal then an absolute blend has been produced (with degree of blending equal to 1). The results are shown in Table 1 and Figure 1. As we can see the results are coherent with our hypothesis: we have higher degree of blending of type AB in group 1 (solving T1 in the second session) and higher degree of blending of type BC in group 2 (solving T2 in the second session). Just to remind that T1 required double analogy with A and B, and T2 required a double analogy with B and C. At the same time there is no difference whatsoever in the degree of blending of type AC which should be expected since none of the target problems required combining base A and base C. The performed analysis of variance showed a significant 2-way interaction between the groups (target problems solved) and the type of blending occurred ($F(2,62)=4.41$, $p<0.016$). The difference in the degree of AB blending is significant, but the difference in the degree of BC blending is not significant. Analyzing our data we found out that very few of the participants in group 2 were able to solve target problem T2 (in fact only 4 out of 16) and therefore they have not done the double analogical mapping with B and C. Thus we cannot expect the blending effect in this case. In contrast, problem T1 was solved by 11 out of the 17 participants. Evidently the second target problem was too difficult. We looked into the solved/unsolved difference and found support for this interpretation. The mean degree of BC blending in group 2 is: 0.148 for the subjects who solved T2 and 0.025 for the subjects who did not solved it, i.e. it is 6 times higher for the subjects who solved the target problem T2. The difference is significant at p-level 0.028 (measured by one-tailed t test, $t=2.45$)

Table 1: Mean degrees of blending in each group.

	# of subjects	AB blending	BC blending	AC blending
group 1 (solving T1~AB)	17	0.102	0.043	0.036
group 2 (solving T2~BC)	16	0.022	0.056	0.035

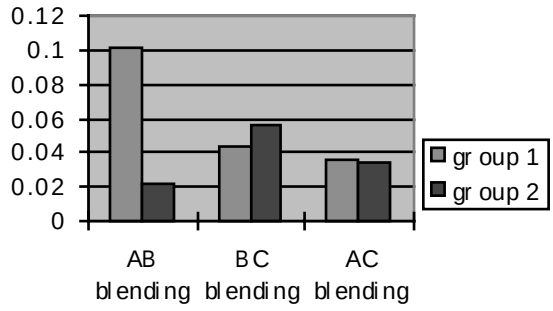

Figure 1: Degree of blending between the base problems reproduction depending on experimental group. There is a significant 2-way interaction between groups and type of blending.

Since we used a very formal method of measuring blending – the number of intrusions as registered in the protocols – we were curious to compare this to a more qualitative judgment done by human experts who may recognize whether there is a real blending or just some general knowledge intrusions or superficial mixture. Two independent judges had to read each protocol (without knowing neither about our hypothesis nor which group this protocol comes from). The experts had to judge whether there was a blending between some old problems. There was a high degree of agreement between the experts (about 10% disagreement where a third expert was called for judgment). The frequencies of blending of type AB, BC, and AC are presented in Table 2 and their percentage in Figure 2.

Table 2: Number of blendings as judged by experts.

	# of subjects	AB blending	BC blending	AC blending
group 1 (solving T1~AB)	17	11	6	5
group 2 (solving T2~BC)	16	5	8	5

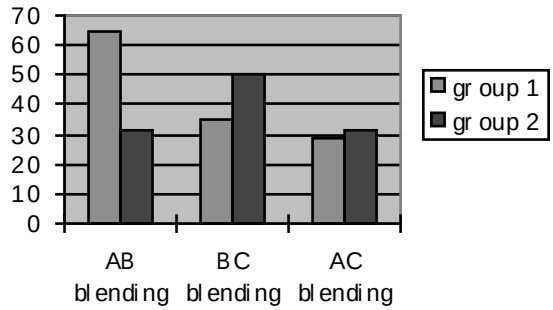

Figure 2: Percentage of blendings as judged by experts.

The results from expert judgments are generally coherent with the measurements of the degree of blending and again we have more AB blends in group 1, and more BC blends in group 2. The number of AC blends is almost equal in both groups. The log-linear analysis declared all the differences insignificant, however.

Conclusions

AMBR mechanisms of memory access and mapping work in parallel and interact with each other and thus predict mutual influence between these processes. One specific prediction is that when the target problem maps only partially with two different bases and a double analogy is required to solve it, then both bases are partially activated and elements from both episodes are brought into WM. In that way a blend between the two old episodes is produced and remembered. That is why a higher degree of blending is expected after subjects having solved such targets requiring double analogies.

This prediction has been experimentally tested in a series of three sessions in which the participants had first to learn the bases (by solving the problems in session 1), then to solve one additional target problem (session 2), and finally to retell the base stories (session 3). It turns out that higher degree of blending between two episodes is observed in the group where the target problem in session 2 required usage of a double analogy with these two episodes.

We consider these results as a first step in a series of experiments which have to test this hypothesis. We are currently running several more experiments varying the material, the design of the experiment and the timing of the sessions.

Acknowledgments

We would like to thank the AMBR research team for their continuous support and stimulating environment.

Abstract

How participants to a joint activity come to develop a shared or mutual understanding of what they are perceiving has long been a problematic issue for philosophers, sociologists, and linguists. We examine the abstract model proposed by Clark and Marshall (1981) whereby speakers and hearers construct mutual knowledge and by which discrepancies in definite reference are repaired. We focus in particular on forms of demonstrative reference that depend upon physical co-presence. We examine an attested example of reference repair in the operating room of a teaching hospital. It involves learning to recognize pertinent structures within endoscopic surgeries, that is surgeries in which internal spaces are rendered visible by inserting a fiber-optic lens into the body of the patient. Clark and Marshall provide a useful vocabulary for discussing referential practices in this applied setting. We are left with some questions about how to interpret certain features of their model, however. We conclude that further theoretical framing is required before we develop a full appreciation of how reference and reference repair is accomplished in day-to-day interaction.

How participants to a joint activity come to develop a shared or mutual understanding of what they are perceiving has long been a problematic issue for philosophers, sociologists, and linguists (cf., Heritage, 19884; Lewis, 1969; Sperber & Wilson, 1986; Stalnaker, 1978). One means of building "common ground" (Clark, 1996), of course, is through demonstrative reference. Even here, however, potential problems abound. When one issues the utterance "It's right here," how is it that one assures oneself that what is presented as *here* is the same as what is taken as *here* by the listener? Further, how do we detect when discrepancies have arisen and how are these discrepancies to be reconciled? We begin this paper by reviewing the pragmatic model of reference repair proposed by Clark and Marshall (1981). We then examine an instance of reference repair in an applied setting to evaluate the usefulness of this model in understanding actual referential practice.

Clark and Marshall's Model of Reference Repair

Clark and Marshall (1981) proposed an abstract model for the repair of direct references based on their proposal for how mutual knowledge is constructed. This proposal can be expressed succinctly by the following formula:

Evidence + Assumptions + Induction Schema = Mutual Knowledge[1]

where *evidence* is the grounds for the speaker and hearer's belief that both understand some matter in the same way, *assumptions* are the things taken for granted when accepting these grounds as warrants, and *induction schema* is a recursive formulation of Lewis' (1969) iterative definition of common knowledge. By this formula, evidence and assumptions are interrelated in that weaker bases of mutuality must be compensated by increasing levels of assumption. Clark and Marshall's taxonomy of evidence is broken into three categories: community membership, physical co-presence, and linguistic co-presence.[2] These evidence types, along with their associated assumptions are listed in Table I.

Mutual understanding proceeds on the assumption that speakers and listeners are each members of many different cultural communities (e.g.,

[1] In later writing (see Clark, 1996), *mutual knowledge* was expanded to *common ground*, a broader notion that subsumed mutual belief, mutual knowledge, mutual assumptions, and mutual awareness.

[2] Clark and Marshall (1981) listed indirect co-presence as a fourth category of evidence. For ease of presentation, we have condensed the categories into three.

Table 1: Bases of Common Ground
(adapted from Clark & Marshall, 1981)

Evidence	Associated Assumptions
1. Community membership	co-membership, universality of knowledge
2. Physical co-presence	
a. Immediate	simutaneity, attention, rationality
b. Potential	assumptions of 2a. + locatability
c. Prior	assumptions of 2a. + recallibility
d. Indirect potential	assumptions of 2b. + associativity
e. Indirect prior	assumptions of 2c. + associativity
3. Linguistic co-presence	
a. Potential	assumptions of 2b. + understandability
b. Prior	assumptions of 2c. + understandability
c. Indirect potential	assumptions of 3a. + associativity
d. Indirect prior	assumptions of 3b. + associativity

African Americans, soccer fans, Presbyterians, pipe fitters, speakers of French) and that membership in these communities imparts special forms of shared vocabulary and knowledge. Reference based purely on community membership assumes that the speaker and hearer hold one or more of these cultural communities in common (i.e., co-membership) and that the object of reference is known to all members of these shared communities (i.e., universality of knowledge). Clark and Marshall theorized that mutual knowledge based on community membership has an extended scope and can be carried from one conversation to another.

A second form of evidence is based on physical co-presence. When speaker and hearer are aware of an object present to both at the moment of reference (sometimes referred to as "triple co-presence"), the situation is labeled *immediate co-presence*. Although this is the strongest form of co-presence for Clark and Marshall, it too has certain assumptions. The speaker assumes that the listener is not only oriented to the object, but is also attending to it (attention) and that both are attending to it at the same time (similtaneity). It also assumes that the listener possesses the faculties to appreciate the meaning of the utterance (rationality). If only the speaker is focusing on the object, but it is available to the hearer (i.e., locatability), *potential physical co-presence* is established. If the hearer does not happen to be attending to the object of reference, but is known to have attended to it previously and can be counted upon to remember it (recallibility), then *prior physical co-presence* can be established. Attributes of components of physically co-present objects can be referred to indirectly provided the hearer recognizes (via community co-membership) the semantic links connecting the attribute or component of the object to the object (assumption of associativity).

The third category of co-presence is *linguistic*. It allows for reference to objects that have been previously introduced into the conversation. Such forms of co-presence are only prior or potential, depending on whether the object is introduced earlier or later in the stream of talk. Both types depend upon a form of assumption Clark and Marshall refer to as "understandibility." As with physical co-presence, more complex forms of linguistic co-presence are possible through association. Unlike community co-membership which is sustained over long periods, Clark and Marshall considered physical and linguistic co-presence to have relatively brief temporal extent.

As evidence for their model, Clark and Marshall direct attention to the way that speakers repair definite references. They described two forms of reference repair: *horizontal* and *vertical*. Horizontal repairs involve enhancing reference by providing additional information without altering the set of underlying assumptions. Vertical repair, on the other hand, involves advancing to a level of co-presence with fewer assumptions. For example, moving from an indirect form of co-presence to a direct form or moving from potential to immediate co-presence or shifting from linguistic to physical co-presence. Because community co-membership has assumptions that are entirely different from those underlying physical and linguistic co-presence, it allows only for horizontal forms of repair.

The model of reference repair presented by Clark and Marshall was largely linguistic. Clark (1996) later elaborated on the notion of common ground. He made a conceptual distinction between *communal common ground*, something that rests largely on community co-membership, and *personal common ground*, with a correspondence to what has been previously described as physical and linguistic co-presence. He expanded his treatment of personal common ground to include "joint perceptual experiences" and "joint actions" (p. 112), that is gesticulation, observed actions, and other

features of the social setting in addition to talk. As we turn to an instance of actual reference repair in an applied setting, we see the importance of taking a broader and more situated view of referential practice. In particular, we begin to see some of the complexities embedded in certain features of Clark and Marshall's model, such as the assumption of locatability.

Analyzing Reference in an Endoscopic Surgery

The setting within which we have chosen to study referential practice is the operating room (OR) of a busy teaching hospital. Within this context, there are multiple forms of work being performed simultaneously. On the one hand, there is a cycle of activity surrounding the performance of a particular surgical procedure itself within which each of the members of surgical team plays a specific role. At the same time, there is instructional work to be done as well. In the fragment to be analyzed here, one participant ("Attending") is a highly-experienced surgeon, ultimately responsible for the safe and successful outcome of the surgery. A second ("Resident") is a surgeon in the final year of his surgical residency, who had by his own estimate participated in 80 to 90 surgeries of the type to be described here (by comparison, the attending surgeon reported that he has performed 1200-1300 of these surgeries over the course of his career). The remaining participant ("Clerk") is a third-year medical student enrolled in a clerkship rotation. This was his first surgical experience. Attending, therefore, is providing guidance and supervision to the resident and both Attending and Resident are responsible for providing instruction to the medical student.

The surgical procedure in which they are engaged is a laparoscopic cholecystectomy, that is the removal of the gall bladder with the aid of an endoscopic camera. Such surgeries were of interest to us because of the manifold challenges to perception and coordination that they pose to participants. Surgeons are called upon to translate what they see on a 2-D TV monitor into a model of what is happening within the not directly inspectable belly of the patient. The image seen on the screen is a magnified view that facilitates precise manipulation on the part of the surgeon, but can be disorienting for newcomers. The orientation of the view on the screen is arbitrary, though the convention is to orient the lens in such a way that the projected image most closely resembles what would be seen in an open surgery (that is a ventral view in which up is anterior and down is posterior). Since participants on opposite sides of the operating table observe different monitors, however, the person assisting the surgeon from the opposite side of the table receives an inverted view.

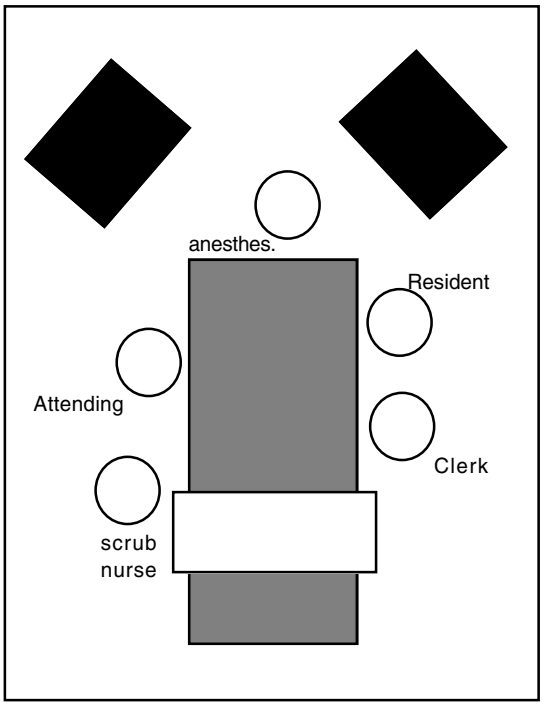

Figure 1. Arrangement of the operating room.

Looking within the endoscopic space is a team effort with different members responsible for operating the camera, "retracting" obstructing organs, and conducting the surgery. This requires substantial coordination in that a view of the workspace adequate to carry out the procedure can only be achieved if all members of the team correctly anticipate the needs of the surgeon. Although the participants work in close proximity to one another, many of the normal resources for effecting mutual orientation are not available to them. Their hands, for example, are occupied much of the time and, as a consequence, cannot be employed for gesture. Further, because they do not attend to the same monitors and because the monitors are located at a distance from where they work, it is difficult for them to use each others' gaze as a cue for orientation as is often done in more typical face-to-face interaction (Goodwin, 1986; Streeck, 1993, 1994).

Attending assists the resident from the left side of the table (see Figure 1). Clerk, standing to the left of Resident on the right side of the table, controls the rod lens of the endoscopic camera. The surgery is considered routine. It consists of isolating the small duct (the cystic duct) through which the gallbladder empties into the common bile duct and the vessel (the cystic artery) that supplies the gallbladder with blood, ligating both with surgical clips, and severing them. The gall bladder is then gently teased from the liver and extracted through one of the "ports" in the abdominal

wall. The greatest technical challenge is correctly identifying the cystic duct and cystic artery, as serious post-surgical complications may arise were clips to be applied to the wrong structures.

Repairing Reference in the OR

Space restrictions prevent us from presenting here a full analysis of the interaction. A more detailed analysis of the fragment can be found elsewhere (Koschmann, Goodwin, LeBaron, & Feltovich, in prep). A transcript can be found in Appendix A. [3] It begins (lines 1-9) with Attending describing the surgical procedure to Clerk. At the same time and throughout the course of this interaction, the resident was performing a blunt dissection to expose the cystic duct and the cystic artery using the tool in his right hand (a "black grasper"). This dissection was performed by burrowing the tip of the grasper into a bundle of connective tissue binding the bottom edge of the gall bladder to the common bile duct and then gently spreading apart the jaws of the instrument. Attending and Clerk observed his progress on their respective monitors.

The expression *cystic artery* is introduced here for the first time (line 2). In terms of Clark and Marshall's model, Attending's use of this expression is authorized by Clerk and Attending's membership in some common community. Attending displays by his choice of language a set of presuppositions about what would be understandable to a third-year medical student. Resident's first demonstrative reference to the cystic artery (line 5) specifies a region in which the cystic artery can be found, though it may not necessarily be visible at the moment in which he makes the reference. In Clark and Marshall's terminology, therefore, these references signal potential physical co-presence. This raises interesting questions about what the assumption of locatability means in this particular situation, however. If it means that the cystic artery is simply available to Clerk's viewing, Resident's utterance would suggest that he believed the cystic artery to be locatable at the moment of reference. If one has never seen a cystic artery on an endoscopic display, however, is it still locatable there?

Clerk's query in line 10 makes visible his orientation to unfolding process. The cystic artery may or may not be visible at that point in time, but his use of the adverb *yet* expresses a confidence that it will eventually be made manifest to all. Attending's reply in line 13 ratifies this view. Like Goodwin's (1999) archeologists excavating through sedimented strata of soil, surgeons must dissect through various layers of anatomical structure. They speak of *planes of dissection*, meaning the surfaces available to sight at specific junctures within a procedure. In an endoscopic surgery, however, the cystic artery will never be physically co-present in the same way that it would in an open surgery since its presence is mediated through a video viewing system. Attending's deictic particle *here*, therefore, anchors not to the conventional origo of the speaker's corporal location, but rather to a virtual origo located in the shared media space.

Resident eventually provides six separate demonstrations of the cystic artery before receiving a tentative sign of recognition on the part of Clerk (line 19).[4] Learning to locate pertinent structures on the video display is an important aspect of "professional vision" (Goodwin, 1994). Resident's *there* (line 18) was coordinated with a point to a white stripe within the bundle of connective tissue being viewed. Although gesture is often characterized by linguists as supplementing speech, Hindmarsh and Heath (2000) described instances in which "The deictic term segments the gesture, displaying just the moment at which it is sequentially relevant" such that "the talk reflexively works on behalf of the gesture" (p. 15).

Resident's repeated efforts to demonstrate the cystic artery, could be described in terms of Clark and Marshall's model of reference repair as an attempt to eliminate the assumption of locatability. That is, he was striving to promote his shared knowledge with Clerk from potential to immediate co-presence. But what does it really mean to be "locatable." The whole idea of "professional vision" is to acquire the ability to see as presumably more-skilled others can see. If locatability assumes not only that the listener can see (in the sense of having adequate vision, an unblocked view, etc.) what is visible to the speaker, but must also be able to see in the same ways as the speaker (i.e., share the speaker's "professional vision"), then it becomes a very complex kind of assumption, in many ways just as complex as the thing it sets out to explain, namely mutual understanding.

As the fragment continues, Attending raises some concerns about Resident's identification of the cystic artery. On paper, Attending's "That may be right" (line 27) might be construed as a tentative positive appraisal. Resident's reply (line 29), however, treats it as an incomplete utterance, as in "That may be right [hepatic]." Resident's efforts to achieve mutual understanding with Clerk, therefore, have revealed a potential discrepancy in understanding among Resident and Attending. The fragment concludes with Resident

[3] The transcription conventions used here are described in Atkinson and Heritage (1984).

[4] Resident's demonstrative reference in line 3 ("Right there") is heard to be referring to the cystic duct, a topic of discussion prior to the transcribed segment, rather than the cystic artery.

and Attending resolving to search further for the cystic artery.

Discussion

Here in a nutshell we see the problem of mutual knowledge. Resident takes some pains to demonstrate to Clerk what he (Resident) believes to be the cystic artery. After some prompting, Clerk declares that he now sees it. Other than his avowal, however, we have no evidence that he indeed sees what Resident has taken such trouble to display. In demonstrating for Clerk what he has taken to be the cystic artery, however, Resident has inadvertently made visible a discrepancy in his presumed common ground with Attending (or, at the very least, a difference in their levels of confidence that the indicated structure is in fact the cystic artery). Clark (1996) defined *grounding* as establishing a claim "as a part of common ground well enough for current purposes" (p. 221). For the purposes of Clerk's instruction, the exchange would seem to have provided ample grounding for his understanding. However, for the purposes of conducting a safe surgery, the concerns raised by Attending might suggest that more grounding is required.

Clark and Marshall provide a useful vocabulary for discussing referential practices in this applied setting. Their model of reference repair, however, hinges upon a calculus of assumption maintenance and herein lies the rub. The conceptual difficulties of mutual knowledge that their model was meant to address have not been completely dispelled, but, instead, arise in new forms when we look more carefully at the underlying assumptions. As we have seen, the assumption of locatability can be quite complex when examined *in situ*. We are in full accord with Clark's shift from a treatment of reference as a simple matter of linguistic interpretation to a more situated model that encompasses "joint actions" and "joint perceptual experiences" and we think that this will lead to a richer understanding of concepts like locatability. For one thing, it would help to illuminate how participants' own unfolding activities contribute to the determinant sense of what is seeable at any given moment. Furthermore, we have much to learn about the interactions between different kinds of bases of shared understanding. Professional vision, for example, draws upon the associated assumptions of both community membership and physical co-presence.

In a situation in which the establishment of common ground is essential, we see just how elusive shared understanding can be to achieve. Our analysis of the fragment of interaction in the OR would suggest that we have a way to go before fully appreciating how these factors enter into our day-to-day practices of reference and reference repair.

Kinds of Kinds: Sources of Category Coherence

Abstract

A fundamental question in the study of concepts is what makes sets of examples cohere as categories. We present results of three studies designed to compare standard taxonomic categories with categories that take their meaning from relationships extending outside of the individual example. An exemplar generation task is used to differentiate relational categories from taxonomic kinds and to compare possible subtypes of extrinsically cohering categories based on goals or thematic contexts. Results provide strong support for the intrinsic—extrinsic distinction and reveal signatures of underlying organization among the types of categories investigated.

Introduction

Categories play a fundamental role in cognition. The internal structure of categories supports numerous functions including classification, prediction, and reasoning. Categories give rise to an extension: the set of examples in the world that are members. The coherence of a category is the meaningful basis according to which these members go together.

One traditional view holds that the correlational structure of the environment determines category coherence due to systematic patterns of within-category similarity and between-category difference (Rosch & Mervis, 1975). Murphy and Medin (1985) propose the theory-based view that challenges the idea that similarity itself explains category coherence. 'Respects' for similarity (i.e., a basis for the selection of features and weights) must be specified in order for concepts to exist as groups of *like* examples. Additionally, they argue that category representations are richer than lists of features and must include relationships that hold within and between examples of categories. The tension inherent in the need for a constrained, yet rich basis of category coherence poses a continued challenge to theorists (Goldstone, 1994).

A useful source of inspiration is structural alignment theory—which has proven successful as an account of comparison processes such as similarity and analogy (Gentner, 1983; Markman & Gentner, 1993; Gentner, Rattermann, & Forbus, 1993). This framework offers a perspective for addressing the question of category coherence in a manner in keeping with the theory view. Respects for similarity can arise from the process of aligning corresponding predicates of two structured representations (Gentner & Markman, 1997; Medin, Goldstone, & Gentner, 1993; Markman & Wisniewski, 1997). Relational similarity drives the alignment process and largely determines the quality of a match. In the same way that structural alignment theory looks to shared relations (more than attributes or objects) to explain similarity, we can look to relationships between objects as a source of category coherence. While theory-based categories may cohere around intrinsic relationships (like the causal link between genetic material and physical features), we focus here on relationships extending beyond the individual example. For instance, the category *barriers* consists of examples that conform to the relationship: BLOCKS (X, Y).

Barr and Caplan (1987) distinguish between the intrinsic properties of a category which are true of an example in isolation versus extrinsic features which hold only in relation to other objects. As an alternative to category members bound together by common intrinsic structure (relations or attributes), category coherence can be derived from relations extrinsic to individual examples. The extreme case of extrinsic coherence is relational categories like *barriers*—members cohere based on fulfilling a core relationship. The roles of X and Y in the blocking relation can be filled by anything—so as long as the relationship holds, membership is secure. The examples of a relational category may have few or no intrinsic properties in common with one another. In this sense, relational categories are akin to analogies. Both 'prison bars' and 'raging river' are members of the category *barrier*, despite their sharing no intrinsic similarity.

Another case in which the category coherence is extrinsic is Barsalou's (1983, 1985) ad-hoc or goal-derived categories which are organized around ideals (properties that optimally promote goal resolution) rather than central tendency. Again, categories such as *things to take out of the house in case of fire* violate the correlational structure of the environment since member examples have few properties in common. Goldstone (1995) makes a useful distinction between default and directed similarity; where the former is the basis of graded structure and broad inferential power of taxonomic categories, while the latter is the focal, context-specific sense of similarity underlying ad-hoc categories or analogical relationships.

Categories may also be grounded by properties beyond the individual example that are not specific relationships. As an example, consider *items associated*

with working at an office desk. Thematic categories consist of examples that tend to cluster or co-occur in particular contexts. As Wisniewski et al. (1996) noted, such categories are often expressed as mass noun superordinates – e.g., *groceries* or *workout equipment*. There may be other relations in addition to spatiotemporal contiguity between particular pairs within a thematic category, but the members need not share any particular similarity.

In the present work, we use an exemplar-generation task to investigate and compare these possible bases for what makes things "go together" as a category. The sources of category coherence are: default similarity to the central tendency, directed similarity to ideals or to a core relationship, and patterns of contiguity in spatio-temporal contexts. We believe that there are kinds of categories that are best explained in terms of each of these sources of coherence, while there are also categories that are grounded in mixed forms of coherence. Barsalou (1985) shows that ideals account for a significant portion of the variance in typicality not only for goal-derived categories, but also taxonomic categories. Furthermore, different kinds of experts have been shown to organize the taxonomic category *tree* in terms of ideals derived from their experience (Lynch, Coley, & Medin, 1999).

Our main goals are: 1) to assess the psychological reality of extrinsically cohering categories in contrast with the intrinsic coherence attributed to standard taxonomic categories; 2) compare types of extrinsically cohering categories; and 3) address the non-uniformity of coherence in real-world categories. We use an exemplar generation task along with several follow-up measures to determine whether these different posited sources of category coherence are made evident in the behavior of the category.

Experiment 1: Exemplar generation

We begin by using exemplar generation as a means of indexing category coherence. Through measuring the content and dynamics of responding, a picture can develop of the organization of the knowledge being accessed. This technique has been used sporadically in the categorization literature. Goal-derived categories have been shown to support exemplar generation, but produce less output and show a lesser degree of correlation of output dominance with typicality than taxonomic categories under short time intervals (Barsalou 1983, 1985; Vallee-Tourangeau, Anthony, & Austin, 1998). In addition, greater output consensus was found for taxonomic than ad-hoc categories.

Several lines of evidence lead to the prediction that taxonomic categories should be easier and more natural than relational categories. As noted above, relational categories are akin to analogies: their members need share only relational similarity, not overall literal similarity. In contrast, the members of taxonomic categories share overall similarity. For example, two instances of *vegetable* are likely to have considerable intrinsic similarity (seeds, skin, etc.), as well as some extrinsic similarity (sold in stores, provide nourishment, for people, etc.). There is considerable evidence that relational similarity is more difficult to access in memory than object similarity (Gentner et al, 1993; Holyoak & Koh, 1995); and acquired later in development (Gentner & Rattermann, 1991). Further, Barr & Caplan (1987) showed that categories characterized by extrinsic features possess a greater degree of graded structure—possibly due to lower category validity of extrinsic properties. Thus we expect that relational categories will be less fluent (fewer runs of responses with minimal inter-item delay), less generative (fewer responses produced), and less consistent (lower agreement between participants) than taxonomic categories.

Evidence on the behavior of goal-derived categories leads us to expect that they should also be less generative than taxonomic categories. The investigation of thematic categories is more exploratory. The fact that members of thematic categories – such as 'ticket' and 'popcorn' for *things associated with going to the movies* -- lack not only intrinsic, but even relational similarity, might lead one to expect low generativity. On the other hand, the fact that thematic associates share spatiotemporal contiguity suggests that members might readily prime one another.

Method

Participants. 75 undergraduates from Northwestern University served as participants in order to fulfill an introductory course requirement.

Materials and design. Eight category cues (see Table 1) were selected for four different types of categories: taxonomic (all count noun superordinates), thematic, goal-derived, and relational. Natural language labels for the categories were determined for optimal clarity. Each participant generated exemplars for two category cues of each type. Item assignment was accomplished by random selection. The experiment used a within-Ss design with four item conditions corresponding to the types of categories.

Procedure. Participants read a set of instructions appearing on the computer screen. They were told they would be shown category cues (words or phrases) and asked to generate as many examples as they could during 4-minute intervals. To illustrate the nature of the task, a sample was shown: examples of *beverage* include water and milk. Participants were asked to work

as quickly and accurately as possible. The category cue remained visible for the duration of the trial. Participants typed into a response window on the screen. For each response, the time of the initial keystroke and the time of typing the return key were recorded. All responses entered for that cue remained accessible to the participant in a history window. This is comparable to a pencil-and-paper version of a listing task, but allowed recording of precise timing information. The eight category cues were presented in a random order. The entire experiment took approximately 35 minutes.

Table 1: Categories used.

Taxonomic	an animal
	a plant
	a fruit
	a vegetable
	a vehicle
	a household appliance
	a type of dwelling
	a musical instrument
Thematic	an item associated with:
	dining out at a restaurant
	going to the movies
	working at an office desk
	preparing for sleep at night
	working out at the gym
	going to the beach
	a party
	taking an airplane trip
Goal-derived	an item to take on a camping trip
	an item to remove from the house in case of fire
	an item not to eat while dieting
	a picnic activity
	a thing to do for weekend entertainment
	a way to advertise something
	an item to sell at a garage sale
	a thing that makes someplace desirable to live
Relational	a weapon
	a trap
	a guide
	a signal
	a barrier
	a tool
	a filter
	a shield

Results

The results are summarized in Table 2. All analyses were conducted by item since each participant only responded to two out of the eight items in each condition. The number of presentations of each item was not equal due to the random selection, but the number of presentations of each type of item was equal. All items were presented at least seven times.

Two analyses of response dynamics were performed on the entire data set (N = 75): response fluency and clustering. *Response fluency* was a measure of how long it took to generate each response. The "downtime" between any two responses was computed as the amount of time between the initial keystroke of each response. Item fluency was determined by the median downtime between responses. Mean fluency (in milliseconds) varied across item condition, as shown in Table 2. Comparison of the means using a one-way ANOVA showed a reliable difference between conditions, $F(3,31) = 6.44$, $p = .002$. As predicted, the Relational condition ($M = 10832$) was significantly less fluent according to post-hoc comparisons (all such tests we report were performed using the Bonferroni correction) than both the Taxonomic ($M = 6370$), $p < .01$) and the Thematic ($M = 6793$), $p < .01$) conditions.

We assessed *clustering* of responses in several ways yielding convergent results. In one analysis, any two responses that occurred within less than 67% of the median downtime for all responses by that participant were considered to be clustered together. To measure the degree of clustering, a ratio was constructed between the number of clustered responses and the number of isolated responses. A value greater than one indicates more clustered than isolated responses.

The clustering ratios are shown in Table 2. A one-way ANOVA was used to assess the differences between conditions, $F(3,31) = 6.76$, $p = .001$. Post-hoc comparisons showed reliably less clustering for Relational ($M = .64$) than for Taxonomic categories ($M = 1.38$), $p < .02$. In addition, significant differences were found between Relational and Thematic ($M = 1.48$), $p < .01$, as well as between Goal-derived ($M = .82$) and Thematic ($p < .04$).

Table 2: Summary of Results of Experiment 1.

	Tax	Thematic	Goal	Relation
Productivity	23.2	21.9	19.1	14.2
Consensus	25.8	18.1	17.3	13.8
Paragons	5.1	2.1	1.1	0.8
Easy-Access	2.5	3.0	1.5	0.6
Fluency	6370	6793	8140	10832
Clustering	1.4	1.5	0.8	0.6

Analyses of response content. A subset of the responses (the first 46 of the 75 participants) was analyzed intensively using a scoring procedure performed by trained undergraduate research assistants. Responses were removed from the analysis on the basis of a clear failure to understand the task or to undertake it seriously. Repeated and blank responses were also removed. A conservative coding of responses was performed: pure synonyms, abbreviations, and minor

syntactic variations (e.g., singular versus plural) were treated as the same response.

Productivity or item output was measured as the mean number of responses produced. A one-way ANOVA was performed to test for differences between Goal-derived (M = 19.1), Relational (M = 14.2), Taxonomic (M = 23.2), and Thematic (M = 21.9). An effect of item condition on productivity was found $F(3,31) = 3.87$, $p = .02$. The effect appears to be driven by the low mean productivity in the Relational condition. Post-hoc comparisons revealed a significant difference between Relational and Taxonomic ($p < .03$). A marginal difference was also found between Relational and Thematic ($p < .07$).

In order to evaluate whether participants tended to generate the same responses to the categories, output *consensus* was measured in two ways. For each item, the percentage of participants who produced each response was computed and the mean was taken across all responses generated for that item. By this measure, output consensus varied as follows: Goal-derived (M = 17%), Relational (M = 14%), Taxonomic (M = 26%), and Thematic (M = 22%). A one-way ANOVA showed a reliable difference between item conditions $F(3,31) = 6.41$, $p = .002$. Post-hoc comparisons showed significant differences between Taxonomic and both Relational ($p = .001$) and Goal-derived ($p < .03$). The difference between Taxonomic and Thematic was marginally significant ($p < .07$).

As a convergent measure, output consensus was also analyzed by computing the percentage of responses that occurred frequently (generated by at least 60% of the participants receiving the item). Few responses were widely agreed upon by participants: Goal-derived (M = 4%), Relational (M = 2%), Taxonomic (M = 12%), and Thematic (M = 5%). Group means were compared using a one-way ANOVA that revealed an effect of condition on output consensus $F(3,31) = 4.50$, $p = .01$. On both measures, agreement was greatest for Taxonomic and lowest for Relational.

The content of the exemplar generation data showed particular responses that occurred with great regularity (produced by at least 85% of participants). To give an example from each type of category: 'car' was a paragon of the Taxonomic category *vehicle*, 'wall' was a paragon of the Relational category *barrier*, 'tent' and 'sleeping bag' were paragons of the Goal-derived category *an item to take on a camping trip*, and 'check' was a paragon of the Thematic category *an item associated with dining out at a restaurant*. The prevalence of such high-agreement responses was computed by counting the number of paragons for each item. This measure is reported as a frequency, not as a percentage of the total set of responses, since the presence of special responses is not likely to follow from the overall breadth of responding. The mean number of paragons is shown in Table 2. A one-way ANOVA showed a significant difference between groups, $F(3,31) = 4.36$, $p = .01$. As confirmed by post-hoc comparisons, Taxonomic categories yielded significantly more paragons than Relational ($p < .02$) or Goal-derived ($p < .04$).

In addition, certain responses were found to occur both early and often in the exemplar generation task. The presence of such easy-access items was determined according to mean list position (normalized by list length). Frequent responses with a mean position score of less than 0.3 were considered easy-access responses. Easy-access responses sometimes, but not always, corresponded with category paragons. For example, the easy-access responses for the Taxonomic category *vehicle* included the paragon 'car' plus 'truck.' 'Wall' was the only paragon as well as the only easy-access response for the Relational category *barrier*. 'Tent' and 'sleeping bag' were both paragons and easy-access responses for the Goal-derived category an *item to take on a camping trip*. For the Thematic category *an item associated with dining out at a restaurant,* the paragon was 'check', but the easy-access responses were 'waiter' and 'menu'. A one-way ANOVA showed an effect of item condition on the frequency of easy-access responses, $F(3,31) = 5.98$, $p < .005$. Post-hoc comparisons showed Relational categories produced reliably fewer easy-access items than Thematic ($p < .005$) and Taxonomic ($p < .03$) categories.

Discussion

A basic pattern can be discerned across the set of results. The Relational and Taxonomic categories are reliably different on nearly every measure tested. This provides strong support for the predicted differentiation of intrinsic and extrinsic forms of category coherence. The analysis of response content reveals that Relational categories (and to a lesser degree Goal-derived categories) are less productive, less consistent, and less likely to have paragons or easy-access responses. The thematic categories are distinct in the high frequency of easy-access responses.

Experiment 2a: Pairwise Similarity of generated exemplars

We suggested above that only the Taxonomic categories possess coherence based on intrinsic similarity. To confirm this claim in terms of the actual responses generated by participants, we obtained similarity ratings for within-category pairs.

Method

Participants. 37 undergraduates from Northwestern University served as participants in order to fulfill an introductory course requirement.

Materials. Stimulus materials were sets of the six responses generated with the highest consensus on half of the category items in Experiment 1 (the half selected were those items yielding the most high-consensus responses). All within-category pairs were tested.

Procedure. Participants received instructions to rate the similarity of pairs of items on a scale from low (1) to high (5). An example of both high and low similarity was provided. All possible within-category pairs were presented in pseudo-random order (no pairs from the same category were presented consecutively). Each pair was presented in random left-right order. Participants used the mouse to click on the button labeled with the numerical rating. A response could be changed by re-selecting before clicking "OK" to continue.

Results and Discussion

Mean pairwise similarity was computed across the fifteen within-category response pairs for each item. Across all participants, Taxonomic (M = 3.8) pairs showed the highest mean similarity while the other conditions were nearly equal: Relational (M = 2.3), Goal-derived (M = 2.4), Thematic (M = 2.4). This difference was confirmed by a one-way ANOVA, $F(3,15) = 13.31$, $p < .001$. Post-hoc comparisons showed highly significant differences between Taxonomic and the other conditions (all $p < .01$).

The results are consistent with our prior findings in showing an advantage for Taxonomic categories over Relational categories. In addition, neither Thematic nor Goal-derived categories showed high within-category similarity. This pattern is consistent with the view that taxonomic categories are based on overall default similarity while the other types are grounded in alternate forms of category coherence.

Experiment 2b: Category transparency of generated exemplars

A measure of the nature of a category's coherence is how readily the common basis can be perceived given a large set of examples. In this study, participants were presented with sets of generated category examples and asked to say what they had in common. As before, an advantage was predicted for Taxonomic categories.

Method

Participants. 25 undergraduates from Northwestern University served as participants in order to fulfill an introductory course requirement.

Materials. The same materials were used as in Experiment 2a. Instead of pairs, the six high-consensus responses for each category were presented together. A packet was prepared with one page for each category. The six responses were displayed on the page in three staggered columns of two to minimize spatially organized sub-groups within the set. The order of the six responses was fixed (alphabetical). The pages of each packet were randomly ordered.

Procedure. On each page of the packet to be completed, participants were given a blank line on which to answer: "What would you say the following examples have in common?" Additionally, three blank lines were provided to: "Try to think of a few more examples that fit well with the group."

Results and Discussion

The results of the commonality task are of principle interest since participants were almost always able to generate consistent additional examples. Participants routinely interpreted the commonality judgement as if the task were to induce the category from the examples. Category transparency for each item was computed as the percentage of participants whose response was scored as a match to the initial category cue used in Experiment 1. Responses that captured the meaning of the category, but differed in word choice, were accepted as matches. Taxonomic (M = 100%) and Thematic (M = 97%) items showed very high mean category transparency. Relational (M = 74%) and Goal-derived (M = 68%) items showed considerably less transparency. A one-way ANOVA revealed an effect of item condition, $F(3,15) = 3.71$, $p < .05$. A planned contrast between Relational and Taxonomic showed a reliable condition difference, $t(12) = 2.19$, $p < .05$.

Taxonomic categories are highly transparent, as should follow from their high intrinsic similarity. In contrast, Relational categories, as expected from their extrinsic similarity grounding, show lower transparency—likewise for Goal-derived categories. While participants were sometimes able to instantiate these original categories from the bottom-up, there were frequent failures as well. The above three types behaved consistently on pairwise similarity and category transparency tasks. However, Thematic categories showed a marked difference: despite low inter-item similarity (Experiment 2a), the connection among the group as a whole was highly transparent. We conjecture that the multiple examples in the current task invited participants to instantiate unifying spatiotemporal contexts.

General Discussion

Results across the two studies strongly bear out our predictions. Taxonomic categories show high intrinsic similarity and all the many advantages in terms of fluency and generativity which follow. Relational categories are markedly less similar, less transparent,

and less generative. The remaining two kinds of categories are intermediate. Goal-derived categories often pattern with Relational categories—not surprisingly, since relations link objects to goals. Thematic categories are in some sense the outlier; while they are highly fluent, they are grounded not in commonality, but in associativity.

Before discussing the implications of these data, there are some concerns to be addressed. Our choice of items represents our best effort to capture each type, but some factors were not precisely controlled. One issue is whether lower production can be attributed to smaller set size. Unfortunately, establishing the size of a relational category is not straightforward; e.g., should examples such as 'lack of education' (listed under barrier) be included? Relational categories may include more abstract or less familiar examples. These factors could play a role in generation.

To summarize, traditional explanations of real-world categories have appealed to feature overlap and the correlational structure of the environment. The emphasis suggested by the theory view of concepts on relations within and between category examples and the success of the structural alignment account of psychological similarity point toward a key role for relations underlying category coherence. The research reported here shows that extrinsic coherence can support categorical organization and points to individual signatures for different kinds of categories.

Given that relational categories appear to bring up the rear on all our measures, should we draw the implication that such categories are not psychologically real or natural? We would answer No, and Yes. Relational categories are indeed less natural than categories based on overall similarity; they do not provide a first-order basis for making sense of the world. But they provide structural organizers for understanding the world in ways that cross-cut object-based categories. We suggest that categories such as *barrier*, *operator*, and *catalyst*, though they may never be as facile as object categories, pay their way as tools of cognition.

Acknowledgments

This research was supported by an NIH-NRSA post-doctoral fellowship to Ken Kurtz and by NSF Grant SBR-95-11757 to D. Gentner. This paper was partially prepared while D. Gentner was a fellow at the Center for Advanced Study in the Behavioral Sciences with support from the William T. Grant Foundation, award #95167795. Abstract

How students learn to use diagrammatic representations is an important topic in the design of effective representations for problem solving or conceptual learning, but few good models of their learning exist. In this paper, we explore the learning process with an experiment using AVOW diagrams as a representation for solving problems in electric circuits. We find that the participants decompose each circuit into a similar set of groups when solving the problems. The natural question is whether these groups are an artifact of the visual form of the circuit, or indeed the result of prior learning. We argue that the decompositions are a result of perceptual chunking, and that they are (at least partly) a result of learning. In support of this, we describe a computational model of perceptual learning, CHREST+, and show that it predicts the decomposition of problems evident in the participants' data.

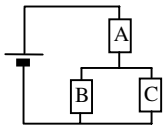
Introduction

The role of effective representations in supporting or enhancing the conceptual understanding of a student is an important topic within educational psychology (Cheng, 1999b; Larkin & Simon, 1987). However, in spite of the educational interest in effective representations, the manner in which students learn with and about different representations is not well understood. The traditional method of looking for chunks, through timing information (e.g. Chase & Simon, 1973), is hard to apply in problem-solving tasks, as the timing information is associated with the solution, and not directly linked to the problem. We instead use a computational model to match the solutions produced by students in a typical diagrammatic reasoning task, and use the model's learnt associations between problem and solution states to argue that students are using learnt perceptual chunks as a guide to problem decomposition.

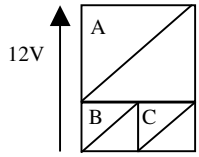
This paper describes an example diagrammatic reasoning task, which involves using AVOW diagrams to compute quantities within circuit diagrams. Based on results from an experimental study, we provide some samples of how students tackle a complex problem within this domain, and observe that the problem is decomposed in a consistent form across the students. The natural question is whether these groupings are based upon the students' prior learning, or are merely an artifact of the target's visual form. We argue that students do learn these groupings, and that their learning process is explainable in terms of the perceptual chunking theory. In support of this, we trained the CHREST+ model, which is based on the perceptual chunking theory, on the same sequence of circuits as was provided to the human participants. We show that CHREST+'s predicted decomposition of the sample problem matches that used by the participants.

Computing Unknowns in Circuits

This paper explores how students learn to use diagrammatic representations for problem solving. As an example domain, we use the task of computing unknown quantities in electric circuits using AVOW (Amps Volts Ohms Watts) diagrams, which represent circuits and the domain laws of electricity using diagrams and constraints on their composition. AVOW diagrams are described in Cheng (1998), and Figure 1 provides an example of how AVOW diagrams are constructed and used for problem solving. Essentially, each resistor in an electric circuit is represented as a separate AVOW box. The dimensions of the box are scaled to represent the quantities within a resistor: current (I) is the width of the box, voltage (V) is the height of the box, resistance (r) is the gradient of the box's diagonal, and power (P) is the box's area. Note that the relations between the box's dimensions encapsulate rules of electric circuits. Thus, the gradient of the box's diagonal is its height divided by its width, which restates Ohm's Law, $r = V/I$. Similarly, the box's area is its height times its width, which restates the Power Law, $P = VI$.



The battery has a voltage of 12V and all three of the resistors have a resistance of 1 ohm. What is the current drawn from the battery?



Each of the AVOW boxes is a square, because each resistor's resistance is 1 ohm. The height of the total diagram is scaled to represent 12V. Hence, the width of the total diagram represents the current, measured to be 8 amps.

Figure 1 : A circuit problem and its AVOW diagram.

Composition of individual boxes is used to represent a circuit of several resistors; the rules for composition preserve the underlying physical laws of electric circuits. In working with this representation, students must first produce an AVOW diagram scaled according to the provided quantities, and the constraints in the diagram ensure that the laws of electricity are followed during its composition. The final AVOW diagram will thus provide information about all other quantities within the circuit, enabling the student to simply measure the appropriate dimension for any unknown quantity. Various studies (Cheng, 1998, 1999a) have shown that AVOW diagrams provide a more effective representation than algebra for learning concepts about electric circuits. An increasingly important element in the design of effective educational material is a better understanding of how humans learn with these representations (Cheng, 1999b). The aim of this paper is to find some indicator in the students' solutions to their underlying learning mechanisms. We achieve this by showing that all participants use a similar decomposition of the circuit problems.

Observing the Problem Decomposition

A study on the use of AVOW diagrams was performed with six participants (2 with A level physics, 4 without). Each participant received basic instruction in the use of AVOW diagrams, and was then asked to construct appropriate AVOW diagrams for a sequence of electric circuits. Solution diagrams were entered on an electronic sketchpad, which allows diagrams to be constructed on screen using a mouse to place elements such as lines, rectangles and parallel lines of various thicknesses, as well as add textual labels. The computer retains a record of each drawing action with detailed timing information; note, the system provides no support for constructing AVOW diagrams *per se*. After an initial 15 minutes' training session on AVOW diagrams and in using the electronic sketchpad, participants were presented with a graded sequence of 30 problems, ending with complex circuits of up to 12 resistors. After each circuit was attempted, the correct AVOW diagram was shown to the participants. We illustrate here how the participants performed on the last of the 'straight-forward' circuits, illustrated in Figure 2(a) with its target AVOW diagram in Figure 2(b). (The remaining four circuits tested for generalisation to more complex circuit types, such as those requiring 3D layouts, and so are not included.)

Figure 4, at the end of this paper, illustrates in detail the progress of three participants on the sample problem. The graphs show the latency between each of the drawing actions required to complete the solution. Noticeable in these examples, and common to all the participants, is the presence of *peaks*, which separate

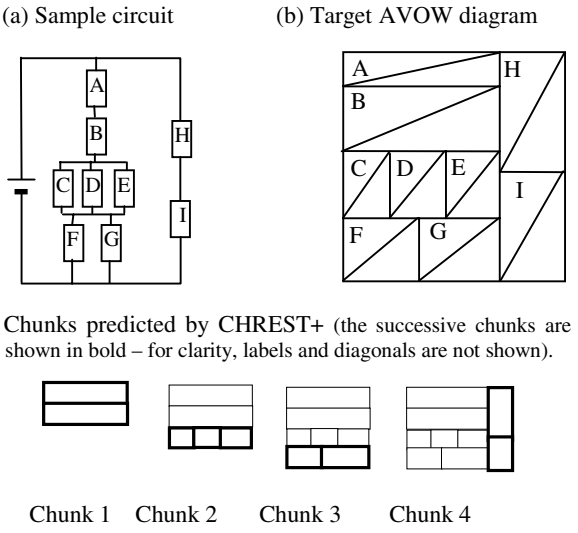


Figure 2 : The sample problem and its solution.

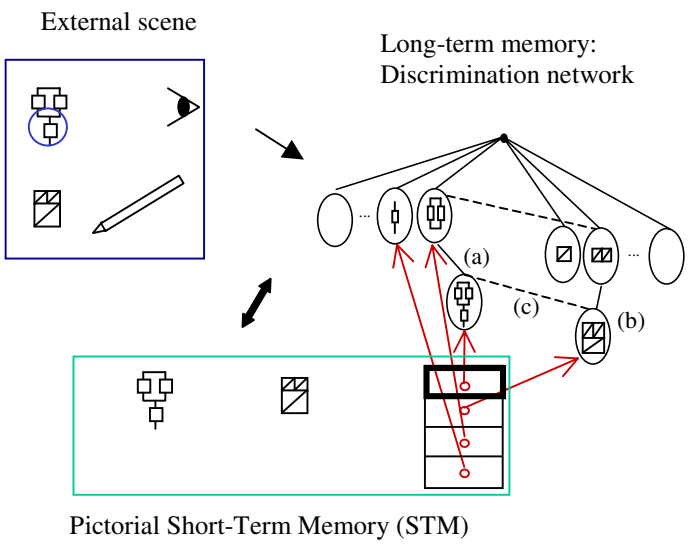
the sequence of actions into a number of stages. Such peaks have also been shown to correlate with meaningful decompositions in other forms of drawing (e.g. Cheng, McFadzean & Copeland, 2001). The figure also illustrates the parts of the AVOW diagram completed during each stage. These stages represent how the participant decomposed the solution.

From this first look at the graphs, we may conclude that the participants are using similar decompositions. These decompositions must be based on features of the target circuit diagram, and the interesting question from the perspective of effective representational design concerns their origin: Are they mere artifacts of the grouping of elements within the circuit, or are they the result of prior training? It is difficult to answer this question directly without some insight into the knowledge which each participant brings to the sample problem. In order to tackle this question, the next section describes a computational model, CHREST+, and shows how it can be used to predict the behavioural characteristics found in the participants' data.

CHREST+ : Learning Perceptual Chunks

The perceptual chunking theory for human memory has had a long history within cognitive science, and forms the theoretical basis of the EPAM/CHREST family of computational models (for a review, see Gobet *et al*., in press). Chase and Simon (1973) first proposed how perceptual chunking could be used in a model of problem solving based on EPAM (Elementary Perceiver and Memorizer) (Feigenbaum & Simon, 1984). The EPAM model assumes an input device (e.g. a simulated eye), a short-term memory (STM) for storing intermediate results, and a long-term memory based around a discrimination network containing



Recognition

The simulated eye is passed over the target stimulus, and the retrieved patterns are sorted through the discrimination network. Matching chunks are retrieved and placed within STM.

Learning

New nodes are added to the network through a process of *discrimination*. Illustrated at (a) and (b), the new pattern has caused an additional test link and node to be created. *Familiarisation* has then filled in the node image with features from the observed pattern. *Equivalence links* (the dotted lines) are formed when CHREST+ has a pointer to both a circuit chunk and an AVOW chunk within its STM at the same time. Here, the model has just learnt link (c).

Figure 3 : The CHREST+ model. The model includes a simulated eye and pen for interacting with the external environment, a fixed capacity short-term memory, and a long-term memory.

chunks of information. However, EPAM itself was only applied to certain perception and memory phenomena, and not more complex problem-solving domains, in part because of the simplified form of its learning mechanisms. This limitation is corrected in the CHREST (Chunk Hierarchy and REtrieval STructures) model, which includes various extensions to EPAM (Gobet, 1996; Gobet & Simon, 2000).

CHREST+ (Lane, Cheng & Gobet, 2000) has been developed to investigate how a memory of perceptual chunks can be used in problem solving with diagrams; the model is illustrated in Figure 3. Like CHREST, CHREST+ learns a discrimination network of perceptual chunks by scanning circuit and AVOW diagrams with its simulated eye. The network consists of a collection of perceptual chunks, which are stored at nodes in a network, interconnected by test links. Patterns are used to retrieve chunks from the network by sorting them, beginning from the root node, through the network against the tests stored at the test links. Once a pattern reaches a node, learning may occur: if the pattern matches the chunk at the node, then more information can be added from the pattern to the chunk (familiarisation); if the pattern mismatches the chunk, then a new test link is added based on the mismatching features, and a new node is created (discrimination). These processes are illustrated in Figure 3: at point (a), a test link for a single resistor is used to distinguish the collection of three resistors from the two in parallel; this link is added during discrimination, and the contents of the node added during familiarisation.

The process of learning about circuit and AVOW diagrams is illustrated in Figure 3. Because the circuit and AVOW diagram representations do not overlap, individual nodes within the network will represent either an individual circuit diagram, or an individual AVOW diagram. In consequence, if CHREST+ is to generate AVOW diagrams when presented with a circuit, it must also associate chunks about circuits with chunks about AVOW diagrams. Accordingly, CHREST+ includes an additional learning mechanism for forming *equivalence links*; these are lateral links (Gobet, 1996) connecting two chunks within the discrimination network. An equivalence link is formed when the model is presented with a circuit diagram and its equivalent AVOW diagram. During the process of recognising the two diagrams, separate chunks will be placed into STM, one for the circuit diagram and one for the AVOW diagram. An equivalence link is then formed between the relevant two nodes in the network. Figure 3 illustrates this process, with an equivalence link formed at point (c). As can be seen, particular problems (circuit diagrams) become associated with information about their solution (equivalent AVOW diagrams). Generating an AVOW diagram for a novel circuit diagram then requires the model to locate chunks (sub-networks) within the circuit diagram for which it has an associated AVOW diagram; the AVOW diagrams for these sub-networks may then be drawn, and a further familiar sub-network located. The process by which CHREST+ incorporates its retrieved AVOW diagram into the evolving solution diagram is provided by specific, handcoded routines – these are akin to the basic training the participants received in AVOW diagrams.

Predicting the Observed Decompositions

We trained CHREST+ using the same sequence of circuits as the participants. By the time CHREST+ reaches the sample problem, it has learnt a discrimination network of 72 chunks, 42 for circuit diagrams and 30 for AVOW diagrams, with 11 equivalence links. When presented with the sample problem, CHREST+ retrieves four separate chunks whilst constructing its solution; these are illustrated in Figure 2(c). Note that the assumption in CHREST+ that information is contained in encapsulated chunks strongly predicts that problems will be decomposed as familiar chunks. Also, because CHREST+'s chunks are associated directly with equivalent AVOW diagrams, we can observe the effect of its circuit decomposition in the breakdown of the AVOW diagram's construction into stages. We now show how the decompositions can be affected by learning, how the participants' data provide reliable decompositions, and how well the participants' data are matched by the model.

Decompositions are Due to Learning

The precise number and content of chunks used by CHREST+ is governed by its experience with the previously encountered problems. By providing different sets of problems, CHREST+ extracts different familiar chunks when decomposing the same sample circuit diagram. For example, presenting the sample problem after initial training on a circuit containing only a single resistor leaves CHREST+ with little choice but to decompose the problem into 9 distinct resistors; a more extensive training sequence allows CHREST+ to identify just 2 sub-circuits within the sample circuit. With the training sequence used, CHREST+ therefore makes a two-fold prediction: that four chunks are identified in the circuit, and that their form is as illustrated in Figure 2(c).

Specifying a Decomposition

Returning to the graphs of the participants' drawing actions shown in Figure 4, we can consider how the decompositions provided by the peaks in the drawing actions compare across participants, and also whether they compare with the model's predicted chunks.

The first participant, CP, in Figure 4(a) has clearly begun from the right-hand side of the figure, then worked out the central triplet of resistors. These stages are preceded by longer pauses between the drawing times (marked by asterisks), and their correspondence to the chunks given by the model is clear: we highlight the stages with vertical divisions, illustrating the current state of the solution at the end of each stage. Similarly with the second participant, SG, who instead begins from the left-hand side; note also that SG requires considerably more time than CP. Note the different order in which the diagram is tackled, although the overall stages are the same. Finally, the third participant, EF, used whole rectangles when constructing the solution; these rectangles were laid out in sequential fashion, beginning from the right-hand side, and then top to bottom. However, from the pauses evident in the times between drawing actions, we can see that this sequence of boxes was divided into the four stages corresponding to individual chunks. The remaining three participants show a similar pattern, but are not illustrated here.

Table 1 : The number of actions each participant made when completing the sample problem, classified as follows: NP – non-peaks; P – peaks; PC – pre-chunk; SB – start+bounding box; L – labels; E – error; Mi – missed chunks; ∑ – totals.

	Participant						
	CP	**DJ**	**EF**	**HA**	**RH**	**SG**	**∑**
NP	19	17	7	16	8	8	75
P	5	5	4	7	3	5	29
PC	3	3	2	3	2	4	17
SB	2		1	1	1	1	6
L		2		3			5
E			1				1
Mi	1	1	1		2		5

Matching Observed Decompositions

We can now directly compare the stage-wise output of the sample circuit's AVOW diagram by CHREST+ with its solution by the participants. We quantify the correspondence between CHREST+'s prediction and the participants' behaviour by counting how many of CHREST+'s chunk boundaries correspond with the participants' peaks. For this analysis, a peak is a time between drawing actions prominently larger than the preceding and succeeding times: the peaks used are highlighted in the figure with asterisks.

For example, the graph for CP shows five peaks. The first and second peaks correspond to CP beginning the problem and creating a bounding box for the entire circuit, as illustrated in the diagram before the first dividing line. Between the third and fourth peaks, CP completes the part of the diagram which corresponds with chunk 4 in CHREST+'s output, and hence we count the third peak as a pre-chunk boundary. Similarly, between the fourth and fifth peaks, chunks 2 and 3 are completed in the diagram. Note that there is no peak corresponding to a retrieval of the 3rd chunk, against the model's prediction. Finally, after the fifth peak, CP completed chunk 1 and then added the labels to all the AVOW boxes; the simplicity of this process is reflected in the low times between these operations.

We therefore explain the five peaks as follows: the first two are for the start and bounding box, and the next three are pre-chunk boundaries. One chunk boundary seems to have been missed. Table 1 summarises the analysis for all six participants.

The analysis shows that nearly all of the peaks correspond with stages in the drawing which we would explain by the use of chunks. Note that, out of the 24 predicted chunks (6 participants and 4 predicted chunks), 17 peaks were clearly identifiable chunk boundaries, and there were only 5 missed chunks. This leaves unaccounted 2 chunks, which were instead created directly from the start, and thus are included with the starting times of the participant: this analysis therefore identifies 19 peaks in the participants' behaviour which precede chunk boundaries out of 24 predicted chunks. These results demonstrate that CHREST+ predicts the decomposition of problems evident in the participants' data, and so support our claim about the role of learnt perceptual chunks in problem decomposition.

Conclusion

This paper has used the perceptual chunking theory, as implemented in CHREST+, to predict specific perceptual chunks learnt from a given sequence of instruction. We have presented results from a study of six participants solving electric-circuit problems using AVOW diagrams. The predictions from the model have been shown to correlate with the stages in problem solving evident in the participants' performance.

To fully understand the participants' problem decomposition and learning pattern, we need to consider more closely what is happening during the peaks in their output timings. Looking at the CHREST+ model, the participants' peaks correspond to the processes of pattern recognition and retrieval. In addition, processes of planning along with some lookahead must be going on. This lookahead and planning probably explains the missed chunks in the preceding analysis. At present, CHREST+ always outputs its solution AVOW diagram as soon as it is found. Through a small modification in its output strategy, CHREST+ could instead retain more than one chunk for solution, and output several together. This would provide CHREST+ with the potential for lookahead, making it a more plausible problem solver, as well as capture the pattern of missed chunks.

The interesting result from this paper is that the chunks used by learners within such domains may be predicted using an established computational model. Further work with this domain should aid in refining the model and its predictions, and also extend it into other domains. In particular, this use of perceptual chunks in decomposing diagrams has already been shown to occur more generally (Cheng, McFadzean & Copeland, 2001). In the longer-term, one of the important applications for this research is likely to be the design of effective computer-based learning environments (Gobet & Wood, 1999).

Abstract

Rescorla (in press) investigated the change in associative strength undergone by cues A and B as a result of reinforcement or nonreinforcement of an AB compound. Many leading theories of associative learning predict that if A and B are equally salient then the associative change experienced by each should be the same regardless of their associative strength preceding AB trials. Rescorla explored this prediction for a compound composed of an excitatory A and an inhibitory B, using rats and pigeons as subjects. We repeated Rescorla's experiment using human subjects and a causal judgment task, and obtained diametrically opposite results to those of Rescorla's earlier study. The implications of this finding are discussed with reference to a number of influential theories of associative learning.

Introduction

It has long been recognised that stimuli presented in compound can, and will, interact and compete for associative strength. This is powerfully demonstrated in the phenomenon of blocking (Kamin, 1969). This refers to the finding that the gain in excitatory strength accruing to a conditioned stimulus (CS), B, following reinforcement (+) of an AB compound is much reduced if cue A has previously been trained as being a good predictor of that outcome (unconditioned stimulus, US). Learning does not simply progress with each cue independently. Instead the two cues seem to compete for a limited amount of associative strength. Such demonstrations of cue competition provided the motivation for the development of models that can deal with the issue of predictive redundancy in associative learning (e.g. Rescorla & Wagner, 1972; Mackintosh, 1975; Pearce, 1987).

A common feature of these models is the idea that the magnitude of associative change depends in some way on the discrepancy (or *error*) between the current associative strength of the presented cues and the strength which the outcome (unconditioned stimulus, US) following these cues can support. Consider, for instance, the Rescorla-Wagner (1972) model (R-W), perhaps the most influential of all of these "error-correcting" theories:

$$\Delta V_A = \alpha_A \beta_{US} (\lambda_{US} - \Sigma V) \qquad (1)$$

where ΔV_A is the change in associative strength of cue A, α_A and β_{US} are rate parameters relating to the salience of cue A and the US respectively, λ_{US} is the asymptote of conditioning supportable by that US, and ΣV is the summed associative strength of all cues present on a trial. Hence R-W states that the error governing associative change for any cue on a trial is based on the combined associative strength of *all* cues present on that trial. This is essential to R-W's explanation of blocking. On A+ trials, V_A will increase, with A coming to predict the US. On AB+ trials, the error term for cue B (and also for A) will be $(\lambda - \{V_A + V_B\})$. But of course as a result of A+ training V_A will already be high, and so the error term will be correspondingly small, such that any increase in V_B will be only very small. Thus the R-W explanation of blocking crucially hinges on the idea that, when determining the associative change undergone by B, the associative strength of other cues present on the trial (A) is also considered.

This use of a common error term governing associative change for all stimuli on a trial has important consequences. Rescorla (in press) noted that, in the absence of additional assumptions, it predicts that equally salient stimuli presented together on a trial will undergo equal associative changes. This prediction holds true regardless of the associative history of the cues in question.

In a recent series of experiments, Rescorla (in press) investigated this prediction in rats and pigeons (using magazine approach conditioning and autoshaping procedures respectively). He looked at the particular instance of an AB compound composed of an excitatory A and an inhibitory B. Specifically, he was interested in the associative change undergone by A and B as a result of either reinforcement or nonreinforcement of the AB compound. If we assume that A and B are of equal salience (ensured by counterbalancing) then, as a result of using a common error term, R-W is constrained to predict that both A and B will show equal associative change following either AB+ or AB- trials. Consider, for example, the AB+ condition. If A and B are equally salient, then $\alpha_A = \alpha_B$. Since both are presented with the same US, β will also be equal when calculating ΔV_A and ΔV_B according to equation (1). And finally, the error term for both A and B will be $(\lambda - \{V_A + V_B\})$. Hence, given that all the terms in the calculation for ΔV_A and ΔV_B are identical, Rescorla-Wagner must predict that on AB+ trials, $\Delta V_A = \Delta V_B$. This prediction of equal associative *change* holds true despite the fact that A (an excitor) and B (an inhibitor) begin these trials with very different associative strengths ($V_A > 0$, $V_B < 0$).

The problem with investigations such as this is one of how to assess the magnitude of associative change for two stimuli that differ in their "baseline" associative strength. It would be unwise to make any strong assumptions with regard to mappings between associative strength and measurable performance, and yet without such mappings we cannot be sure that two equal-sized changes in performance at different points on the performance scale represent equal-sized changes in associative strength.

Condition	Stage 1		Stage 2		Test

	R-	S-	W+	X+	
	T-	U-			

Table 1. Experimental design.
+: outcome; -: no outcome; ?: exposure trial.

Rescorla suggested an elegant way of avoiding this problem, by comparing performance to A and B when they were embedded in compounds designed to ensure comparable overall levels of performance. We adopt this technique in our experimental design (Table 1). Consider the Compound Reinforcement (CR) condition. A and C are initially trained as equivalent excitors, while B and D are trained as equivalent inhibitors. So following Stage 1, compounds AD and BC should have equal strengths, as each contains one of two equal excitors and one of two equal inhibitors. We then reinforce the AB compound. If this results in equal changes to the associative strengths of A and B (as predicted by R-W), then the AD and BC compounds should remain equal after Stage 2 (as each starts at the same level and receives the same change). If instead the strength of A increases more than that of B, then responding to AD will be greater than to BC. Conversely, if the strength of the inhibitory B increases more than that of the excitatory A, then BC will give rise to more conditioned responding than AD. A similar argument can be applied to the Compound Nonreinforcement (CNR) condition: if FG- trials cause a greater decrement in V_F than V_G then we expect the FI compound to be rated lower than GH: if V_G decreases more than V_F we expect the opposite.

Using this kind of logic, the results of Rescorla's experiments indicated that reinforcement of AB led to a greater increase in the associative strength of the inhibitory B than the excitatory A, while nonreinforcement of AB led to greater associative loss in the excitatory A than the inhibitory B. Rescorla (2001) carried out a similar investigation, this time with an AB compound consisting of an excitatory A and a neutral B. Again, AB+ trials led to a greater increase in V_B than V_A, whereas nonreinforcement gave a greater decrement in V_A than V_B. This indicated that the previous result was not simply due to some special property of conditioned inhibitors. Instead it seems that initial associative strength is an important factor in determining the distribution of associative change among the elements of a compound. This, of course, runs contrary to the predictions of R-W.

This prediction of equal change does not apply only to elemental theories such as R-W. Consider Pearce's (1987) configural model. This model proposes that a compound stimulus is best viewed as a unitary event that is separate from its elements, but able to generalise to them. Whereas according to an elemental model, an AB compound is decomposed into separate A and B elements, in a configural model it is represented as a single "AB" configuration. Generalised responding to other stimuli (e.g. A alone or B alone) occurs to the extent that these stimuli are similar to previously experienced configurations.

So on AB+ trials in Stage 2 of the CR condition, a configural model such as Pearce's learns an association between an AB configural unit and the US. Assuming that A and B are equally salient, this excitatory learning will generalise equally to each of them (they each have the same degree of similarity to AB), and so the model is constrained to predict equal associative change for A and B as a result of AB+ trials. Again no reference is made to the associative history of the cues. A similar story applies to the CNR condition: any change in association from an FG configural unit to the US will generalise equally to F and G.

Dickinson, Shanks & Evenden (1984) noted many similarities between Pavlovian conditioning in animals and the acquisition of causal judgments in human subjects. However, Le Pelley & McLaren (in press) demonstrated that not all phenomena in the animal learning field have analogues in studies of human causal learning. Given the importance of the previously described findings in elucidating the mechanisms underlying associative change, we aimed to repeat Rescorla's (in press) experiment using a causal judgment task with human subjects. This is of particular interest to us as, if we were to replicate Rescorla's findings in human subjects, it would invalidate the APECS model of associative learning that we have developed in recent years (Le Pelley & McLaren, in press; Le Pelley, Cutler & McLaren, 2000; see also McLaren 1993, 1994).

APECS is a model of learning and memory, based on the popular backpropagation algorithm (Rumelhart, Hinton & Williams, 1986), but with a couple of important differences. Firstly, APECS employs configural representation. Thus each different mapping of input to output is represented by its own hidden unit, which could equally well be termed "configural units". Secondly, APECS uses adaptive generalisation coefficients to determine the amount of generalisation between similar input patterns. As a result, once the weights appropriate to a mapping have developed, the learning in those weights can be protected against interference. This is achieved by reducing the learning rate parameter for the configural unit carrying that mapping. The effect is to "freeze" the weights to and from a certain configural unit at the value they hold immediately following experience of that configuration. Crucially, this freezing of weights to and from a certain configural unit occurs only if that configural unit has a negative error value, i.e. *if it is part of a mapping that predicts an incorrect outcome for the current input*. APECS has different learning rate parameters for input–hidden and bias–hidden connections. The former are frozen to prevent interference; the latter remain high. Hence extinction (suppression of inappropriate responses) is achieved by an increase in the negative bias on the hidden unit carrying the inappropriate mapping, rather than by reduction of weights (which would cause the original mapping to be lost from the network). Given appropriate input cues, the negative bias on the hidden unit can be overcome and the original mapping retrieved. So bias acts to change the retrievability of previously learnt mappings, such that

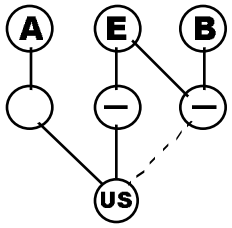

Figure 1. Associations developed following Stage 1, according to APECS. Excitatory connections are shown by solid lines, inhibitory associations by dotted lines. Negative bias on hidden units is indicated by a minus sign.

APECS addresses both learning (in formation of weights) and memory (in changes of retrievability).

Consider the processes at play in the CR condition, according to APECS. During Stage 1, the network will learn an excitatory connection from a representation of A to a configural unit, and from the configural unit to the output. Hence this configural unit comes to represent the A+ mapping. A different configural unit will be recruited to carry the E+ mapping. On BE- trials, presentation of E will cause positive activation to flow to the output via this E+ excitatory pathway. This positive activation is inappropriate on a trial on which the US is not presented: as a result the output unit will take on a negative error. This negative error will be propagated back along the excitatory connection to the E+ configural unit. This configural unit will therefore take on a negative error, as it is part of a mapping predicting an inappropriate outcome for the current input. This negative error means that, on BE- trials, the weights to and from the E+ configural unit will be frozen, as stated above. Instead the E+ configural unit will take on a negative bias to reduce expression of this excitatory mapping on these nonreinforced trials. In addition, excitatory associations will develop from B and E to a new configural unit, representing the BE configuration. This unit will develop an inhibitory association to the output in order to further counter any positive activation flowing to the output via the E+ hidden unit. By a similar argument, this BE- configural unit will develop negative bias on E+ trials. Hence following Stage 1, the situation for cues A, B and E is as shown in Figure 1 (this also applies to cues C, D, F, G, H and I and J, all of which have an equivalent partner in A, B or E following Stage 1).

What now happens on AB+ trials? The US will receive some positive activation via the A+ mapping learnt in Stage 1. However, it will also receive some negative activation via the BE- mapping (which can never be *totally* suppressed by development of negative bias). As a result the US will not be perfectly predicted on these trials, and yet is presented. Therefore the output unit will have a positive error. How can this error be reduced? Well, the positive error on the US unit will be propagated back to the BE- configural unit. But it is propagated along a negative connection, and so the BE- unit will take on a negative error (again, it is part of a mapping predicting an incorrect output on this trial). Thus weights to and from this unit are frozen. Extra negative bias can still be applied to the unit to reduce the negative activation flowing to the output, though, and this will help to reduce the output error. The positive output error will also be propagated back to the A+ configural unit along the positive connection. Thus the A+ configural unit will have a positive error. Both its weights and its bias are therefore free to change: the connections from A input to A+ configural, and from A+ configural to output, will increase. This too will reduce the output error.

In our previous expositions of APECS, we have always made the assumption that changes in weights occur faster than changes in bias. Thus we assume that changes due to learning take place faster than changes in memory, i.e. that learning represents rapid acquisition, and memory represents a more gradual decline in retrievability: this seems reasonable. We saw above that on AB+ trials, the weights of the A+ mapping are free to increase, whereas only the bias of the BE- mapping may change to reduce the effective strength of the inhibitory mapping. Therefore APECS is constrained to predict that, on these AB+ trials, the associative strength of the excitatory A will increase more than that of the inhibitory B. This is of course opposite to Rescorla's result.

A similar argument holds for the CNR condition. On FG- trials, the F+ hidden unit will have negative error (so only its bias may change), while the JG- unit has positive error (so that its weights and bias may both change). In this case APECS must predict that, on FG- trials, the associative strength of the inhibitory G will decrease more than that of the excitatory F, again opposite to Rescorla's result.

In summary, these results follow from the idea of adaptive generalisation. AB+ training generalises more to A+ than it does to BE- because AB and A predict the same outcome. Similarly FG- learning generalises more to GJ- than to F+ as FG and GJ predict the same outcome (no US).

Rescorla noted a problem with his paradigm that could cast doubt on the results obtained. AB compound presentation may result not only in development of A–US and B–US associations, but also in development of within-compound A–B associations. Consideration of these A–B associations complicates any inference of unequal associative change drawn from the results. Suppose A and B undergo equal changes as a result of AB+ trials. The formation of an A–B association might be expected to enhance responding to the inhibitory B (as it has been paired with an excitor), and reduce responding to the excitatory A (as it has been paired with an inhibitor). Thus even if the change in the A–US and B–US associations were equal, one would expect that AB+ trials would augment responding to B more than to A. Similarly, nonreinforcement of the AB compound might result in equal A–US and B–US decrements, but responding to A may fall further as it forms an association to the inhibitory B.

Rescorla controlled for the effect of within-compound associations in his Experiments 5 and 6. His findings were unchanged: Stage 2 AB+ trials gave a greater change in B than A, and *vice versa* for Stage 2 AB- trials. We were also careful to control for the effect of within-compound associations. In Stage 2, in addition to AB+ trials subjects also experienced CD "exposure trials". On these trials subjects saw cues C and D paired, but were not told whether or not the outcome occurred. Hence on these trials within-compound C–D–associations would form while C–US and D–US associations remain unchanged. The effect of A–B association formation would thus be matched by development of C–D associations. Therefore any difference between

AD and BC following Stage 2 could only be due to unequal changes in A–US and B–US associations on AB+ trials. The same holds true for the CNR condition.

Our investigation used an allergy prediction paradigm with human subjects. This paradigm has been used successfully in several studies of human causal learning (e.g. Dickinson & Burke, 1996; Le Pelley, Cutler & McLaren, 2000). Participants play the role of a food allergist judging the likelihood that various foods will cause an allergic reaction in a hypothetical patient. The foods, then, constitute the cues; the allergic reaction is the US. Following training, subjects rated how strongly certain individual foods, and compounds of two foods, predicted the occurrence of an allergic reaction. These ratings were taken as our measure of the strength of conditioning. This was a within-subjects experiment: subjects experienced all the different contingencies concurrently.

The Filler trials were included to ensure equal numbers of positive and negative trial types in each stage. In addition, they increase the number of different trial types seen by subjects, again following Dickinson & Burke and Le Pelley et al. This creates a large memory load, hopefully preventing subjects from basing their ratings on inferences made from explicit episodic memories of the various trial types. Instead subjects should have to rely on associative processes to provide an "automatic" measure of the causal efficacy for each cue. Using a large number of trial types makes us more confident that it is indeed associative, rather than cognitive, processes being tapped in our study.

Method

Participants Twenty members of Cambridge University (10 female, 10 male; age 19-49) took part in the experiment.

Procedure At the start of the experiment each subject was given a sheet of instructions presenting the "allergy prediction" cover story for the experiment. They were told that in the first block they would arrange for Mr. X to eat different meals on each day, and would monitor whether he had an allergic reaction or not as a result. In relation to the exposure trials (that do not bear on the issue at hand in this paper), subjects were told that occasionally the results of eating the foods had been lost. On these trials they would know the foods eaten in the meal, but not the result of eating those foods. They were also told that later on they would be asked to rate some of the foods according to how strongly they predicted allergic reactions.

On each conditioning trial, the words "Meal [meal number] contains the following foods:" followed by the two foods appeared on the screen. Subjects were then asked to predict whether or not eating the foods would cause Mr. X to have an allergic reaction, using the "x" and "." keys (counterbalanced). The screen then cleared, and immediate feedback was provided. On positive trials the message "ALLERGIC REACTION!" appeared on the screen; on negative trials the message "No Reaction" appeared. If an incorrect prediction was made, the computer beeped. On the exposure trials of Stage 2, the same message appeared, but now subjects were cued to enter the initial two letters of each of the foods. This was to ensure that they paid attention to the pairings of foods when no allergy prediction was required. The 24 foods used were randomly assigned to the letters A to X in the experimental design for each subject.

As shown in Table 1, there were 16 trial types in Stage 1, and 8 in Stage 2. Stages 1 and 2 were split into 8 sub-blocks, with each trial type appearing once in each sub-block (hence subjects saw each trial type 8 times). The order of trials within each sub-block was randomised, as was the order of presentation on the screen (first/second) within each compound pair.

After Stage 1, subjects were asked to rate their opinions of the effect of eating certain foods on a scale from -10 to +10. They were to use +10 if the food was very likely to cause an allergic reaction in Mr. X, -10 if the food was very likely to prevent the occurrence of allergic reactions which other foods were capable of causing, and 0 if eating the food had no effect on Mr. X (i.e. it neither caused nor prevented allergic reactions). For clarification, participants also had access to a card on which the instructions on how to use the rating scale were printed. Once a meal had been rated it disappeared from the screen and the next appeared: participants could not revise their opinions upon seeing later meals. Subjects were given a second rating test after Stage 2, when they were asked to rate meals containing either one food or two. Exactly the same test procedure was used.

Results and Discussion

The results of Test 1 indicated that we had been successful in generating conditioned excitation (to A and F, mean rating 8.63) and inhibition (to B and G, mean rating –8.1), as compared to Q (mean rating 0.6), which is never paired with the US and hence should remain neutral. Planned comparisons revealed that the average of A and F (which are equivalent) was significantly higher than Q, which was in turn significantly higher than B and G (which are also equivalent) [$F(1,19)=65.9$ and 93.2 respectively, ps<0.001].

Figure 2 shows the mean rating of the casual efficacy of each of the meals of interest as judged in the test following Stage 2. We see that the compound AD is rated higher than BC. This is confirmed statistically [$F(1,19)=5.87$, $p<0.05$]. This implies that reinforcing the AB compound led to a greater increase in the associative strength of the excitatory A than the inhibitory B. This is, of course, diametrically opposite to Rescorla's earlier findings with rats and pigeons.

In addition, we see that FI is rated significantly higher than GH [$F(1,19)=4.43$, $p<0.05$]. This implies that nonreinforcement of the FG compound led to a greater decrement in the associative strength of the inhibitory G than the excitatory F. Again, this is opposite to Rescorla's findings.

Like Rescorla's, our results suggest that the distribution of associative changes among the elements of a compound depends on the associative history of those elements. This asymmetry in associative change contradicts any model employing a common error term governing associative change

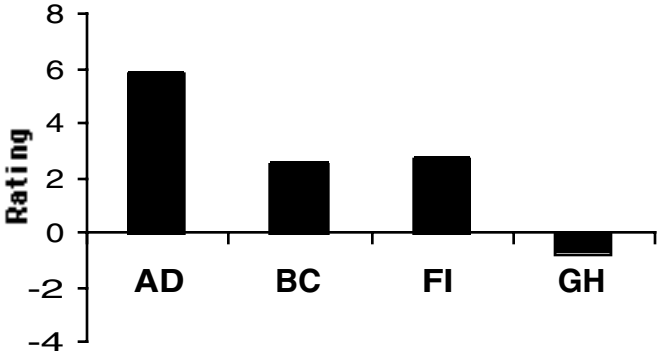

Figure 2. Mean ratings given to the cues of interest.

for all stimuli present, as these models are constrained to predict equal changes for these stimuli.

However, unlike Rescorla's results, we found that it is the cue whose associative strength is *less* discrepant from that supported by the outcome of the trial that undergoes the greater associative change. Our empirical findings agree with the predictions of the APECS model of learning and memory outlined earlier. This was confirmed by simulation. We performed 20 simulations with APECS, each representing a different subject. Each trial involved 1000 learning cycles. A hidden unit is defined as being "active" when it receives positive activation from the input layer. Thus if cue A is presented to the network, any hidden unit representing a configuration that includes cue A will be active. Activity extends into the period immediately following each trial, when no inputs are presented (again for 1000 learning cycles). The learning rate parameters for input–hidden and hidden–output units are both 0.8 when a hidden unit is active and has a positive error, and 0 when it is not. The parameter for bias–hidden changes is 0.3 when a hidden unit is active, 0 when it is not. The exact values of these parameters are unimportant: the pattern of results is robust under quite large variations in the values used. The results of the simulation are shown in Figure 3. As expected, we see that AD is rated higher than BC, and FI is rated higher than GH. Both differences are significant [$F(1,19)=20.2$ and 3.2 respectively, $ps<0.05$]. This is, of course, the pattern seen in our empirical data, and the opposite of Rescorla's results.

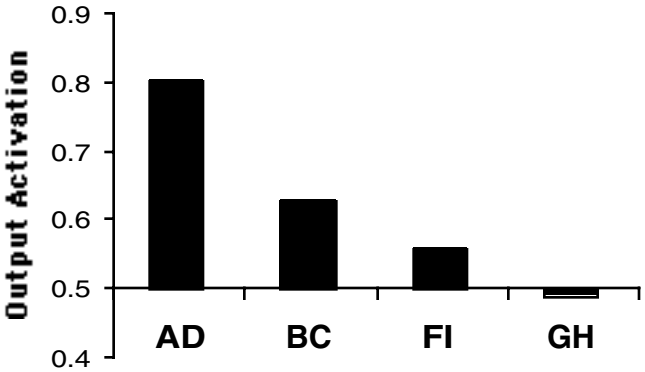

Figure 3. Simulation of the data using APECS.

The theories explicitly considered thus far describe cue competition effects in terms of modifications in the effectiveness of the US. If the US is surprising (i.e. error is high) then it is able to support more learning than if it is already predicted (and therefore less surprising). The contribution of the CS to learning is assumed to be fixed, and is determined by its salience (α, or the parameter for learning weights in APECS). In addition to such US-centred views, there exist a number of influential theories of associative learning that instead ascribe cue competition to variations in the processing of the CS. For example, blocking of B on AB+ trials following A+ pretraining might be interpreted as reduced processing of B as a result of earlier learning about A's predictive power. Typically, these CS-processing models specify a role for attentional processes in determining the distribution of associative change undergone by the cues of a compound. The attention paid to a cue depends on the associative history of that cue, so perhaps these theories would be better-suited to explaining our results.

Mackintosh (1975) proposed just such a model of selective attention. This theory states that good predictors of an outcome will retain a higher salience (i.e. will receive greater attention) than poorer predictors. The calculation determining the attention to be paid to stimulus A relies on a comparison of the predictive power of A *for the outcome occurring on that trial* with the predictive power of all other presented cues for that same outcome. This calculation is carried out after every trial. If cue A is a better predictor of the outcome of that trial than any other cue present, its salience increases for the next trial, and *vice versa*. Hence this model proposes that CSs followed by their expected outcomes (be this reinforcement or nonreinforcement) garner greater salience. CSs followed by surprising events (again, be this reinforcement or omission of reinforcement) lose salience.

According to the Mackintosh theory, learning about each element of an AB compound is governed by the discrepancy between λ and the *individual strength of that element* (rather than the discrepancy between λ and the summed strengths of A and B), modulated by the attention it receives. Thus:

$$\Delta V_A = \alpha_A \beta_{US} (\lambda_{US} - V_A) \qquad (2)$$

where α_A represents the attention paid to cue A.

Consider the CR Condition of our experiment. During Stage 1, A is consistently followed by the US, and B is consistently followed by no US. Thus both will begin Stage 2 with fairly high salience, as they are both good predictors of their respective "outcomes" (which for B is actually nonreinforcement). On Stage 2 AB+ trials, however, A is a better predictor of the outcome (reinforcement) than B, which predicts nonreinforcement. Hence attention to A will remain high, while that for B will be reduced rapidly: increments in V_A will remain relatively high over Stage 2 trials, while increments in V_B will become progressively smaller. As a result, Mackintosh (1975) is able to predict that over all Stage 2 trials, the increment in V_A will be greater than that for V_B. This is, of course, exactly the pattern seen in our empirical data. A similar story holds for the CNR contingency – on Stage 2 FG- trials, the inhibitory G is a better predictor of nonreinforcement than the excitatory F. Hence attention to G will remain high over Stage 2, while attention to F will fall. So overall we might expect a greater decrement in responding to G than to F.

In general, then, and in agreement with our data, Mackintosh (1975) is able to predict that the stimulus whose associative strength is less discrepant from the outcome of the trial (i.e. the better predictor of the outcome) will show the greater change on compound training.

Intriguingly Mackintosh's (1975) can also explain Rescorla's empirical data, which are diametrically opposed to our own, by appealing to the notion of overtraining (Mackintosh, personal communication). If we train subjects on Stage 1 until the associative strengths of excitors and inhibitors closely approach their asymptotic values, then the predictions made by the theory change dramatically.

As a result of this overtraining, A and B will also have very high salience (near asymptote) at the start of Stage 2.

On the initial AB+ trial, then, both will be well processed (as the calculation to update the salience of a cue is performed *after* each trial). Given that the error term governing associative change for a cue involves only the current associative strength of that cue, rather than the summed strength, the stimulus whose associative strength is more discrepant from that supportable by the outcome of the trial will undergo greater change. In other words, on the initial AB+ trial, it will actually be the *poorer* predictor of the trial's outcome (B) that undergoes the greatest associative change, as this cue will have the greater error term. Notably, if A's associative strength is near asymptote (λ), its error term according to equation (2) will be near zero. Given that it is error that drives changes in associative strength, this means that any change in V_A will be only very slight. Of course the modulation of attention discussed earlier will still occur. Thus following this initial trial, attention to A (a good predictor of the outcome) remains high, while that for B (a poor predictor of the outcome) will be reduced. So subsequent changes in V_B will become increasingly smaller. However, given that V_A was already near asymptote at the start of Stage 2, it will undergo little further increase over Stage 2 trials. In other words, the effect of Stage 1 training outweighs any influence of attentional modulation in Stage 2. In fact, the effect of attentional modulation may be reduced even further in the case of an overtrained contingency if we follow Sutherland & Mackintosh's (1971, p. 491) suggestion that the high attentional strengths developed as a result of overtraining are "sticky": a high α value is reduced more slowly than an intermediate value. As such the high value of α_B will persist over several AB+ trials. This, combined with B's high error value on these trials, will result in large increments in V_B over several trials before more significant reductions in α_B start to take their toll on the size of the increments. Thus by appealing to overtraining in Stage 1, Mackintosh (1975) is able to predicts Rescorla's finding that V_B increases more than V_A as a result of AB+ trials.

On this analysis, then, the difference between Rescorla's experiment and our own is that in the former, Stage 1 conditioning led to near-asymptotic associative strengths such that any effect of selective attention in Stage 2 was outweighed. The notion of sticky α values developed as a result of overtraining will further reduce the influence of attentional processes. In our experiment, however, we must assume that Stage 1 training did not approach asymptotic levels, such that both cues in the Stage 2 compound were free to undergo associative change as dictated by their salience.

Conclusion

In common with Rescorla's earlier experiments, our results indicate that a cue's associative history is important when determining the magnitude of its associative change. Unlike Rescorla's experiments, however, our data indicate that it is the better predictor of an outcome that undergoes the greater associative change on compound conditioning. This finding may reflect different rules governing the distribution of associative change among elements of a compound in humans and animals, or may simply be a result of different levels of initial training in the human and animal studies. Given only the results of the current experiment we cannot choose between a "US processing" model of learning and memory employing adaptive generalisation with configural representation (APECS), and a model of selective attention in which CSs compete for attention (Mackintosh, 1975). However, taken in conjunction with several other findings from this laboratory (Le Pelley, Cutler & McLaren, 2000, Le Pelley & McLaren, in press; Le Pelley & McLaren, this issue), we believe that the results of all the human data may be better explained by APECS.

Abstract

This paper examines the nature of stimulus representation in associative learning systems. Specifically, it addresses the issue of whether representation is elemental or configural in nature. We use a human causal learning paradigm, employing contingencies more commonly associated with studies of retrospective revaluation. Whereas most models of retrospective revaluation view it as an entirely elemental process, our results show that it has a configural component. However, the results also prove troublesome for simple configural theories employing fixed generalisation coefficients. It is possible to explain the data using an elemental theory employing configural representation. Our favoured explanation, however, involves a configural theory employing adaptive generalisation. We present such a theory, APECS, and show through simulation that it is well-equipped to deal with our findings.

Introduction

Recent years have seen a great deal of debate concerning the nature of stimulus representation in associative learning systems – more specifically, over how stimulus *compounds* should be represented, and how generalisation between similar compounds should be dealt with. Consider, for example, rewarding the compound AB. Elemental theories (e.g. Rescorla & Wagner, 1972; Mackintosh, 1975; Wagner, 1981) propose that such compounds are represented as being comprised of separable A and B elements that gain individual associative strengths. The conditioned responding shown to a particular stimulus compound is then found by simply adding together the individual associative strengths of each of the elements of that compound.

We sought to test this fundamental assumption of elemental theories, using a causal judgment procedure with human subjects. Our experimental design is shown in Table 1. We used an allergy prediction paradigm – participants play a food allergist trying to judge the likelihood that various foods will cause an allergic reaction in a fictional patient. The foods, then, constitute the cues; the allergic reaction is the outcome. Following training, subjects rate how strongly certain individual foods, and compounds of two foods, predict the occurrence of an allergic reaction. These ratings are taken as our measure of associative strength.

We train two stimulus compounds, AB and CD, to be predictors of the outcome, and then in Stage 2 one of the elements of each compound is extinguished. Cues A and C have an identical training history, as do B and D. The question is, what effect does this treatment have on the originally experienced compounds (AB and CD) as opposed to "elementally equivalent" compounds made up of identically trained cues that have never been seen in compound before (AD and BC)?

An elemental theory predicts no difference between the two types of compound. If the associative strength of a compound is given by adding together the strengths of all the separate elements contained in that compound, then whether or not those elements have been seen in compound before should have no effect. The Rescorla-Wagner (1972) model (R-W), for example, states that:

$$\Delta V_A = \alpha_A \beta_{US} \left(\lambda - \sum V \right) \qquad (1)$$

where ΔV_A is the change in associative strength of cue A, α_A represents the salience of cue A, β_{US} represents the salience of the US, λ relates to whether the US is actually present on a trial (taking a positive value if the US is present, 0 if it is not), and ΣV is the summed associative strength of all cues present on a trial. According to R-W, following Stage 1 all of cues A to F will have associative strengths of 0.5λ (ignoring the effect of α and β, which will be equivalent for all the different cues as a result of counterbalancing). In Stage 2, extinction trials will reduce V_A and V_C to 0. According to an elemental rule, the associative strength of a compound is found by summing the associative strengths of all of the elements of that compound. The associative strength of AB will be given by the total of the associative strength of A (0) plus the strength of B (0.5λ), i.e. 0.5λ. Of course, the compounds BC and AD are also both made up of one element with a strength of 0, and the other with a strength of 0.5λ, and so all of the compounds AB, CD, BC and AD should give rise to the same level of conditioned responding, as they are all elementally equivalent.

Subjects also received EF+ trials in Stage 1, with no further training of either cue in Stage 2. Given that neither E nor F is experienced in Stage 2, the associative strength of EF should remain at λ (as $V_E=V_F=0.5\lambda$). Hence R-W predicts that EF should receive a higher rating than the other

Stage 1			**Stage 2**

compounds, which should all receive similar ratings.

However, it is important to note that the AB+, A- design we are using is more commonly associated with studies of retrospective revaluation (see Le Pelley & McLaren, in press, for a review). This term is used to describe changes in the associative status of previously trained cues in the absence of those cues. For example, it is typically found that A- trials following AB+ training lead to an increase in the causal efficacy of B, even though B itself is absent on these trials. This is the phenomenon of unovershadowing, and would be revealed in our experiment by higher ratings given to B and D than to E and F, which receive no such revaluation in Stage 2.

Findings of retrospective revaluation are problematic for many theories of associative learning. R-W, for example, states that α, the salience of a cue, is positive for a cue that is actually presented on a trial, and zero for all absent cues. Hence the theory incorrectly predicts that there will be no learning about absent cues. So V_B remains unchanged at 0.5λ during Stage 2, with R-W thus constrained to predict that B, D, E and F will all receive similar ratings on test.

It is possible, however, to adapt R-W to allow it to predict unovershadowing. Van Hamme & Wasserman (1994) proposed that absent cues, rather than having $\alpha=0$, should take on a negative value of α, thus engaging the learning process with a negative sign. So on Stage 2 A- trials, while A's association to the outcome becomes weaker, the association from the absent cue B to the outcome will become correspondingly stronger. Markman (1989) proposed that only absent *but expected* cues should take on negative α. Dickinson & Burke (1996) suggested that this expectancy arises as a result of within-compound associations formed during Stage 1 compound training. During AB+ trials, subjects learn not only that A and B predict the US, but also that A predicts the presence of B, and *vice versa*. Presentation of A on A- trials now creates an expectancy of the absent cue B, and it is this expectancy that imbues it with negative α.

Modified R-W now predicts that B will be rated higher than E and F (which are not revalued) following Stage 2. It also predicts that AB will receive a similar rating to EF. According to unmodified R-W, the rating of AB falls during Stage 2 as A is extinguished and B remains unaffected. Modified R-W, on the other hand, states that as V_A falls (asymptoting at 0), V_B will increase (asymptoting at λ). Given these opposing changes in associative strength, the overall associative strength of the AB compound (given by V_A+V_B) should remain roughly constant.

Note, however, that modified R-W is still an elemental theory. As such it is still constrained to predict that compounds AB and CD will receive the same rating as the elementally equivalent compounds BC and AD.

The other trial types listed in the experimental design are relevant to a different issue in associative learning theory: they are not discussed here. We were careful to ensure equal numbers of positive and negative trial types in each stage. Following Dickinson & Burke (1996), we also made sure that each subject encountered a large number of different trial types (16 in Stage 1, 8 in Stage 2). This creates a large memory load, hopefully preventing subjects from basing their ratings on inferences made from explicit episodic memories of the various trial types. Instead subjects should have to rely on associative processes to provide an "automatic" measure of causal efficacy for each cue. Using a large number of trial types makes us more confident that it is indeed associative, rather than cognitive, processes being tapped in our study.

Method

Participants Sixteen members of Cambridge University (9 female, 7 male; age 19-49) took part in the experiment.

Procedure At the start of the experiment each subject was given a sheet of instructions presenting the "allergy prediction" cover story for the experiment. They were told that in the first block they would be arrange for Mr. X to eat different meals on each day, and would monitor whether he had an allergic reaction or not as a result. In relation to the exposure trials (that do not bear on the issue at hand in this paper), subjects were told that occasionally the results of eating the foods had been lost. On these trials they would know the foods eaten in the meal, but not the result of eating those foods. They were also told that at the end of the experiment they would be asked to rate each of the foods according to how strongly it predicted allergic reactions. The 24 foods used were randomly assigned to the letters A to X in the experimental design for each subject.

On each conditioning trial, the words "Meal [meal number] contains the following foods:" followed by the two foods appeared on the screen. Subjects were then asked to predict whether or not eating the foods would cause Mr. X to have an allergic reaction, using the "x" and "." keys (counterbalanced). The screen then cleared, and immediate feedback was provided. On positive trials the message "ALLERGIC REACTION!" appeared on the screen; on negative trials the message "No Reaction" appeared. If an incorrect prediction was made, the computer beeped. On the exposure trials of Stage 2, the same message appeared, but now subjects were cued to enter the initial two letters of each of the foods. This was to ensure that they paid attention to the pairings of foods when no allergy prediction was required.

There were 16 trial types in Stage 1, and 8 in Stage 2. The order of trials was randomised over each set of 16 or 8. Participants saw each meal 8 times in Stage 1 and Stage 2. The order of presentation on the screen (first/second) within each compound pair was also randomised.

In the final rating stage subjects were asked to rate their opinions of the effect of eating a number of meals containing either one food or two on a scale from -10 to +10 (in fact, subjects were also given a short rating test at the end of Stage 1 – again the results of that test do not bear on the work presented here and so will be ignored.). They were to use +10 if the meal was very likely to cause an allergic reaction in Mr. X, -10 if eating the meal was very likely to prevent the occurrence of allergic reactions which other foods were capable of causing, and 0 if eating the meal had no effect on Mr. X (i.e. it neither caused nor prevented allergic reactions). For clarification, participants also had access to a card on which the instructions on how to use the rating scale were printed. Once a meal had been rated it disappeared from the screen and the next appeared, so that participants could not revise their opinions upon seeing later meals.

Results and Discussion

Figure 1 shows the mean rating of the casual efficacy of each of the meals of interest as judged on test. In this figure, and in the following analysis, the ratings of equivalent cues

(i.e. cues or compounds that have received an identical training history) have been averaged for each subject. Thus we averaged the ratings of AB and CD, BC and AD, A and C, B and D, and E and F. No significant differences existed between equivalent cues [$F_{max}(1,15)=1.97$, $p>0.1$].

A one-way, repeated measures ANOVA was carried out on these ratings as a preliminary to assessing the effects of interest by means of planned comparisons. There was a significant main effect of meal [$F(10,150)=13.98$, $p<0.001$].

In common with earlier studies of retrospective revaluation, we see that B and D are rated higher than E and F on test [$F(1,15)=8.72$, $p<0.01$]. Given that B, D, E and F all received exactly the same number of pairings with the outcome in Stage 1, this finding implies that the ratings of B and D have changed as a result of Stage 2 A- and C- trials. This demonstration of learning about absent cues violates the assumption of the original R-W model that learning can only proceed to cues presented on a trial. However, it is consistent with modified R-W, in which absent-but-expected cues engage the learning process with a negative sign.

The ratings for AB/CD are actually very similar to those received by EF: the difference between them is not significant [$F<1$]. This again disagrees with original R-W, which states that extinction of A should reduce the causal efficacy of the AB compound relative to EF. And again it is consistent with modified R-W, which proposes that as V_A falls on A- trials, V_B rises, such that the rating for AB will remain roughly constant. In further support of this idea we see that the ratings given to B/D do not differ significantly from those given to compounds AB/CD [$F<1$]. From the standpoint of an elemental theory, this finding implies that the associative strength of compound AB is almost entirely due to the strength of cue B, which is the prediction made by modified R-W.

Of most interest, though, is the finding that the ratings for AB/CD (the compounds actually experienced during training) are higher than those for AD/BC, even though all of these compounds are elementally equivalent. This is confirmed statistically [$F(1,15)=10.72$, $p<0.005$]. This finding is troublesome for any theory that proposes that stimuli in an associative network are represented in a wholly elemental manner, as such theories are constrained to predict that AB, CD, BC and AD will receive equal ratings on test.

Thus it is clearly insufficient to view a compound AB as simply being composed of separable A and B elements which gain associative strength independently. Instead it seems that the fact that A and B have been seen together before is important when determining the response to the AB compound, i.e. there is importance attached to the unique *configuration* of A and B cues. This heightened responding to previously experienced configurations will not apply to the BC compound, as B and C elements have never been experienced in configuration during training. Hence if configurations of cues are taken into account we can explain the finding that AB/CD are rated higher than BC/AD.

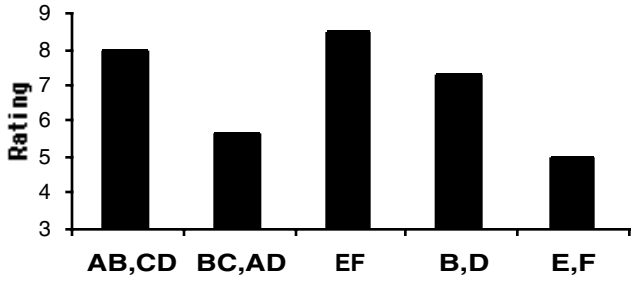

Figure 1. Mean ratings given to the cues of interest.

It is possible to modify R-W even further in order to encompass this importance of specific configurations of cues. Wagner & Rescorla (1972) suggested that, in addition to activating individual cue elements, presenting a compound stimulus also activates a unique element representing that configuration of cues (a "configural element"). Thus presentation of AB will activate elements for A and B, and also an AB element. As regards the learning process, all elements are treated in exactly the same way. If we assume that all elements have equal salience, then following AB+ trials, $V_A=V_B=V_{AB}=1/3\lambda$. Note that this is still very much an elemental theory in nature: the associative strength of a compound is given by summing the individual strengths of all of its elements, whether those elements represent compounds or single cues.

We can combine this with the idea of negative α. On A- trials following AB+ training, elements for both B and AB will have negative α: neither is present, but both are retrieved via within-compound associations. As A extinguishes (until $V_A=0$), B and AB will become more excitatory, such that the overall strength of the AB compound (given by $V_A+V_B+V_{AB}$) remains roughly constant across A- trials. There is no configural element for the BC compound, however, as this configuration has never been experienced during training. Thus the associative strength of the BC compound will be given by (V_B+V_C). Given that this compound does not receive the extra excitatory influence of a configural element, it is bound to receive a lower rating than AB. This "configural element" adaptation of Van Hamme & Wasserman's modified R-W therefore allows us to explain the finding that AB is rated higher than BC.

However, this "double modification" leads to further incorrect predictions. Firstly, it predicts that AB will be rated higher than B. Presentation of AB activates A, AB and B units. The latter two have excitatory connections to the US, and their influence will sum. Presentation of B only activates the B unit, so the excitatory influence will be less. In fact, the ratings for AB and B do not differ. Secondly, it predicts that B will receive a similar rating to BC. Given that $V_C=0$, both will rely on the B–US association for all their excitatory strength. In fact, B/D is rated significantly higher than BC/AD [$F(1,15)=5.64$, $p<0.05$].

Perhaps a consideration of context will help. Presenting USs in a context makes the context itself a weak excitor of the US. In terms of our experiment, subjects come to realise that the patient is quite prone to allergic reactions regardless of which particular foods he has eaten. Cues presented on nonreinforced trials (e.g. A and C) will become weak inhibitors of the US to counter this general excitatory influence. A and C do in fact receive negative ratings on test (mean –1.6), adding weight to this argument. If V_A and V_C are negative then we can resolve the problems outlined above. The predicted rating for AB will fall due to A's inhibitory influence: B's rating will not be affected in this way: AB and B will

receive similar ratings. Furthermore, BC will now be rated lower than B due to C's negative effect.

In summary, it would seem that an elemental rule (a) employing configural elements, and (b) allowing negative learning about absent-but-expected elements, might explain our empirical data, as long as the role of context is also taken into consideration. Figure 2 (black bars) presents simulation results for this experiment using just such a model. Comparison with the empirical data in Figure 1 shows close agreement (r^2=0.98). The exact parameters used are relatively unimportant – we simply note that it is possible for such a model to explain the patterns present in our data.

Another approach to explaining our data is to reconsider the contention of elemental theories that a stimulus compound is composed of separable A and B elements. Recently this idea has been challenged, notably by Pearce (1987), whose configural theory proposes that a compound stimulus is best viewed as a unitary event that is separate from its elements, but able to generalise to them. In other words, it would be a single, "AB" configuration that developed an associative connection to the outcome. Generalised responding to other stimuli occurs to the extent that these stimuli are similar to previously experienced configurations.

Specifically, Pearce's (1987) configural theory states that:

$$\Delta V_X = \beta_{US}(\lambda - V_X) \qquad (2)$$

where V_X (the associative strength of configuration X) is given by the sum of the *conditioned* responding to configuration X and the *generalised* responding to X as a result of its similarity to other trained configurations. The extent to which generalisation occurs between two configurations depends on their similarity:

$$S_{X,Y} = \frac{nc_X}{nt_X} \cdot \frac{nc_Y}{nt_y} \qquad (3)$$

Thus the similarity (S) between configurations X and Y is equal to the proportion of the total elements in configuration X that are common to the two configurations, multiplied by the proportion of the total elements in configuration Y that are common to the two configurations. Then:

$$\begin{matrix}\text{Generalised strength} \\ \text{from Y to X}\end{matrix} = S_{X,Y} \times V_Y \qquad (4)$$

Consider, for instance, compounds AB and BC in our experimental design. Each configuration has two elements, one of which (B) is common. Hence they will have a similarity of 0.25, so any conditioned responding to AB will generalise by a factor of 0.25 to BC.

In our Stage 1, a representation of AB will develop an associative strength of λ (again ignoring β, which will be equal for all configurations). In Stage 2 A is extinguished. A has a similarity of 0.5 to AB, and hence receives generalised strength of 0.5λ from it. In order to counteract this excitatory influence A must itself take on a strength of -0.5λ (to prevent conditioned responding when it is inappropriate).

On test, responding to AB is given by the sum of its own conditioned strength and its generalised strength from A (to which it has a similarity of 0.5). Hence:

$$V_{AB} = \lambda + 0.5(-0.5\lambda) = 0.75\lambda$$

The same holds true for CD. How about responding to AD? This configuration has never been seen before, and hence will receive only generalised strength. It has a similarity of 0.25 to AB and to CD, and a similarity of 0.5 to A. Thus:

$$V_{AD} = 0.25(\lambda) + 0.25(\lambda) + 0.5(-0.5\lambda) = 0.25\lambda$$

Hence this configural theory predicts that responding to AB will be greater than for AD.

This kind of configural theory thus seems tailor-made to explain the different ratings given to elementally equivalent old and new compounds. The problem for a configural theory such as Pearce's is that it cannot explain the occurrence of retrospective revaluation. In common with the original R-W model, Pearce predicts that B's rating should not change as a result of A- trials. Following Stage 1 AB+ trials, V_B should be 0.5λ (as B has a similarity of 0.5 to configuration AB, which will have developed an associative strength of λ). However, given that the compound AB is not seen again, its conditioned associative strength will not change, and so B's rating (which depends on generalisation of excitatory strength from the trained AB compound) will remain unchanged. Is it possible to modify a configural theory such as Pearce's to also explain the phenomenon of retrospective revaluation? The answer at present seems to be no, and we leave it for others to challenge this conclusion.

The problem for such configural rules seems to lie in their use of fixed, non-adaptive generalisation coefficients. The generalisation between two similar stimuli takes a set value that cannot change whether the two stimuli are reinforced or not. An alternative possibility is to use adaptive generalisation coefficients that vary dynamically, such that the generalisation between two similar stimuli can change on a trial-by-trial basis according to whether the two stimuli predict the same or different outcomes. For more on the value of adaptive generalisation coefficients, see McLaren (1993, 1994) and Le Pelley & McLaren (in press).

Consider the AB+, A- contingency used in our experiment. On Stage 1 AB+ trials, subjects learn that when A and B are presented together, the outcome is expected. Following these trials, they have no reason to believe that what holds for A in the presence of B should not hold true for A alone. Hence generalisation to other compounds containing A might be set high as a default. Stage 2 A- trials provide evidence against this idea, though. As a result generalisation between A- and AB+ should be reduced, in order to prevent new learning (that A alone is not reinforced) from interfering with old (that A and B in compound are reinforced). This leaves AB as a good predictor of the outcome, while simultaneously allowing complete extinction of A. The fact that the generalisation between the AB compound and its ele-

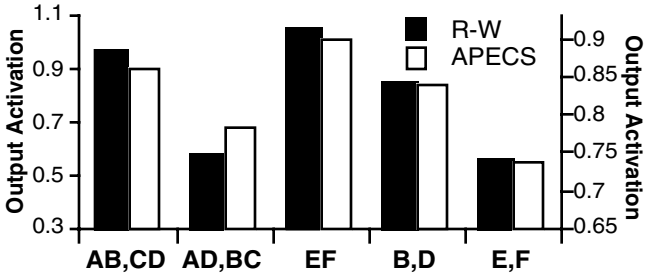

Figure 2. Simulation results for modified R-W with configural elements (black bars) and APECS (white bars).

ments is allowed to change as subjects move from Stage 1 AB+ trials to Stage 2 A- trials provides a mechanism for change in the causal efficacy of B as a result of these A- trials. As it turns out, a model employing configural representation with adaptive generalisation coefficients is indeed well-equipped to explain our empirical data.

A suitable candidate is the APECS model presented by Le Pelley & McLaren (in press). In this instantiation of APECS, each different pattern of stimulation is represented by its own hidden unit, which can equally well be termed "configural units". The mechanics of learning in APECS are similar to those of standard backpropagation (Rumelhart, Hinton & Williams, 1986), but differ in that APECS employs adaptive generalisation coefficients: once the weights appropriate to a mapping have developed, the learning in those weights can be protected against interference. This is achieved by reducing the learning rate parameter for the configural unit carrying the mapping. The effect is to "freeze" the weights to and from a certain configural unit at the value they hold immediately following experience of that configuration. Crucially, this freezing of weights to and from a certain configural unit occurs only if that configural unit has a negative error value, i.e. *if it is part of a mapping that predicts an incorrect outcome for the current input*. Specifically, APECS has different learning rate parameters for input–hidden and bias–hidden connections. The former are frozen to prevent interference; the latter remain high. Hence extinction (suppression of inappropriate responses) is achieved by an increase in the negative bias on the hidden unit carrying the inappropriate mapping, rather than by reduction of weights (which would cause the original mapping to be lost from the network). Given appropriate input cues, the negative bias on the hidden unit can be overcome and the original mapping retrieved.

Consider an AB+, A- contingency. During Stage 1, the network will learn associations from A and B input units to a hidden unit representing the AB configuration. It also learns an excitatory association from this hidden unit to the output: A and B in compound come to predict the outcome.

Now consider the inter-trial interval (ITI) between AB+ trials, when no inputs are presented. According to the logistic activation function employed with APECS, when no inputs are presented the hidden units will have an activation of 0.5 (see Rumelhart et al., 1986). This activation will feed along the AB+ pathway learnt on the preceding trial, and activate the US unit. This is obviously inappropriate when no inputs are presented. The US unit will take on a negative error, which is propagated back to the AB configural unit. As explained earlier, a negative error means that the weights to and from the hidden unit are frozen. In order to suppress the expression of the US during the ITI, the AB configural unit will therefore take on a negative bias.

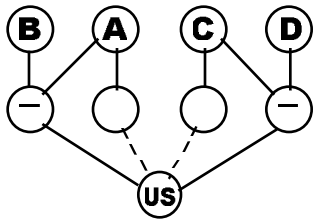

Figure 3. Associations developed by APECS following AB+, CD+ then A-, C- training. Excitatory connections are shown by solid lines, inhibitory associations by dotted lines. Negative bias on hidden units is indicated by a minus sign.

In Stage 2 the network experiences A- trials. Given that this configuration has not been seen before, a new hidden unit is recruited to carry the mapping. Of course, as a result of the associations built up during Stage 1, A has an excitatory connection to the US (via the AB configural unit). However, the US is not presented on these trials: the AB unit carries an inappropriate mapping, and so will take on a negative error. As a result its weights are frozen, and it will take on an increased negative bias in order to suppress expression of the US (i.e. to allow extinction of A). Thus the learning about the mapping from A and B to the output has not been lost from the network, it has simply become harder to retrieve. In addition, an inhibitory mapping will develop from the new A- hidden unit to the outcome in order to counter the positive activation flowing via the AB configural unit. The situation for cues A, B, C and D following Stage 2 training is shown in Figure 3.

Note that the negative bias taken on by the AB configural unit is a result of presentation of A alone leading to inappropriate output activation on A- trials. Now on test both A and B are presented together. Presentation of both cues (each with an excitatory connection to the AB configural unit) will be sufficient to overcome the negative bias built up by this unit, and so the mapping from the configural unit to the US will be expressed as before. In other words, the presence of the extra retrieval cue on test (B, compared to A alone in Stage 2) allows retrieval of the original AB+ mapping. Adaptive generalisation protects the AB+ mapping from the effect of extinction of A. Hence APECS predicts that extinction of A will have little effect on the rating received by AB, and thus that AB and EF will receive similar ratings (as is seen in Figure 1).

What if the compound BC is presented on test? As a result of the processes previously mentioned, C will be completely extinguished and so will not cause any activation of the output. Presentation of B will send some positive activation to the AB configural unit. However, without the additional positive influence of A, B alone will be unable to completely overcome the negative bias on this unit. As a result less positive activation will flow to the US than if A were also present. Thus APECS correctly predicts that AB will receive a higher rating than BC.

How about unovershadowing? Again, APECS explains the phenomenon as being a result of the attempt to minimise interference between old and new learning through adaptive generalisation. We saw that the AB configural unit starts Stage 2 with a reasonable negative bias (built up during ITIs following AB+ trials in Stage 1). This unit then takes on additional negative bias on the initial A- trials of Stage 2. However, if this negative bias is allowed to grow too much then the network will lose the information that B has in the past predicted the US, as presentation of B will be insufficient to impact on this negative bias. This would be an undesirable consequence of learning about A. In order to protect this learning, over the course of Stage 2 A- trials, as the inhibitory connection via the A-only hidden unit becomes stronger, the bias on the AB configural unit lessens.

Thus on initial A- trials, the network achieves extinction of A by suppressing the original excitatory pathway. This makes sense: given the limited evidence for the causal efficacy of A, its failure to predict the US may be a freak occurrence. It is undesirable to lose the information that A predicts the US on the basis of this limited evidence. Extinction by suppression of a pathway allows for rapid reactivation of that pathway should A now come to predict the US again. But with increasing evidence that A genuinely does not predict the outcome, the balance shifts. The original suppression is lifted to prevent loss of information about the other cues that A was trained with, which probably were the cause of the outcome originally. Extinction of A is now achieved more permanently by development of an inhibitory association to the outcome. This is sufficient to balance the increased excitation flowing from A to the US via the now less suppressed AB unit. This lesser suppression of the AB unit, meanwhile, reduces its negative bias to levels below that developed in Stage 1, meaning that presentation of B will now cause greater US activation than E or F (as the EF unit has not undergone this de-suppression). Unovershadowing is the result. For a more detailed discussion of APECS and unovershadowing, see Le Pelley & McLaren (2001).

There is a problem, however. As things stand APECS incorrectly predicts that BC should receive a rating similar to B. We can overcome this problem by considering context, as described earlier, so that A and C become weakly inhibitory. Figure 2 (white bars) shows the results of a simulation of this experiment using APECS. Again, comparing this to Figure 1 reveals close agreement between empirical and simulated data (r^2=0.98). The simulated results are actually the average of 16 simulations run with APECS, each representing a different subject. Each trial involved 1000 learning cycles. A hidden unit is defined as being "active" when it receives positive activation from the input layer. Thus if cue A is presented to the network, any hidden unit representing a configuration that includes cue A will be active. Activity extends into the period immediately following each trial, when no inputs are presented (again for 1000 learning cycles). The learning rate parameters for input–hidden and hidden–output units are both 0.8 when a hidden unit is active and has a positive error, and 0 when it is not. The parameter for bias–hidden changes is 0.3 when a hidden unit is active, 0 when it is not. Thus we make the reasonable assumption that changes due to learning take place faster than changes in memory, i.e. learning represents rapid acquisition, and memory represents a more gradual decline in retrievability. We also included an input unit representing context, that was active on every trial. Context will have a far lower salience than the foods used on each trial: we use a parameter of 0.028 for changes in weights from the context unit. The simulation results are robust under quite large variations in the parameters used.

Conclusion

Retrospective revaluation has typically been assumed to be best explained in terms of changes in the associative strengths of separable stimulus elements. Perhaps unsurprisingly, then, the most influential theories attempting to account for retrospective revaluation (e.g. Van Hamme & Wasserman's [1994] modification of R-W; Dickinson & Burke's [1996] modification of Wagner's [1981] SOP model) have been elemental in nature. The results presented here, however, suggest that this simple elemental view of retrospective revaluation is incorrect. Our data conflict with the fundamental assumption of simple elemental theories that a compound AB is best represented as being composed of separable A and B elements that gain strength independently. Instead there is a configural component involved in retrospective revaluation that is ignored in these earlier theories. It is possible to account for the data using an elemental theory modified to give a role to "configural elements". Alternatively, a model employing configural representation with adaptive generalisation also provides a good account of our results.

Abstract

Two experiments examined perspective switching in comprehension and retrieval of spatial information. Participants read route or survey descriptions of environments line by line. Reading times were recorded. For half of the descriptions, the perspective of the last sentence was switched. True/false verification of sentences from both perspectives followed the descriptions. Switching perspective increased reading times but increased verification times only for survey sentences. This suggests that perspective switching exacts a cost in comprehension, but that the cost dissipates after information retrieval, especially for route descriptions. The second study examined which aspects of perspective, viewpoint or terms of reference, accounted for switching costs by using hybrid descriptions. Switching terms of reference slowed reading times more than switching viewpoint. Together, the experiments suggest that switching perspective plays a role in comprehension that diminishes with repeated retrieval. They also point to a fundamental asymmetry between route and survey perspectives, one that depends on orientation.

Introduction

All animals, human or otherwise, must be able to gain knowledge about their surroundings in order to survive. Like other animals, humans often gain this knowledge first-hand by navigating through their immediate surroundings. However, unlike other animals, humans also have the ability to transmit this knowledge to others by language.

Whether the world is experienced first-hand or through descriptions, the world is viewed from a particular perspective. In text comprehension, maintaining a consistent perspective makes the text more coherent and comprehensible to the readers (Black, Turner, & Bower, 1979).

Although there is a general agreement that we perceive the world from specific viewpoints, the role of perspectives on spatial memory is less certain. In particular, there is a considerable debate about whether or when spatial relations are encoded independently of perspective.

If spatial memory is formed in a perspective-dependent manner, it should be more accessible from one perspective over the others. Therefore, when people describe spatial layouts from memory, they should prefer to maintain a consistent perspective in their descriptions since memory associated with a specific perspective is more accessible than others (Levelt, 1982). There is some evidence that supports this view. When readers take a particular viewpoint during text comprehension, they later remember the information better from that viewpoint (Black, Turner, and Bower, 1979; Abelson, 1975).

Other evidence suggests that for constrained well-learned environments, spatial memory can equally be accessible from multiple perspectives. Taylor and Tversky (1992) demonstrated that when people learned route or survey descriptions of spatial layouts and later were asked inference questions about them, they were as fast and accurate to questions from the read perspective as from the new perspective. In spontaneous descriptions of naturalistic environments, people mixed route and survey perspectives about half the time (Taylor & Tversky, 1996). The choice of a perspective also seems to depend on the pragmatics of the situation much more than an inherent bias toward any particular perspective. During a conversation, speakers often use not only their own perspective, but also the perspective of their addressee's or some perspective independent of both (Schober 1993; Tversky, Lee, & Mainwaring, 1999).

In visual cognition, there is a similar inquiry about the nature of spatial memory derived from perception and navigation. There is some evidence that spatial relations are encoded in a viewpoint-dependent manner (Diwadkar & McNamara, 1997; Shelton & McNamara; Rieser, 1989). For example, Diwadkar and McNamara (1997) had participants study the locations of objects in a room from a single perspective and then learn to recognize the layout from three other views. A recognition test of the layout from different viewpoints showed faster response times for the learned viewpoints than the novel viewpoints. However, memories of large-scale spaces seem to encode spatial relations in a viewpoint-independent manner, in which familiar and

novel views of spatial layouts are equally accessible (Evans & Pezdek, 1980; Presson, DeLange, & Hazelrigg, 1989).

So far, the evidence seems to suggest that maintaining a consistent perspective is important when learning a new environment, but the effect of perspective is less clear for retrieving well-learned environments. The present study is an attempt to understand the role of perspectives in spatial descriptions during both on-line comprehension and subsequent retrieval of the layouts from memory.

As an extension to Taylor and Tversky study (1992), we studied acquisition of environments by text that maintained a consistent perspective or switched perspectives. Testing was from same or switched perspective. We expected that the cost of switching perspective be large when under construction of spatial mental models but diminished after repeated retrieval.

Experiment 1

Method

Subjects. Thirty-nine undergraduates, 18 male and 21 female, from Stanford University participated individually in partial fulfillment of a course requirement. The criterion of 67% correct response eliminated the data of three men and four women.

Materials. Descriptive texts were prepared for sixteen fictitious environments. Each environment consisted of two intersecting roads and three adjacent landmarks. The descriptions were given either in a route or a survey perspective.

Route Description

Go east on High St and you will intersect with a much narrower Green Ave.
Turn right on Green Ave and on your right, you will see the stock market.
Past the stock market, on your right on Green Ave, you will see the mortgage bank.
On your right on Green Ave, past the mortgage bank is the legal firm.

Survey Description

High St runs east-west, intersecting a much narrower Green Ave, which runs north-south.
South of High St on the west side of Green Ave is the stock market.
South of the stock market on the west side of Green Ave is the mortgage bank.
On the west side of Green Ave, south of the mortgage bank is the legal firm.

Figure 1: Route and Survey Descriptions

A route perspective takes an imagined navigator through an environment describing landmarks relative to the navigator in terms of *left* and *right*. A survey perspective takes bird's eye view of the environment describing landmarks relative to each other in terms of cardinal directions.

Each description consisted of two introduction sentences, followed by four sentences that described the spatial layout of the environment. Figure 1 shows examples of the spatial descriptions.

In order to examine the perspective switching cost during on-line comprehension, the last sentence of the study phase was presented either in the same perspective as the preceding descriptions or in a new perspective. Figure 2 shows the perspective switch in both directions for the target sentence.

Perspective Switch: Route to Survey

Past the stock market, on your right on Green Ave, you will see the mortgage bank.
On the west side of Green Ave, south of the mortgage bank is the legal firm.

Perspective Switch: Survey to Route

South of the stock market on the west side of Green Ave is the mortgage bank.
On your right on Green Ave, past the mortgage bank is the legal firm.

Figure 2: Perspective Switch during On-line Comprehension

Four statements (i.e. two statements each for route and survey perspective) followed the target sentences for true/false verification. These questions provided assurance that participants formed accurate mental models of the spatial layouts. Since the questions used in both perspectives, half required perspective switching with respect to the study perspective. All of the questions were inference questions, querying the spatial relations that could be inferred but were not directly specified in the descriptions. An example of route inference statement is "The stock market is on your right when you face the mortgage bank from Green Ave.", and an example of a urvey statement is "The mortgage bank is north of the legal firm and west of Green Ave.".

Design and Procedure. Subjects were told that they would read descriptions of various environments. They were asked to study and remember them because after each scene, they will be given true/false questions to test their memory of the scene. They were then given a practice trial, so that they would be familiar with the overall nature of the experiment. The trial consisted of a route and a survey environment followed by four test questions.

For the actual trial, subjects read sixteen texts, i.e. eight route and eight survey descriptions, and then answered four true/false questions for each description. The order of presentation and the assignment of experimental condition to environments were randomized across subjects. The texts appeared on the screen one sentence at a time. Each sentence remained on the screen until participants pressed a key to indicate that they were ready to move on to the next sentence. The reading time for each sentence was recorded. After reading a description, participants answered four test questions by pressing assigned keys for true and false. Both

response time and accuracy were recorded for each question. The question order was randomized across subjects. The experiment was conducted on a Apple PowerMac computer controlled by PsyScope software package (J.D. Cohen, MacWhinney, Flatt, & Provost, 1993).

Results

The reading time during the study phase indicates the amount of time that subjects needed to comprehend the descriptions. Using repeated measures design, reading times (RT) per syllable were compared between route and survey perspective for all study sentences except for target sentences. Subjects studied survey texts longer (351 msec/syllable) than route texts (311 msec/syllable). $F(1, 31) = 12.39$, $p < 0.001$.

The target sentence was the last sentence in the study phase. Half of the target sentences switched perspective from preceding study descriptions and the other half kept the same perspective. Target sentences were analyzed for two factors: perspective of the target sentence and perspective consistency.

On the average, subjects read route targets marginally faster (456 msec/syllable) than survey targets (513 msec/syllable; $F(1,31) = 3.02$, $p < 0.10$). They read targets that kept the same perspective much faster (397 msec/syllable) than the targets with a new perspective (572 msec/syllable; $F(1,31) = 30.89$, $p < 0.00001$.

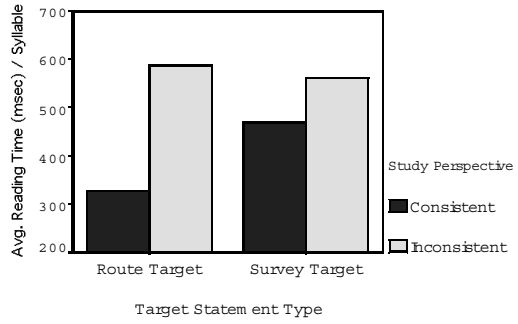

Figure 3: RT/syllable for Target Sentences: Effects of Perspective Switch during On-line Comprehension

Furthermore, there was an interaction between target perspective and perspective consistency ($F(1,31) = 10.43$, $p < 0.003$). Figure 3 illustrates that on the average, reading a route target sentence that was preceded by a description with a consistent route perspective was much faster (0.33 s/syl) than reading a route target sentence preceded by a survey description (0.59 s/syl). Although a same general pattern holds for survey target sentences, the difference in RTs is smaller (0.47 s/syl and 0.56 s/syl for consistent and inconsistent perspectives respectively).

For the true/false verification statements, we collected both response time (RT) and accuracy data. We analyzed response times for question perspective and study perspective. We also checked for effects of target perspective since it differed from study perspective half the trials. These analyses are reported for correct RTs to true questions, since RT analyses for incorrect answers or false questions yielded no significant results. It seems that subjects needed to correctly verify an accurate mental model to produce a consistent perspective effect.

Route questions were verified faster and more accurately than the survey questions (423 ms/syl for route, 476 ms/syl for survey; $F(1,31) = 9.02$, $p < 0.005$; 83% for route, 75% for survey, $F(1,31) = 7.90$, $p < 0.008$). There was no effect of target perspective on the response time ($F(1,31) = 0.0005$; $p > 0.98$).

The effect of perspective consistency was also significant but this was due only to survey questions, as there was a significant interaction between the question perspective and its consistency with the study perspective. $F(1,31) = 9.71$, $p < 0.004$. Subjects responded equally fast to route statements, regardless of perspective (426 ms/syl for route vs. 419 ms/syl for survey) but were faster to survey questions when they had studied from survey perspective (429 ms/syl; 523 ms/syl for route) (see Figure 6). Accuracy data for this interaction was not significant but was consistent with the RT results, assuring us that there is no speed-accuracy tradeoff.

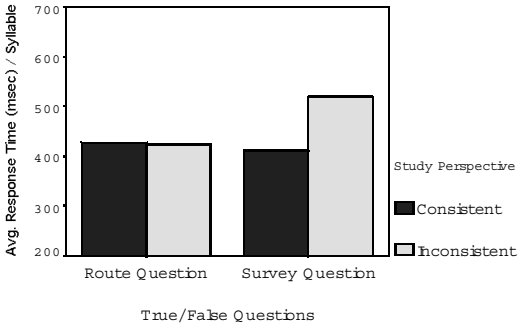

Figure 4: RT/syllable for T/F Questions: Effects of Perspective Switch during Memory Retrieval

Discussion

As predicted, switching perspective during on-line text comprehension resulted in a longer reading time, supporting cognitive costs for perspective switching during acquisition.

The interaction between target type and perspective consistency suggests that perspective consistency is more important for route descriptions. Since a route perspective is relative to a moving referent, the knowledge of current location and orientation of the

referent is crucial to processing the incoming route information. Switching from survey to route descriptions forces the reader to establish the current orientation of the referent without the benefit of inferring this knowledge from the previous text. Since survey descriptions are based on a fixed orientation perspective, consistency has no advantage over switched perspective in establishing the orientation information.

For the true/false verification statements, there was an effect of perspective switch, but the effect size was diminished from that of on-line comprehension. Furthermore, the effect completely disappeared for the route statements. The results indicate that retrieval from spatial memory is less perspective-dependent than on-line comprehension. The diminished effects of perspective for memory together with previous findings of perspective-independent memory (Taylor & Tversky, 1992) suggest that conversion from perspective-dependent to perspective-independent spatial memory may be a gradual process. If so, the present results indicate that route and survey perspective have different timetable for this conversion.

Finally, subjects took longer to study survey descriptions than route descriptions. This result is opposite that of Taylor and Tversky (1992). Although readers of route perspectives may have had greater cognitive loads due to continual updates and integration of changing location and orientation of the referent, they still read the description faster. It may be that any such difficulty is compensated by other factors, such as greater familiarity with intrinsic spatial terms (e.g. left/right) than extrinsic terms (e.g. north/south) in everyday route descriptions.

Experiment 2

We have established that switching between route and survey perspectives during study has cognitive costs. The nature of these costs seems different for route and survey perspectives. What are some of the factors that might account for these differences?

Route and survey descriptions differ in at least two ways. One is the way orientation is described. Route descriptions use intrinsic spatial terms, such as *left* and *right,* which change with the changing orientation of the navigator. Thus, they adopt a person-centered reference frame. Survey descriptions use extrinsic spatial terms, such as *north* and *south*, which fix the orientation in space, adopting an environment-centered reference frame.

Another difference is the viewpoint of the observer. Route perspectives are embedded within the environment, whereas survey perspective are external and above the environment.

In this experiment, we created hybrid descriptions that take route-like viewpoints but update its orientation using extrinsic terms. For example, a route description such as "Go down the street, turn right, and the building will be on your right" can be converted to a hybrid description like "Go north on the street, turn east, and the building will be south of you."

Using hybrid descriptions, we can examine if the perspective switching costs are due to changes in orientation terms or changes in viewpoint. If orientation terms are crucial, we expect hybrid results to mirror the survey results. If viewpoint is important, we expect hybrid results to mirror the route results.

Method

Subjects. Sixty-four undergraduates, 30 male and 34 female, from Stanford University participated individually in partial fulfillment of a course requirement. 67% accuracy criterion eliminated two men and eight women.

Materials. The stimuli were similar to those used in Experiment 1 with few changes. In addition to route and survey descriptions, hybrid descriptions were added for the study and the test phase. Figure 5 shows an example of a hybrid description.

Hybrid Description

Go east on High St and you will intersect with a much narrower Green Ave.
Turn south on Green Ave and west of you, you will see the stock market.
Past the stock market, on the west side of Green Ave, you will see the mortgage bank.
West of you on Green Ave, south of you past the mortgage bank is the legal firm.

Figure 5: Description in Hybrid Perspective

Both descriptions and targets were given in each of three perspectives. Two fictitious environments were added to the sixteen environments in Experiment 1 to match the number of environments with the experimental conditions. In addition, four true/false questions per environment were reduced to three, one each from route, survey, and hybrid perspective. Finally, the number of practice trials was increased to three, one for each description type.

Design and Procedure. Except for the changes in the materials described in the previous section, the procedure is identical to Experiment 1.

Results

The reading time results replicated those of Experiment 1. The new results for this experiment show how switching perspectives with hybrid descriptions affect on-line comprehension and memory.

We analyzed reading times for the target sentences for two factors: perspective of the target sentence and perspective consistency with study. Each factor has three perspectives: route, hybrid, and survey.

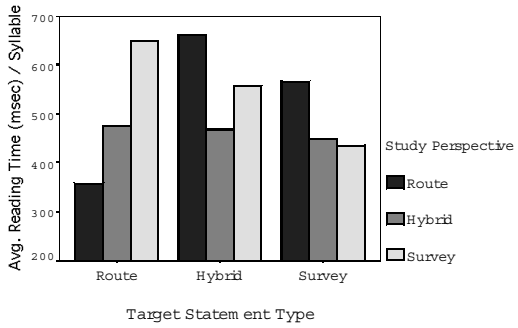

Figure 6: RT/syllable for Target Sentences: Effects of Perspective Switch during On-line Comprehension

There was an interaction between target perspective and study perspective (see Figure 6). $F(4,212) = 20.55$, $p < 2e\text{-}11$). Planned contrasts on hybrid target sentences showed faster reading times for hybrid (468 msec/syl) than route descriptions (661 msec/syl; $t(212) = 4.89$, $p < 1e\text{-}6$), and reading times for hybrid was marginally faster than survey descriptions (556 msec/syl; $t(212) = 2.16$, $p < 0.02$; Bonferroni group $p_{crit} = 0.0025$). Direct comparison between route and survey descriptions showed that a perspective switch from route to hybrid took marginally longer than a switch from survey to hybrid ($t(212) = 2.73$, $p < 0.004$; $p_{crit} = 0.0025$).

Similarly, route target sentences were read faster after route (357 msec/syl) than either hybrid (474 msec/syl; $t(212) = 3.04$, $p < 0.0015$) or survey descriptions (649 msec/syl; $t(212) = 4.55$, $p < 5e\text{-}6$). In addition, a perspective switch from survey to route took significantly longer to understand than a switch from hybrid to route ($t(212) = 7.60$, $p < 1e\text{-}11$).

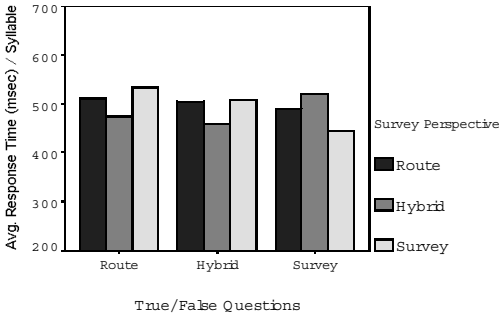

Figure 7: RT/syllable for T/F Questions: Effects of Perspective Switch during Memory Retrieval

Finally, survey target sentences were read faster when preceded by survey descriptions (435 msec/syl) than by route descriptions (566 msec/syl; $t(212) = 3.41$, $p < 0.0004$), but not by hybrid descriptions (448 msec/syl; $t(212) = 0.34$, $p > 0.35$). A direct comparison between route and hybrid descriptions showed a perspective switch from route to survey to take longer than a switch from hybrid to survey ($t(212) = 3.07$, $p < 0.0015$). Overall, hybrid statements behaved more like survey statements than like route statements.

True/false verification statements failed to replicate the results from Experiment 1, as there was no significant main or interaction effects (see Figure 7).

Discussion

The hybrid perspective provided an "intermediate" perspective between route and survey perspective. Its viewpoint was embedded like a route perspective but its reference terms were like survey perspective (i.e. north, south, east, and west). Which of these two factors would play a role in exacting cognitive costs during comprehension? The answer turned out to be both.

Reading times for target sentences were longer when the perspective was switched from route to hybrid than when consistent. Since the route and the hybrid descriptions were identical except for orientation terms, orientation terms contributed to the perspective switching costs. Similarly, when perspective was switched from survey to hybrid, longer reading times resulted. Since a survey description differs from a hybrid in the viewpoint of the observer, viewpoint also contributed to the perspective switching costs, although the effect size was much smaller than that of the orientation terms.

Target reading times for the route statements confirmed this hypothesis. Switching from the hybrid to route perspective increased the reading times, implicating orientation terms or reference frames. Since a switch from survey to route required a change in both orientation terms and the viewpoint, reading times were even longer than for a switch from hybrid to route. The advantage of hybrid over survey study perspectives for reading route targets further supported the significance of the viewpoint in the perspective switching costs.

For the survey targets, the overall results corroborated the other findings, except that there was no perspective cost when readers switched from hybrid to survey perspective. This suggests that orientation terms exact a greater cost than viewpoint.

Overall, there were strong and consistent effects of perspective switching costs due to changes in orientation terms. The effects due to viewpoint changes were weaker, since there was a significant effect for the route targets, a marginal effect for the hybrid targets, and no effects for the survey targets.

During the sentence verification, all effects between conditions disappeared. These results were consistent with Taylor and Tversky (1992) but differed slightly

from the results of Experiment 1. Both experiments are consistent with the claim that perspective effects diminish during the retrieval phase compared to the study phase, especially when the retrieval is done repeatedly from multiple perspectives. Answering true/false questions from three different perspectives might have accelerated the process.

Conclusion

When people describe a large-scale environment, they typically adopt route or survey perspectives, or a combination of both (Taylor & Tversky, 1996). These two perspectives are also readily understood, suggesting that they capture a natural way of understanding the world.

Previous work suggested that mental representations of constrained, well-learned environment acquired from descriptions are perspective-free, that is, statements about the environments from either perspective are verified equally quickly and accurately, irrespective of study perspective (Taylor & Tversky, 1992). However, other studies have suggested perspective-dependent representations (Diwadkar & McNamara, 1997).

The present experiment provided evidence that maintaining a consistent perspective during learning facilitates acquisition of new environments, that is, switching perspective exacts a cost in reading times. However, after acquisition and during testing for memory of the environment, costs of switching perspectives diminish considerably (Exp 1) or disappear (Exp 2). Perspective-independent responding could indicate that the mental representations are more abstract than any particular perspective, allowing equally efficient retrieval from either perspective. Alternatively, it could indicate multiple representations or increased efficiency of comprehending various perspectives.

Spatial perspectives include both viewpoints and terms of reference, as well as other factors, such as referent object. In particular, survey descriptions take an overhead viewpoint and use the cardinal direction terms of reference. Route descriptions take viewpoints within environments and use intrinsic direction terms, *left, right, front,* and *back.* In the second experiment, a hybrid description was constructed using a route viewpoint and survey reference terms. Switching reference terms exacted a greater cognitive cost than switching viewpoint, suggesting that overall reference frame is more critical in spatial descriptions than viewpoint.

Abstract

Based on the apparent paucity of input, and the non-obvious nature of linguistic generalizations, Chomskyan linguists assume an innate body of linguistically detailed knowledge, known as Universal Grammar (UG), and attribute to it principles required to account for those "*properties of language that can reasonably be supposed not to have been learned*" (Chomsky, 1975). A definitive account of learnability is lacking, but is implicit in examples of the application of the logic. Our research demonstrates, however, that important statistical properties of the input have been overlooked, resulting in UG being credited for properties which are demonstrably learnable; in contradiction to Chomsky's celebrated argument for the innateness of structure-dependence (*e.g.* Chomsky, 1975), a simple recurrent network (Elman, 1990), given input modelled on child-directed speech, is shown to learn the structure of relative clauses, and to generalize that structure to subject position in *aux*-questions. The result demonstrates that before a property of language can *reasonably* be supposed not to have been learned, it is necessary to give greater consideration to the indirect positive evidence in the data — and that connectionism can be invaluable to linguists in that respect.

Introduction

Chomskyan linguists argue that language acquisition cannot strictly be a matter of learning — the child's target grammar is "*hopelessly underdetermined by the fragmentary evidence available*" (Chomsky, 1968) — rather it must rest on a set of innate linguistic principles; the goal of the Chomskyan linguist is to determine the contents of this set, known as Universal Grammar (UG). The idea is to attribute to UG all and only the principles required to account for those "*properties of language that can reasonably be supposed not to have been learned*" (Chomsky, 1975). Learning theory is thus of central importance to the enterprise, but, oddly, a definitive account of the notion of learning that Chomskyans adopt is lacking, and is given only implicitly in the examples of the principles attributed to UG. Statistical approaches, however, and the notions of generalization and analogy have been explicitly rejected as irrelevant (Chomsky, 1975). In this paper we demonstrate that this rejection is a serious error — that UG has been attributed with principles to account for properties of language that are demonstrably learnable from the statistical properties of the input.

Chomsky's celebrated argument for the innateness of the principle of structure-dependence (Chomsky, 1975) serves as an example. Chomsky claims that, during the course of language acquisition, children entertain only hypotheses which respect the abstract structural organization of language, though the data may also be consistent with structure-independent hypotheses, *i.e.* relationships over utterances considered only as linearly ordered word sequences. As support for this claim, Chomsky notes that though questions like (1) are apparently absent in the child's input, questions like (2) are never erroneously produced — a claim subsequently

1) *Is the man who is smoking crazy?*
2) **Is the man who smoking is crazy?*

empirically tested and substantiated by Crain and Nakayama (1987, also see Crain 1991). Chomsky suggests that it is reasonable to suppose that children derive *aux*-questions from declaratives, and exposed to only simpler structures, might hypothesize either of two sorts of rules: a structure-independent rule — *i.e.* move the first '*is*' — or the correct structure-dependent rule. Chomsky claims that "*cases that distinguish the hypotheses rarely arise; you can easily live your whole life without ever producing a relevant example to show that you are using one hypothesis rather than the other one*" (Piatelli-Palmarini, 1980). The fact that children do not produce questions like (2), despite that the correct rule is supposedly more complex, and that the learner might not encounter the relevant evidence leads Chomsky to suggest that "*the only reasonable conclusion is that* UG *contains the principle that all such rules must be structure-dependent*" (Chomsky, 1975).

As a number of researchers have noted, however, there are several weaknesses in this argument. Slobin (1991), for instance, points out that the conclusion rests on the assumption that *aux*-questions are derived from declar-

atives by movement — an assumption which lacks justification — as well as on the equally questionable assumption of the autonomy of syntax. The argument has also been widely criticized for its reliance on the extremely limited conception of learning as hypotheses generation and testing. And the premise that the relevant evidence is not available to children has repeatedly been argued to most likely be false. As Sampson (1989) points out, evidence to distinguish the two hypotheses is provided by any utterance in which *any* auxiliary precedes the main clause auxiliary; thus evidence is available not only in questions like "*Is the jug of milk that's in the fridge empty?*" (from Cowie, 1998), but also "*Is the ball you were speaking of in the box with the bowling pin?*", or "*Where's this little boy who's full of smiles?*", or even "*While you're sleeping, shall I make the breakfast?*" None of these forms seem to be of the sort that a person might go for long without encountering; the latter three examples, in fact, are taken from the CHILDES database,[1] and Pullum and Scholz (2001) estimate that such examples make up about one percent of a typical corpus.

These are strong criticisms, but a conclusive counterargument, or an alternate account of the acquisition of *aux*-questions remains to be given. This paper builds on recent work with simple recurrent networks (SRNs; Elman 1990) to close this gap — *i.e.* to provide a proof that the correct form of *aux*-questions is learnable from data uncontroversially available to children.

Figure 1 shows the general structure of an SRN. The recurrent connections from the hidden layer to the context layer provide a one-step state memory. At each time step the activation values of each of the hidden units is copied to the corresponding unit in the context layer, and the connections from the context layer back to the hidden layer make these values available as additional inputs at the next time step. The network receives its input sequentially, and at each step attempts to predict the next input. At the outset of training, the connection weights and activation values are random, but to the extent that there are sequential dependencies in the data, the network will reduce its prediction error by building abstract representations that capture these dependencies. Structured representations thus emerge over time as a means of minimizing error.

Elman (1991, 1993) provided such a network with a corpus of language-like sentences which could be either simple (transitive or intransitive), or contain multiply embedded relative clauses (in which the head noun could be either the subject or object of the subordinate clause). The input was presented as word sequences, where words were represented as orthogonal vectors — a localist representation — so that no information about either the words or the grammatical structure was supplied; thus the network had to extract all information (*e.g.* the grammatical categories, number agreement, subcategorization frames, and selectional restrictions) from regularities in the input. The network learned the structure of such sentences so as to predict the correct agreement patterns between subject nouns and their corresponding verbs, even when the two were separated by a relative clause with multiple levels of embedding, *e.g.* *boys who like the girl who Mary hates hate Mary*.[2,3]

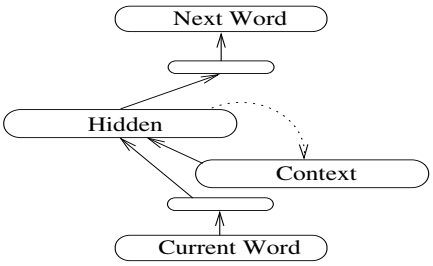

Figure 1: An SRN. Solid lines represent full connectivity; the dashed line indicates unit-to-unit connections. The unlabeled layers are reduction layers.

Such networks have also been shown to go beyond the data in interesting ways. Elman (1998) and Morris et al. (2000) showed that SRNs induce abstract grammatical categories which allow both distinctions such as *subject* and *object*, and generalizations such that words which have never occurred in one of these positions are nonetheless predicted to occur, if they share a sufficient number of abstract properties with a set of words which have occurred there.

Together these results suggest that an SRN might be able to learn the structure of relative clauses, and generalize that structure to subject position in *aux*-questions — and thus to learn the aspect of grammar in question despite not having access to the sort of evidence that has been assumed necessary. This paper reports on simulations which show that this is the case. An initial experiment verifies that the two results combine in the required way; then an SRN is shown to generalize from training sets based on CHILDES data to predict (1), but not (2). This result clearly runs counter to Chomsky's argument, and thus both draws into question the validity of poverty of the stimulus arguments in general, and shows that neural networks provide a means of assessing just how impoverished the stimulus really is.

Abstractions and Generalization

Training sets similar to those used by Elman (1991, 1993) were used to test whether an SRN would generalize to predict relative clauses in subject position in *aux*-questions from data which contained no such questions. An artificial grammar was created such that it generated *a) aux*-questions of the form 'AUX NP ADJ?',

[1]The second through fourth examples are from Brown's Adam, Korman's' St, and Manchester's Anne, respectively.

[2]The network succeeded only if either the input was structured, or the network's memory was initially limited, and developed gradually.

[3]An SRN's performance with such recursive structures has also been shown to fit well to the human data (Christiansen and Chater, 1999).

and *b)* sequences of the form 'A_i NP B_i', where A_i and B_i were of varying content and length. Proper names and NPs of the form 'DET (ADJ) N (PP)' were generated in both types, and NPs with relative clauses were generated for the 'A_i NP B_i' type, but were restricted from appearing in *aux*-questions. Some representative examples are given in Figure 2.

A_i *Mummy* B_i	*is Mummy beautiful?*
A_i *the dog* B_i	*is the dog hungry?*
A_i *the little girl* B_i	*is the little girl pretty?*
A_i *the cat on the mat* B_i	*is the cat on the mat fat?*
A_i *the boy who is smiling* B_i	*

Figure 2: Examples of the various types of utterances generated by the artificial grammar.

A three-stage training set was generated from this grammar, with the degree of complexity in NPs increasing at each stage, and the percentage of *aux*-questions decreasing — crudely approximating the structure of child-directed speech. Names constituted 80% of the NPs in the first set, and the remaining 20% was shared among the other NP forms (such that the more complex the form, the fewer the instances of it), with relative clauses making up only 1%; there were 40% *aux*-questions, and 60% 'A_i NP B_i' forms. In the second set, names constituted 70% of the NPs, relative clauses made up 2.5% of the remainder, and the percentage of *aux*-questions decreased to 30%. And in the third set, 60% of the NPs were names, relative clauses made up 5% of the remainder, and the percentage of *aux*-questions decreased to 20%. Each training set consisted of 50,000 examples. An SRN was trained on each set successively, for 10 epochs each, and tested with the structures in (1) and (2) after each epoch.[4] The network received the input in the same form as used by Elman (1991, 1993), *i.e.* a localist representation was used, and the data was presented one word at a time.

Figure 3 shows the networks predictions (after the third stage of training) for successive words of the question "*Is the boy who is smoking crazy?*" As should be expected, the network predicts an AUX as a possible first word, a name or a DET as a continuation when presented with '*is*', and a noun or an adjective as possibilities after '*is the*'. These sequences all occur in the training sets. But, following presentation of '*is the boy*', not only is an adjective or a preposition predicted, but also a relativizer — a sequence which never occurs in the training sets. And upon presentation of '*who*' the network predicts an AUX, and when given '*is*', predicts a participle; the network has thus generalized to predict the

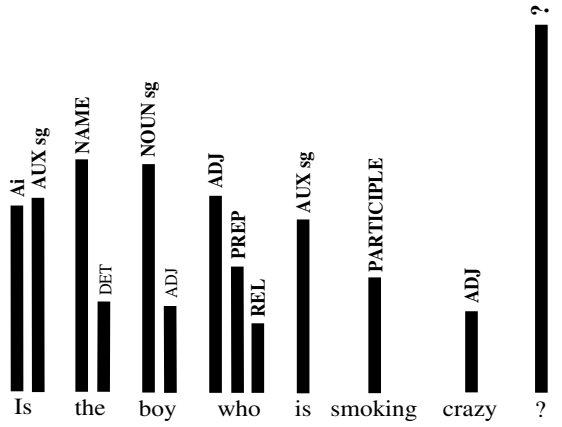

Figure 3: The SRN's categorized predictions for the test sentence "*Is the boy who is smoking crazy?*" Target words appear under the network's predictions; and the strength of the predictions is represented vertically.

relative clause.[5] The network does not, of course, make the predictions corresponding to the ungrammatical form in (2) — *i.e.* the network does not predict a participle following '*who*'; the training sets do not contain copula constructions, and so there can be no hypothesis of a movement derivation. Rather, the network has apparently formed an abstract representation of NPs which includes NPs with relative clauses. That this is so is shown by the networks prediction of an adjective when presented with '*is the boy who is smoking* ____'; the sequence '... PARTICIPLE ADJ ...' never occurs in the training sets, and thus the prediction indicates that the network has formed an abstract representation of *aux*-questions, and generalized over the NP forms.

That the data available to children are sufficient to provide for this generalization, however, remains to be shown.

Child-Directed Speech

There are a number of features of child-directed speech that run counter to the notion that the child's input is "*meager and degenerate*" (Chomsky, 1968) — *i.e.*, that appear to be important for language acquisition, and particularly for the issue at hand. Complexity increases over time — which has been shown to be a determinant of learnability (*e.g.* Elman, 1991, 1993) — and there are also arguably meaningful shifts in the distribution of types, and the limitations on forms.

The increasing complexity of the child's input is especially relevant to the problem here, since it is directly linked to the frequency of occurrence of relative clauses.

[4]The networks were simulated with *LENS* (Rohde, 1999), and trained with a fixed learning rate of 0.01, using a variation of cross entropy which assigned smaller errors for predicting incorrectly than for failure to predict. The architecture shown in Figure 1 is used, with 100 input and output units, 50 units in the reduction layers, and 500 units in both the hidden and context layers.

[5]The fact that the network predicts '*who*' given '*is the boy*' is, on its own, not enough — early in training, the network will make this prediction, but when presented with '*who*' will predict a '*?*', apparently mistaking the relativizer for an adjective. That the network *is* predicting a relative clause is shown by the fact that it predicts '*is*' when subsequently given '*who*', and a participle when then given '*is*'. Since participles are restricted to only occur in relative clauses, the latter is decisive.

Complexity in the child's input is introduced in a way akin to the staged presentation of data used to train the network in the experiment described above; Figure 4 charts the occurrences of tagged relative clauses — *i.e.* marked with '*who*' or '*that*' — found in child-directed speech in the CHILDES' Manchester corpus (Theakston et al., 2000). Pronominal relatives (*e.g.*, '*the girl you like*') show a similar increase, and occur approximately as frequently. And prepositional phrases increase in frequency slightly more dramatically; they seem to occur approximately twice as often as relatives.[6]

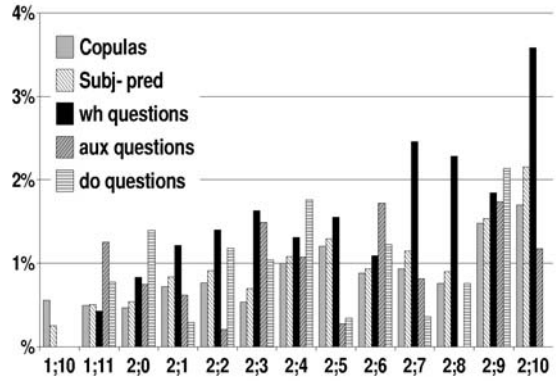

Figure 4: The percentage of NPs that contain relative clauses, for each month, averaged over all twelve children in the Manchester corpus.

The difference between the distribution of types in child-directed speech and speech between adults is also potentially significant. Child-directed speech contains a much greater proportion of questions — estimated at about one third of the child's input (Hart and Risley, 1995; Cameron-Faulkner et al., 2001) — and thus there is more of a balance between types. This may be critical in establishing the multiple roles that, *e.g.*auxiliaries, can take on; and also to reserve representational space for the the large variety of question forms. Figure 5 shows the percentages of copula constructions, subject-predicate forms (*e.g.*, transitives and intransitives), and *wh*-, *do*-, and *aux*-questions for representative months near the beginning, middle, and end of the time period covered by the Manchester corpus.

And finally, *aux*-questions in the child's input not only lack relative clauses in subject position, but are limited in a way that both predicts this absence, and potentially allows for the correct generalization to be formed. In child-directed speech, *aux*-questions with a determiner in the subject noun phrase — like '*Is the boy crazy?*' — are almost never used; the *aux*-questions in child-directed speech overwhelmingly use proper names, pronouns, deictics, *e.g.* '*Is that ...*', and other such forms which do not provide the correct context for a relative clause. Thus, given the low frequency of relative clauses in general, one should expect them to almost never occur in subject position.

These are ideal conditions for an SRN. The target generalization is supported by the appearance of relative clauses in all other positions in which noun phrases occur, and making the generalization incurs little cost since the context in which the generalization applies seldom occurs. If this were not the case, and questions like '*Is the boy crazy?*' were common, then the generalization would be threatened — each such occurrence would produce a false prediction which backpropogation would attempt to eliminate.

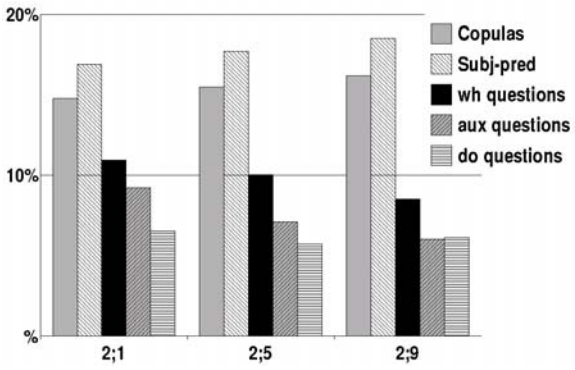

Figure 5: The percentage occurrence of various forms, at three stages, averaged over all children.

Motherese and the Generalization

Training sets generated on the basis of this analysis were used to determine if an SRN would generalize to predict (1), but not (2) from input of this sort. As before, the training sets contained *aux*-questions of the form 'AUX NP ADJ?'; but here the 'A_i NP B_i' forms were eliminated, and copula constructions, subject-predicate forms, and *wh*- and *do*-questions were added. The prohibition on NPs with relative clauses in *aux*-questions extended also to *wh*- and *do*-questions — *i.e.* NPs with relative clauses could occur in object position in these forms, but not in subject position. Thus these training sets also contained no evidence of the sort assumed to distinguish the structure-dependent hypothesis. Some examples from these training sets are given in Figure 6. The proportions of these general types, and the frequency of relative clauses and prepositional phrases, were manipulated in each portion of the training set to match with successive portions of the Manchester data — *e.g.*, the type distributions can be read directly from figure 5. And, as per the observation of the previous section, noun phrases in *aux*-questions were restricted to be, almost exclusively, names. The three training sets again consisted of 50,000

[6] A precise count of the prepositional phrases has not been made — in part because of the lesser significance to the current research issue, and in part because it is considerably more problematic to determine whether or not a prepositional phrase is within a noun phrase. But, (Cameron-Faulkner et al., 2001) analyzed a sample from this same corpus, and they report that prepositional phrases make up about 10% of all fragments, which may be indicative of their general frequency.

Mummy is beautiful.	*is Mummy beautiful?*
the little boy bites.	*is the little boy nice?*
the dog likes Mummy.	*is the dog hungry?*
does Mary smoke?	.
who likes Mary?	.
who does Mary like?	.
who likes the cat on the mat?	
who does the girl at the shop like?

examples each; and again the network was trained for 10 epochs on each set, and was tested with the structures in (1) and (2) after each epoch.

Figures 7 and 8 chart the sum-squared error for (1) and (2) after each stage of training. As the figures show, the network succeeds in generalizing to predict (1), and generates significant error — and progressively larger error — at several points, when presented with (2).[7] The reasonably small error generated by the network when presented with '*who*' in the context of '*is the boy* _' shows that the relativizer is predicted. And the contrast in the errors generated by the subsequent presentation of either '*is*' or '*smoking*' shows clearly that the network has learned to predict an AUX after a relativizer, rather than entertaining the possibility of it's extraction, as in (2). Note, as well, that this contrast is monotonically increasing — at no point in training does the network predict a participle to follow the relativizer. And, for (1), the network's error is quite low for each successive word, including the presentation of the adjective after the participle, despite that '... PARTICIPLE ADJ ...' never occurs in the training sets. In contrast, for (2), as well as the error produced by the presentation of '*smoking*', the network also generates a substantial error upon the subsequent presentation of '*is*'; And though when presented with '*is the boy who smoking is* ' the network successfully predicts an adjective, the success is illusory: when subsequently presented with '*crazy*' the network's predictions are somewhat random, but a period is predicted more strongly than a question mark.

The network does, however, have some difficulties with this input. Although the grammar restricts relative clauses to the form 'REL AUX VERB*ing*', the network persists in predicting noun phrases and adjectives after the auxiliary — presumably because the '*is*' that occurs in initial position in *aux*-questions, followed by a noun phrase, and the '*is*' in declaratives, followed by an adjective, are relatively more frequent in the data than the '*is*'

[7]The SRN responsible for these results incorporates a variant of the developmental mechanism from (Elman, 1993). That version reset the context layer at increasing intervals; the version used here is similar, but does not reset the context units unless the network's prediction error is greater than a set threshold value.

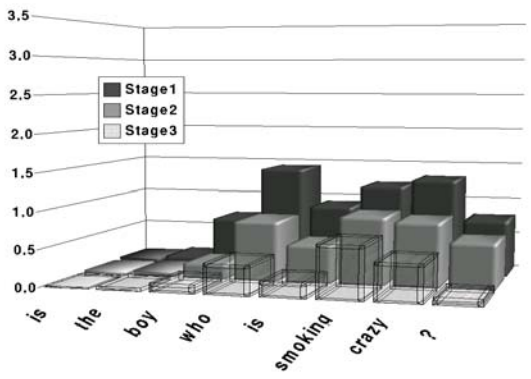

Figure 7: The sum-squared error after each word of the test sentence "*Is the boy who is smoking crazy?*" at the end of each stage of training.

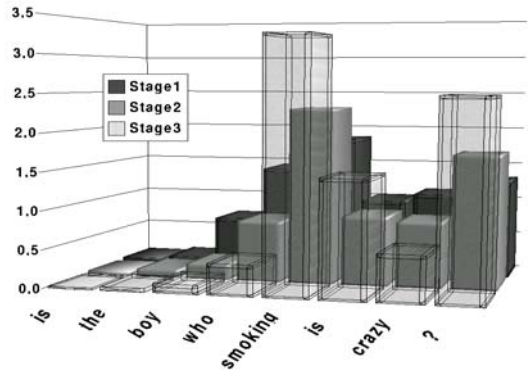

Figure 8: The sum-squared error after each word of the test sentence "*Is the boy who smoking is crazy?*" at the end of each stage of training.

in relative clauses. These erroneous predictions, however, gradually erode. And it is worth noting that they would be correct for a more realistic grammar.

The error associated with the adjective following the participle most likely has a similar source. Relative clauses occur only in either sentence final position, or preceding an auxiliary or a verb; thus the network initially expects participles to be followed by either a verb, a period, a question mark, or most prominently, an auxiliary. Again the problem is somewhat persistent, but is gradually resolved; by the end of the third stage such predictions, though remaining, are substantially weaker than the correct predictions — thus, arguably, not truly problematic. And it is plausible that such errors would not arise were the grammar to be made yet more realistic. The grammar used here contained little variation in terms of either NP types, syntactic structures, or lexical items, and thus generalizations were based on a quite limited set of distributional cues. Lifting the artificial limitations on the grammar might also help to eliminate such errors: questions like

'*what's the lady who was at the house called?*' — in Manchester's *ruth28a.cha* — are not only evidence of the sort assumed not to be available, but also data which discourage these sorts of false predictions.

But, such errors are also potentially meaningful. The most prominent and persistent of the errors is the prediction of an auxiliary following the participle, *i.e.*, '*is the boy who is smoking* <u>*is*</u> ...'; in fact an auxiliary is predicted as a possible continuation after any NP, *e.g.*,'*is the boy* <u>*is*</u> ...'. And this is an error that children make as well (Crain and Thornton, 1998).

Discussion

The objective here was to provide a proof that the structure of aux-questions is learnable from the input available to children. To make the results convincing, we have been careful to avoid providing the network with input that could be controversial with respect to its availability, and have represented the input in a way that encodes no grammatical information beyond what can be determined from its statistical regularities.

The fact that a neural network generalizes to make the correct predictions from input represented in this way, and modeled on child-directed speech — but limited to contain no data of what has been considered the relevant sort — shows that poverty of the stimulus arguments must give greater consideration to the indirect evidence available to the child. The statistical structure of language provides for far more sophisticated inferences than those which can be made within a theory that considers only whether or not a particular form appears in the input. And there is a growing body of evidence that children, not only neural networks, make use of the statistical properties of the input in acquiring the structure of language (*e.g.* Aslin et al., 1998; Gomez and Gerken, 1999). Thus learnability arguments cannot ignore those properties.

But discovering what those properties are, and determining their potential worth in language acquisition is difficult. This work shows that neural networks provide a means of dealing with this problem. As demonstrated here, neural networks can be used to assess just how impoverished the stimulus really is, and so can be invaluable to linguists in establishing whether or not a property of language can reasonably be assumed not to have been learned.

Abstract

We present the results of a study designed to show that dissociations between lexical and similarity-based boundary partitions for a set of items can be produced in the laboratory. This is achieved by an incremental process of learning to assign a category label to items increasingly far removed (in similarity space) from the center of that category and approaching a different category. This process occurs in parallel with a compression effect in psychological similarity space such that increasingly distant items labeled as members of category A nonetheless come to be viewed as more similar to category B (the category to which they are in fact closer in pre-category learning similarity space) than they are by people who have not learned the category distinction.

Introduction

Although patterns of similarity are related in a more complex way to categorization and concept learning than was once thought, the evidence is mounting that such relationships are crucial to the partitioning of a set of items into categories (Medin, 1989; Medin, Goldstone, and Gentner, 1993; Goldstone, 1994a; 1994b). Among the most interesting recent findings is the discovery that the psychological similarity space usually assumed in the effort to measure relationships among category members is not static, but may actually undergo a change in its metric properties during the process of category learning. Thus, for example, Goldstone and his colleagues have found repeatedly that people who have learned to categorize a set of items make more reliable discriminations between pairs of items that cross the category boundary than people who have not learned to categorize them (Goldstone, 1994a; 1994b) This expansion or acquired distinctiveness effect seems to involve a stretching of the psychological similarity space in the region of the category boundary, with the result that smaller changes along the category relevant dimensions are sufficient to produce a just noticeable difference (JND).

Category clusters might also be formed by a process of compression in the region of similarity space that contains a set of items, with the result that a larger change is required to produce a JND. A number of researchers have found evidence for this process as well (Kurtz, 1996; Livingston, Andrews, and Harnad, 1998). Either of these processes, expansion or compression of the similarity space, is sufficient to produce a categorical distinction between sets of items, and thus looks promising as a general mechanism for concept learning. On such an account, a concept is formed when regions of psychological similarity space are warped so as to create a relatively more compact representational structure that can be more readily manipulated as a unit.

This description of a general mechanism for category learning is called into question, however, by recent findings concerning the relationship of language labels to category similarity structures. Malt, Sloman, Gennari, Shi, and Wang (1999) asked native speakers of English, Spanish, and Chinese to name each member of a set of sixty containers. They then asked these same people to sort these sixty items into groups based on their overall similarity. Perhaps not surprisingly, language communities differ in their lexical partitioning of the set of items. Chinese speakers partition the set using five words, English speakers use 7, and Spanish speakers use 15. The variation in grain is not the result of simply forming a greater number of subcategories in,

say, Spanish, of the same larger category boundaries found in Chinese; there is substantial non-shared variance in these lexical groupings.

The real surprise comes when one examines the clustering of items that occurs during the sorting task. Malt, et al., found that the sorts were very similar across language communities, in spite of the disparity in lexical boundaries for the set. There seems to be a dissociation of lexical boundaries from category boundaries based on similarity, and this creates something of a theoretical problem for the account of category learning given above. Indeed, it constitutes a puzzle for any theory of conceptual structure that suggests that there is a central tendency in the representation of the members of a category. The widely held belief that terms derive their meanings from their links to coherent concepts seems inconsistent with this result.

Unfortunately, we have no information about the kinds of judgments that people might have made of Malt, et al.'s set of containers *prior* to learning to name and categorize them. We therefore have no way of knowing how this odd state of affairs came to pass, nor whether it really constitutes a disconfirmation of the claim that psychological similarity space warps in a coherent fashion during category learning.

How might an item come to have a name other than that of its nearest neighbors with whom it shares a region in similarity space? One possibility discussed by Malt, et al. (1999) is that a series of intermediate cases could be introduced, one at a time, each inheriting the name of its nearest neighbor, and each more remote from the category to which the name was initially attached. If the chain of items spans the boundary between two categories, one could wind up with instances that are labeled as members of category A, the point of origin for the chain, even while having more in common perceptually with the members of category B. The dissociation of lexical and similarity groupings occurs because the former is based on nearest exemplar pairings introduced incrementally, while the latter is based on the warping of similarity space described above.

In order to test this hypothesis, we constructed a set of stimuli whose distribution in similarity space allowed for partitioning into two categories while leaving a set of items in the space between these groupings to allow the building of a naming chain from one to the other. Success at building such a chain would constitute an existence proof for this process, and comparison of data from people who learned to categorize the set with data from people without category or name-learning experience would allow us to determine whether this process alters the character of any warping of the similarity space.

Method

Participants

Participants were seventy-eight Vassar College undergraduates who were given course credit in an introductory psychology course. Twenty people participated in preliminary research to select an appropriate stimulus set. The remaining fifty-eight people participated in the experiment reported here, twenty-two of them in a control group, and eighteen in each of two experimental groups.

Stimuli

Ten members of the Nemipteridae family of fish (threadfin breams) and ten members of the Labridae family (wrasses) were selected for preliminary analysis from Burgess, Axelrod, and Hunziker (1997). Each stimulus was color photocopied, glued onto a blank card (5.1 by 10.8 cm), laminated, and then randomly assigned a number from 1 to 20, which was printed on the back of the card. Following examination of the two-dimensional solution to a multidimensional scaling analysis (MDS) of the similarity judgments of twenty people on all 190 possible pairs (see Procedure below), the set was culled to remove outlying cases. These were then replaced with items that occupied the central region of the 2D space, which appeared to be defined by the dimensions of degree of body striping, and the ratio of body width to length. These replacement items were selected without regard to membership in the two original categories.

Procedure

Participants were assigned either to a control condition (N=22) or to one of two learning conditions (N=18 each group). Participants in the control condition were asked to judge the degree of similarity between all possible pairs of the twenty stimuli (190 pairs). The participant was seated at a table upon which the stimuli had been placed face up, and was allowed to inspect the entire stimulus set for one minute. The stimuli were then turned over, revealing the numbers on the back, and the experimenter began naming pairs in a previously determined random order. The participant was instructed to turn over each corresponding pair, look at the two items, and verbally rate the similarity of the stimuli on a 9-point scale from 1 (most similar) to 9 (most different). Ratings were provided to one decimal place.

For control group participants, the similarity judgment task was the only task required. All control group participants were run through the procedure in a block before work began with the experimental group. This allowed us to complete an MDS analysis of the data from this group to confirm the pattern of similarity relationships in the set and the choice of stimuli for building the chain between categories. As expected, the MDS analysis of the control group data revealed that

stimuli clustered in two core groups consisting of eight and seven items, respectively. The five remaining stimuli were intermediate cases, four of which formed a chain between the two larger groups. One intermediate stimulus that was not part of the chain was treated as a neutral stimulus, and did not appear in the training task. It served as the means to a test for demand effects in the data set (see Results, below).

This analysis of the pre-categorization similarity space allowed us to design the stimulus sets for the learning group. Learning participants were first taught to categorize the core set of fifteen stimuli. Stimuli were presented individually, in blocks of fifteen that included all members of both categories. The participant was asked to label each picture as either *gracilia* or *aurora*. The experimenter gave immediate feedback, recorded the response, and then presented the next picture. Order of presentation within each trial block was random. Training continued until the participant met the criterion of two consecutive errorless trial blocks (30 stimuli), or a total of 20 trial blocks had passed, whichever came first.

Once category training on the core stimuli was complete, the first stimulus in the chain was introduced into the subsequent trial block. Which stimulus this was depended on the direction in which the chain was being built. For half of the study participants, the chain was built from *gracilia* to *aurora* (the G-root group) and for half it was built in the opposite direction (the A-root group). Assignment to these subgroups was random. The first chaining stimulus introduced was the one closest to the root category in the MDS space derived from the control group data.

Once this new stimulus was introduced into the set, training continued as before, except that trial blocks now contained one additional stimulus. Order of presentation was still random, except that the new chaining stimulus was always presented immediately after its nearest neighbor in the root category. Training using this newly expanded set continued until the participant met the criterion of two consecutive trial blocks in which all chaining stimuli presented up to that point had been correctly categorized, or a total of 5 trial blocks (after introduction of the new item), whichever came first. Once the participant met criterion for one chaining stimulus, the next stimulus in the chain was introduced into the subsequent trial block. The new chaining stimulus always followed the previously learned one, which appeared randomly in the trial block along with the 15 core stimuli and any other chaining stimuli. Training was halted when the participant met the training criterion after the introduction of the fourth and final item in the chain.

Once training was completed, the participant took a short break before completing the similarity judgment task. Procedures for this task were exactly as for the people in the control group, and are described above.

Results

Six people in the learning group did not meet the criterion for successful learning by the conclusion of training. All six of these people were in the G-root group. Data for those who failed to reach criterion were excluded from all analyses. Mean similarity ratings were calculated separately for the control and learning groups, and, within group, mean similarities were calculated for *aurora-aurora* (A-A) pairs, *for aurora-gracilia* (A-G) pairs, and for *gracilia-gracilia* (G-G) pairs. Separate analyses were then performed for the two different chaining groups, using the same control group data for comparison in both cases.

In order to determine whether category learning produced compression and/or expansion effects in the A-root group, we performed a 2 (group: control vs. learning) by 3 (pair type: A-A, A-G, G-G) analysis of variance (ANOVA) on mean similarity ratings with repeated measures on the second variable. The analysis revealed a significant main effect of pair type, $F(2,76) = 149.506$, $MSE = 63.152$, $p < .0001$; and a significant interaction effect, $F(2,76) = 9.952$, $MSE = 4.202$, $p < .001$. (See Figure 1). For the G-root group, the same 2 (group: control vs. learning) by 3 (pair type: A-A, A-G, G-G) ANOVA with repeated measures on the second variable revealed significant main effects of group, $F(1,32) = 9.488$, $MSE = 22.437$, $p < .005$, and pair type, $F(2,64) = 57.551$, $MSE = 20.376$, $p < .0001$. The interaction effect was not significant. (See Figure 2.)

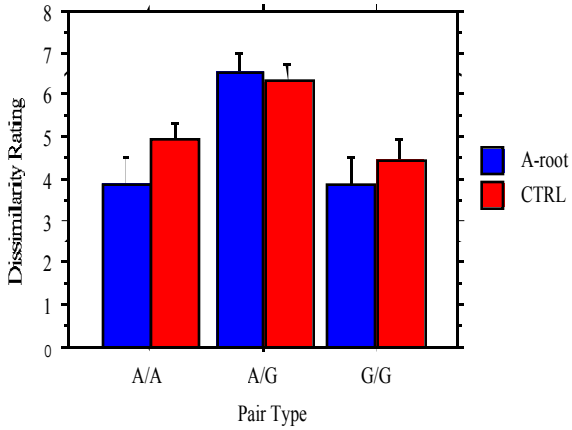

Figure 1. Comparison of the mean similarity ratings of the control group and the group who learned a chain of items rooted in the *aurora* category. Interaction of group with pair-type is shown.

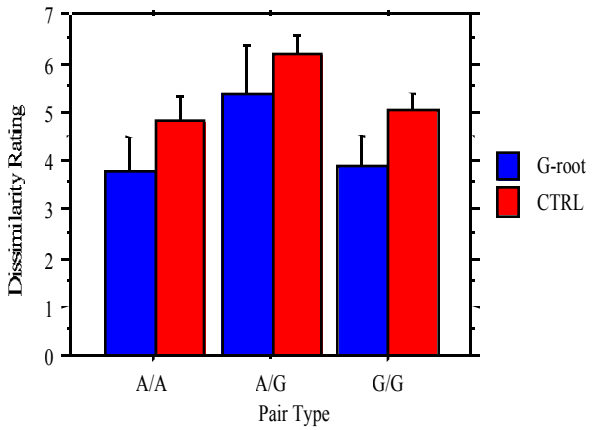

Figure 2. Comparison of the mean similarity ratings of the control group and the group who learned a chain of items rooted in the *gracilia* category. Interaction of group with pair-type is shown.

Thus, compression occurred in both learning groups, i.e., item pairs were judged to be more similar relative to control group ratings, particularly for the within-category (A-A and G-G) pairs. No expansion occurred, i.e., between-category pairs (A-G) were not judged to be less similar by the learning groups than by the control group.

Neutral Stimulus Analysis

Goldstone, Lippa, and Shiffrin (2001) have devised an ingenious technique for detecting the presence of demand effects in data of this kind. The analysis works by comparing the pattern of changes in similarity relationships among items in a learning set relative to a neutral item not included in training. If the similarity judgments of pairs including the neutral item change in ways that are predictable from the compression or expansion effects that occur for categorized items, this must be due to actual changes in the underlying similarity space and not demand effects, since the neutral item was never categorized.

For our data set, the absolute difference for each participant between all possible within-group and between-group pairs of pairs involving the neutral stimulus was calculated, averaging separately across each group. Separate 2 (group: learning vs. control) by 2 (pair of pair type: within vs. between) ANOVAs with repeated measures on the second variable were conducted for both the A-root and the G-root groups. The pattern of results was the same as that reported above. There was thus no evidence that the observed compression was due to a demand effect for either group.

MDS Analysis

In order to better understand the nature of the changes taking place in psychological similarity space we performed a multi-dimensional scaling analysis of the mean similarity ratings of all three groups (control, A-root, and G-root). The full matrix of mean similarities from each of the three groups was entered into an INDSCAL analysis. The two-dimensional solution provides a relatively good fit to the data (R-squared = .872), and is plotted in Figure 3. The locations of all twenty stimuli for each of the three groups (control, A-root, and G-root) are depicted, and the pattern of changes in similarity is shown by arrows connecting three points. The point at the tail end of the arrow represents the location in the space of the stimuli as judged by the control group. The middle point shows the locations of the twenty stimuli as judged by the G-root group, while the points at the tips of the arrow heads show the locations of the twenty stimuli as judged by the A-root group. The graph gives a sense of the compression that occurs in the similarity space as categories are learned. Note that the greater relative proximity of items following compression of the similarity space has the effect of making them a more easily identified grouping, even though there is no statistically significant increase in mean inter-item differences across the category boundary. Most importantly, the graph shows how the chained items move toward the central tendency of their nearest neighbor cluster, even when the label training ties them to the more remote cluster.

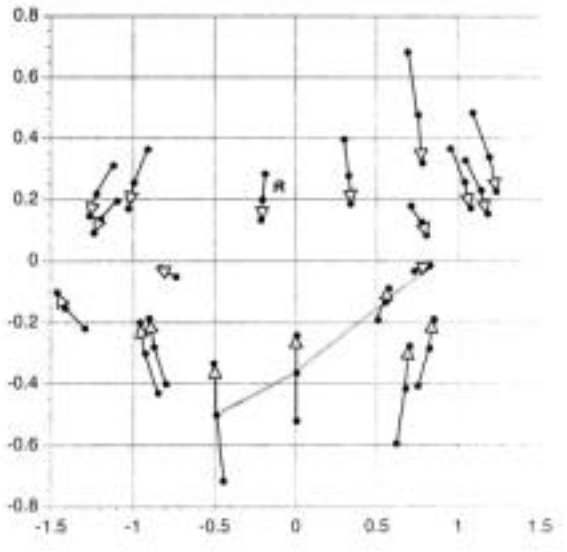

Figure 3. Shows the two-dimensional MDS analysis (INDSCAL) of similarity relationships among the twenty stimulus items for all three groups. The arrow labeled R is for the neutral item (see text). The four arrows linked by a shaded line are the chaining items.

The remaining points on the right side of the graph are the core items in the *aurora* category, while those on the left are the core items in the *gracilia* category. The space of similarities for the control group is represented by closed circles found at the tails of the arrows. The circles at the tips of the arrow heads represent the space of similarities for the experimental group that learned a chain that begins in the *aurora* category and extends toward the *gracilia* category. The filled circles found roughly in the middle regions of the arrows represent the space of similarities for the group that learned a chain that begins in the *gracilia* category and extends toward the *aurora* category.

Discussion

The domain of words must map in some predictable way to the domain of concepts if there is to be anything to the story that says words have meaning in virtue of the concepts to which they are linked. This is why Malt, et al.'s (1999) finding of an apparent dissociation between lexical boundaries and category boundaries in similarity space is so provocative. The experiment reported here demonstrates one process by which names might become attached to items that are remote in similarity space from the core of the concept to which the name typically refers. Note that although we did not measure typicality in this study, one further prediction would be that chained items should be seen as atypical of the category they name.

More important than the demonstration of a procedure for producing this dissociation are the data showing how this effect is related to the warping of similarity space previously shown to occur during category learning. This effect was clear in comparisons of the A-root group (people who learned a chain that begins with an item well within the region of the *aurora* group) with the control group. Analysis of variance revealed the same pattern of within-category compression found in previous research (e.g., see Kurtz, 1996; Livingston, et al., 1998). The effect is less clear in the G-root group. Compression occurs in this case, but it occurs for between category pairs as well as for within-category pairs. Obviously, the direction in which we tried to build chains made a difference, an observation further confirmed by the fact that all of the study participants who failed to reach our learning criterion were in the G-root chaining group. The nature of the difference between our two experimental groups, and its consequences for similarity judgments, can be seen in Figure 3.

First, notice that the chains differ in how deeply rooted they are in their originating categories. The *aurora*-based chain begins with an item well inside the region of similarity space that encompasses the category, and it does not extend very deeply into the region occupied by the *gracilia* category. Exactly the opposite is true for the G-root chaining group. Thus, even when people are learning to label the last two items in the chain leading deeply into *aurora* territory as *gracilia*, the region of space that they occupy is being compressed still further around the central tendency of the *aurora* category. It is therefore not surprising that one sees evidence of what counts as between-category compression for this group, because those last two items in the chain are considered *gracilia* for purposes of this analysis.

Looked at from this lexical perspective, the result seems straightforward enough, but the effect is far more interesting for what it tells us about how category learning warps similarity space. Notice that the lexical chaining effect seems to have relatively little effect on the direction in which similarity space is compressed during learning. The overall magnitude of the effect is different in the two cases, an effect that is likely the result of the fact that the task is more difficult and so produces slower and less robust learning in the G-root group, but the space warps in the same way in both cases. This warping, based on the pattern of structure and variation in the whole set of items, overrides local tendencies associated with rogue items chained in from elsewhere. As can be seen in Figure 3, the result is that the chained items move in the direction of the nearest region of compression, even while they are being labeled as members of the more remote cluster. The similarity-based warping of the representational space occurs independently of labeling. Thus are lexical and similarity-based category dissociations produced.

If this account is correct, several further predictions follow. We have already mentioned the predictions for typicality. Over long periods of time, we would also expect chains that stretch far from their roots would become unstable and break, with items at the ends of those chains receiving new labels more in keeping with those of their similarity-space neighbors. Linguistic analysis of patterns of lexical evolution should reveal such phenomena in the history of any language. We would also expect this pattern to be most common for artifact categories, where genuinely new instances are introduced with some frequency, and the perceptual and functional feature landscape is quite fluid. We are currently conducting a replication and extension of the study reported here using artifact categories and additional control groups. Finally, these results have deeper implications for the nature of the relationship between systems for representing lexicons, at least and systems for representing category information. These two systems must remain in register to some extent, but it is clear that each is sufficiently modular with respect to the other to permit some rather remarkable dissociations to develop in very short order.

Acknowledgments

Our thanks to the Undergraduate Research Summer Institute at Vassar College, and to Maria Jalbrzikowski and Paul Francaviglia for their assistance in the conduct of this experiment.

Abstract

This report considers differences in induction of biological properties between children and preadolescents based on differences in stimuli processing in these two groups. Two studies test predictions that young children, but not preadolescents, base their inductive inference on aggregating information from different sources rather than relying on a single source of information. In both experiments 4-5 year-olds, 7-8 year-olds, and 10-11 year-olds were presented with an inductive task. In Experiment 1, linguistic labels were fully crossed with relationship information, whereas in Experiment 2 perceptual similarity information was fully crossed with relationship and labeling information. While 10-11 year-olds relied exclusively on inheritance across experiments, 4-5 year-olds relied on an aggregate of multiple sources of information, and 7-8 year-olds fell between these two extremes. In addition, while the relative weight of inheritance on inferences increased with age, the weights of other information sources decreased. These results support the hypotheses suggesting that between 8 and 10 years of age children undergo a developmental shift from a holistic feature-integration induction to knowledge-based induction based on a single most predictive source.

Introduction

Inductive inference, or extending knowledge from known to novel instances, is ubiquitous in human cognition. For example, if one learned that a particular cat uses acid-based enzymes for digestion, one would expect other cats also to use acid-based enzymes for digestion, without having factual knowledge of digestion in cats.

The simplest case of inductive inference is induction over individuals, when attributes or relations are generalized from a single entity to another single entity, with both entities beings members of the same category (e.g., *This Bird has biological property X*, *therefore that Bird has biological property X*). There is a large body of research demonstrating the ability of young children to perform specific induction of biological properties (e.g., Gelman, 1988; Gelman & Markman, 1986, 1987; Gutheil, Vera, & Keil, 1998; Johnson & Solomon, 1997; Rosengren, Gelman, Kalish, & McCormick, 1991; Sloutsky & Lo, 2000; Sloutsky, Lo, & Fisher, in press; Solomon, Johnson, Zaitchik, & Carey, 1996; Springer, 1996; Springer & Keil, 1989). In addition, several lines of research have emerged in an attempt to determine what aspects, or what information cues, of compared entities children rely on when performing such induction.

One important aspect of previous research is that the majority of tasks pitted one information cue (or source of information) against another (e.g., appearance versus label, or appearance versus inheritance). This was necessary to establish the predictive value of each cue relative to a competing cue. At the same time, people typically face stimuli comprising multiple sources of information bundled together, with several sources supporting induction, but each having different predictive value. In particular, while the Target may comprise a bundle of cues $C_{i-1}C_{j-1}C_{k-1}$ (a particular appearance, inheritance, and category label), one entity may comprise another bundle $C_{i-1}C_{j-1}C_{k-2}$ (e.g., sharing appearance and category label with the Target), whereas another entity may comprise $C_{i-2}C_{j-2}C_{k-1}$ (e.g., sharing only inheritance with the Target). For example, a baby boy shares inheritance with his mother, whereas he shares appearance (at least in terms of his size and outfit), gender, and linguistic label "baby boy" with his neighbor baby boy. Would people induce from one baby boy to another or would they induce from a baby boy to his mother? It is reasonable to expect that when performing induction, adults would rely on a single most predictive cue: age to predict sleeping patterns, sex to predict gender development, and inheritance to predict blood type. However, it remains unclear how children perform induction across entities sharing multiple sources of information. Do they perform induction by relying on a single cue or do they aggregate information from different cues? In addition, if they rely on a single source of information, does the

importance of this source change in the course of development? Or if they rely on multiple sources of information, does the relative importance of each source change in the course of development?

Answers to these questions depend on how young children process multiple information cues. If they process each cue separately, one cue at a time, then due to working memory limitations (see Hitch & Towse, 1995, for a review), they should invariably rely on one most salient cue. On the other hand, if they process complex information in a holistic manner without attending to specific dimensions of stimuli (Shepp, 1978; Smith, 1989a, 1989b), they should rely on an aggregate of multiple sources. These different processing mechanisms may result in different developmental scenarios. If young children process cues separately, and development is a function of increasing working memory, then both young children and adults should rely on a single cue, with adults exhibiting larger flexibility in cue selection. For example, in the baby boy example, adults, but not young children, should use different cues when inducing gender development versus inducing the blood type. On the other hand, if, unlike adults, young children process cues holistically, then young children and adults should exhibit more profound differences, with young children relying on multiple sources of information, while adults relying on a single, most predictive source. Therefore, answers to the posed questions are important for understanding of developmental mechanisms of knowledge generalization and inductive inference, as well as general principles of the development of stimuli processing.

The overall experimental approach is as follows. The task consisted of presenting participants with triads of pictures. Each triad included a Target (a Baby animal), Test Stimulus A (a neighbor animal "who played with the baby") and Test Stimulus B (an animal "who gave birth to the baby"). Within each triad, participants were asked to generalize an unobservable biological property from the Test stimuli to the Target (e.g., blood color). In Experiment 1 the Target and the Test stimuli received labels and inheritance information, while perceptual similarity was kept constant. For half of the triads the Target shared a linguistic label with Test A while on the other half it shared a label with Test B. In Experiment 2, in addition to relationship information and labels, participants were also presented with perceptual information (with one Test stimulus being perceptually similar to the Target, while the other one being dissimilar), with the three attributes fully crossed.

Experiment 1

Method

Participants Participants were 45 children and preadolescents recruited from one daycare center and one elementary school located in middle class suburbs of Columbus, Ohio. There were three age groups, with 15 participants in each: (1) 4-5 year-olds (5 boys and 10 girls; M = 4.5 years; SD = .66 years); (2) 7-8 year olds (7 boys and 8 girls; M = 7.7 years; SD = .51 years); and (3) 10-11 year-olds (7 boys and 8 girls; M = 10.4 years; SD = .68 years). These participants were selected on the basis of returned parental consent forms.

Design and Materials The experiment had a mixed design with age as a between-subject factor and the information condition as a within-subject variable. The information condition had two levels: (1) Inheritance only information (when the Target shared only inheritance information and not labeling information with the Mother) and (2) Inheritance + Label information (when the Target shared both inheritance information and the label with the Mother). Note that in the Inheritance only condition the Target shared the label with the Friend, whereas in the Inheritance + Label condition, the Target had a label that was different from that of the Friend.

The order of Inheritance only and Inheritance + Label trials was counterbalanced across participants. Each participant was presented with eight stories (four stories in the Inheritance only condition and four stories in the Inheritance + Label condition).

Materials consisted of triads of line-drawing pictures with a fully shown Target animal, and Test A and Test B stimuli hidden behind trees, stories, biological properties, and auditorily presented linguistic labels. Each triad of stimuli had two labels, so that either Test A or Test B shared the label with the Target, whereas the other Test stimulus had a different label. To avoid confounds with existing knowledge about specific animals, we used only artificial labels, each consisting of a short two-syllable word (e.g., Jiga, Gapo, etc.). The labels were presented as count nouns (e.g., “look, this is a Jiga”). After each label was introduced, children were asked to repeat the label.

Procedure

The experiment was conducted in a single 10-15 minute session, during which participants were read four short stories, one story at a time. Each story constituted a trial that included three phases: stimuli presentation, comprehension/memory check, and inductive inference. Each participant was asked a total of 16 inductive inference questions with four questions for each of the four stories. Participants were tested individually in a quiet room by a female experimenter.

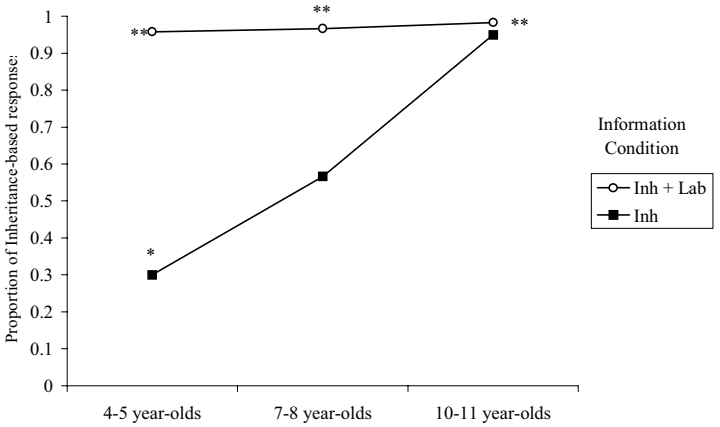
First, participants were read a cover story describing a baby animal who saw two adult animals playing in the forest. One of these animals was introduced as the one "who used to play with the baby," while the other was introduced as the one "who gave birth to the baby." The order of presentation of the Test stimuli was counterbalanced across the stories, and the order of introduction of attribute pairs was randomized across trials and across participants. Then participants were told that each of the Test stimuli (i.e., Mother vs. Friend) has a particular biological property (e.g., thick blood vs. thin blood) and asked which of these properties are likely to be shared by the Target (i.e., Baby).

Results and Discussion

Proportions of Inheritance-Based induction broken down by age group and information condition are presented in Figure 1. As shown in Figure 1, in the Inheritance only condition (Inh), the proportion of Inheritance-Based generalizations differed across the age groups. In the group of 4-5 year-olds this proportion was at 30% (below chance, Confidence Interval from 17.3% to 40%, $p < .01$) and in the group of 7-8 year-olds this proportion was at 57% (not statistically different from chance). At the same time, in the group of 10-11 year-olds the proportion of Inheritance-Based induction was at 95% (Confidence Interval from 86% to 99%, ps $< .001$). As opposed to Inheritance only condition, in the Inheritance + Label condition (Inh + Lab), the majority of participants of all age groups (over 95% in each group) responded in an Inheritance-Based manner.

Proportions of Inheritance-Based induction were subjected to a two-way (age group by information condition) repeated measures ANOVA. The analysis revealed significant main effects of age group, $F(2, 42) = 10.7$, $p < .0001$, and information conditions, $F(1, 42) = 42.3$, $p < .0001$, and a significant age group by information condition interaction, $F(2, 42) = 10.5$, $MSE = 4.5$, $p < .0001$. Post-hoc Bonferroni tests of the main effect of age indicated that children in the two youngest groups performed Inheritance-Based induction significantly less frequently than did children in the oldest group, all ps $< .05$. The second main effect (indicating that in the Inheritance + Label condition participants performed Inheritance-Based induction more frequently than in the Inheritance only condition) was largely driven by the interaction. To analyze the interaction, t-tests with Bonferroni adjustments for multiple comparisons were performed within each age group. The analysis pointed to significant differences between the Inheritance + Label and the Inheritance only conditions in the group of 4-5 year-olds and 7-8 year-olds, both ts > 5, ps $< .01$. At the same time, there were no such differences in the group of 10-11 year-olds, $t < 1$. Therefore, younger children were more likely to perform Inheritance-Based induction when both Inheritance and Label information supported such induction than when induction was supported by Inheritance information alone. At the same time, older children relied solely on inheritance information, while ignoring labeling information altogether.

Figure 1. Proportion of Inheritance-Based induction by age group and labeling condition



Note: ** Above chance, $p < .01$; * below chance, $p < .01$

However, Experiment 1, while presenting suggestive evidence, does not rule out an alternative explanation that 4-5 yea-olds perform induction across similarly labeled entities, while ignoring inheritance information altogether. To test this alternative, we conducted Experiment 2, where additional information cues were added to the design. If young children rely on multiple sources of information when performing induction, their induction should be a function of the number of information sources shared by compared entities. Another goal of Experiment 2 was to examine whether or not the relative importance of each source change in the course of development?

Experiment 2

Method

Participants Participants were 96 children recruited from two daycare centers, two elementary schools, and one middle school located in middle class suburbs of Columbus, Ohio. These participants represented three age groups each consisting of 32 children: (1) 4-5 year-olds (15 boys and 17 girls, $M = 4.8$ years; $SD = 0.63$ years); 7-8 year-olds (14 boys and 18 girls, $M = 7.6$ years; $SD = 0.74$ years); and 10-11 year-olds (15 boys and 17 girls, $M = 11.2$ years; $SD = 0.54$ years).

Design and Materials This experiment had a mixed design with age as a between-subject factor, perceptual similarity (i.e. Target perceptually similar to Test A vs. Target perceptually similar to Test B) as a between-subject variable, and information condition as a within-subject variable. The crossing of perceptual similarity and information conditions resulted in four cells. (1) Inheritance only (Inh) where the Target shared only inheritance information with the Mother. (2) Inheritance + Label (Inh + Lab) where the Target shared inheritance and the label with the Mother. (3) Inheritance + Perceptual Similarity (Inh + PS) where the Target shared inheritance and appearance with the Mother. And (4) Inheritance + Label + Perceptual Similarity (Inh + Lab + PS) where the Target shared inheritance, the label, and appearance with the Mother. All materials were identical to those used in Experiment 1, except that stimuli in the present experiment showed the Target, Test A, and Test B fully.

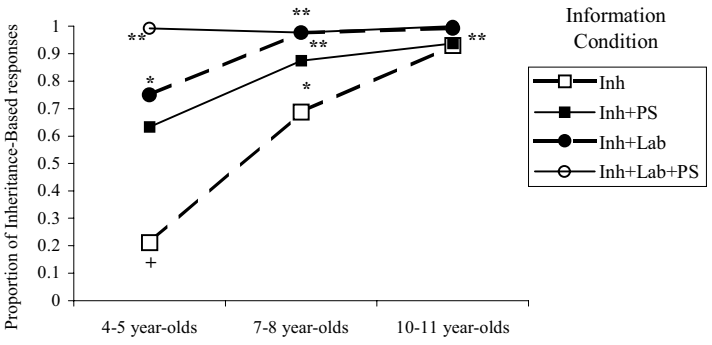
Similarities among stimuli were estimated in a calibrating experiment with 10 adult participants judging similarity between each pair of stimuli. Similarity scales ranged from 5 (very similar) to 0 (very dissimilar). The mean similarity rating for those pairs that we deemed dissimilar was .63 (*SD* = .43), while for those that we deemed similar it was 4.45 (*SD* = .23), $t(18) = 24.86$, $p < .0001$.

Procedure The procedure was identical to that in Experiment 1.

Results and Discussion

Proportions of Inheritance-Based responses, broken down by age group, similarity, and information conditions, are presented in Figure 2.

Figure 2. Proportion of Inheritance-Based induction by age group and information condition



Note: * Above chance $p < .05$; ** above chance $p < .005$; + below chance, $p < .005$.

As shown in Figure 2, participants of different age groups differed in their reliance on various information sources in the course of induction. In the group of 4-5 year-olds, the proportion of Inheritance-Based induction increased with the number of available information sources ranging from 20% in the Inh condition to 65-75% in the Inh + Lab and Inh + PS conditions, and to 99% in the Inh + Lab + PS condition. At the same time, in the group of 10-11 year-olds no such differences were observed: in this group proportions of Inheritance-Based induction were at ceiling across the information conditions. The group of 7-8 year-olds was between these extremes with differences among the conditions being larger than in the group of 10-11 year-olds, but smaller than in the group of 4-5 year-olds.

In short, data in Figure 2 suggest that preadolescents relied only on inheritance information, while ignoring other sources of information. At the same time, participants of the two younger groups relied on multiple sources of information. Another aspect of the findings, as indicated in Figure 2, is a sharp developmental increase in the importance of inheritance information.

Results presented in Figure 2 were subjected to a 3-way (age group * similarity condition * information condition) ANOVA with age group and similarity condition as between-subjects factors and labeling condition as a repeated measure. All main effects were significant. First, there was a significant main effect of age group, $F(2, 90) = 26.1$, $MSE = 4.3$, $p < .0001$, with 4-5 year-olds generalizing biological properties from the Mother significantly less frequently than children in the two older groups (63% vs. 88% vs. 96%), post-hoc Bonferroni tests, *p*s < .0001. Second, there was a significant effect of perceptual similarity condition, $F(1,90) = 15.1$, $MSE = 4.3$, $p < .0001$, with a tendency to perform an Inheritance-Based induction more frequently when the Mother looked similar to the Target (90% vs. 76%). Third, there was a main effect of Information condition, $F(1,90) = 57.4$, $MSE = 4.3$, $p < .0001$, with the overall tendency to perform Inheritance-Based induction more often in the Inheritance + Label than in the Inheritance only condition (95% vs. 71%).

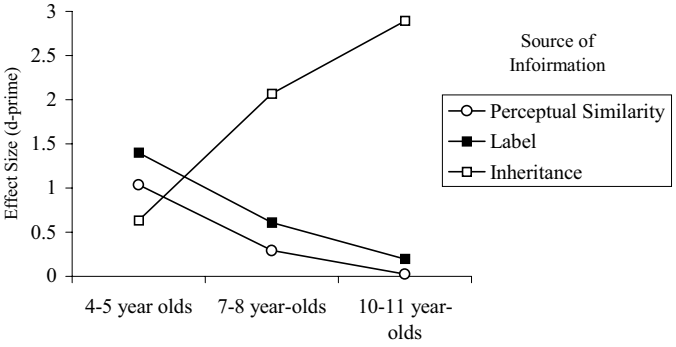
The two latter main effects, however, were largely driven by the two significant interactions. First, there was a significant age group by perceptual similarity interaction, $F(2, 90) = 6.8$, $MSE = 4.3$, $p < .003$, with significant effects of perceptual similarity on induction in the youngest group, both *t*s for both within-subject conditions > 3, *p*s < .01, but no such effects in the older groups (all ps > .27). Second, there was a significant age group by information condition interaction, $F(2, 90) = 3.3$, $MSE = 3.0$, $p < .0001$, with large (i.e., 54%) differences between the Inheritance + Label and the

Inheritance only conditions in the youngest group, t (31) = 6.8, $p < .0001$, and smaller (i.e., 29% and 6%, respectively) differences in the older groups, both ts > 2.3, ps < .05. No other interactions were significant.

To analyze interactions, t-tests, comparing means for each condition, were conducted within each age group. In the group of 4-5 year-olds, the proportion of Inheritance-Based generalizations exhibited the following differences (1) Inh (21%) < Inh + PS (64%) = Inh + Lab (75%) < Inh + PS + Lab (99%), all ts > 3, ps < .01, for differences. In the group of 7-8 year-olds, the proportion of Inheritance-Based generalizations exhibited the following differences: Inh (69%) < Inh + PS (88%) = Inh + Lab (98%) = Inh + PS + Lab (98%), all ts > 2.8, ps < .05, for differences. At the same time, in the group of 10-11 year-olds no significant differences among the conditions were found, all proportions ranging between 99% to 100%, all ps > .1.

Data presented in Figure 2 allowed us to estimate the relative contribution of inheritance information, shared label, and perceptual similarity to generalizing biological properties from the Mother. To do so, we calculated effect sizes for each of these sources of information, by dividing differences between marginal means for each of the sources (e.g., M perceptual similarity – M no perceptual similarity) by pooled standard deviations (Cohen, 1988). These estimated contributions of inheritance information, perceptual similarity and labeling broken down by age group are presented in Figure 3.

Figure 3. Relative contribution (effect sizes) of different sources of information to inductive inference by age group



Effect sizes exhibited the following patterns: while relative contributions of labels and perceptual similarity tend to decrease with age, the contribution of inheritance increased dramatically with age. In particular, effect sizes due to labels and perceptual similarity decreased from 1.4 and 1, respectively, in the youngest group to 0.2 and 0.02, respectively, in the oldest group. At the same time, effect sizes due to inheritance increased from 0.65 in the youngest group to 2.9 in the oldest group. In short, while for children of the youngest group all sources of information made sizable contributions to induction (all d-primes 0.65), participants of the oldest group (i.e., preadolescents) relied almost exclusively on inheritance information. At the same time, 7-8 year-olds were between these two extremes. In particular, for this group, inheritance information made a greater contribution than either perceptual similarity or labeling information, while the effect size due to labeling was still quite sizable (d-prime = 0.61).

In short, 4-5 year-olds exhibited maximal proportions of Inheritance-Based induction when all three sources of information supported this induction, 7-8 year-olds were at the maximum when at least two sources supported Inheritance-Based induction, and 10-11 year-olds were at the maximum even when only inheritance information was available.

General Discussion

The reported findings fit predictions well, supporting our contention that young children rely on multiple sources of information when performing induction. The larger the informational overlap between the Target and the Test stimuli, the more likely that a biological property would be generalized from the Test to the Target. For example, Inheritance alone contributed less than Inheritance + Perceptual Similarity or Inheritance + Label, which, in turn, contributed less than Inheritance + Label + Perceptual Similarity.

Findings of the reported experiments point to two important developmental changes: (1) increasing reliance on a single source of information and (2) increasing salience of inheritance information accompanied by decreasing salience of labeling and perceptual similarity.

The first change supports the developmental scenario in which processing develops from holistic to specific. As predicted by this scenario, young children tended to perform induction relying on multiple sources of information, whereas preadolescents, regardless of the number of sources of information, performed induction relying on a single source. Of course, it could be argued that the observed pattern of responses could stem solely from the second change – the increasing importance of inheritance information. However, previous research suggested that preadolescents do not focus on inheritance per se when performing induction, but they rather focus on a single attribute that they deem most predictive (Sloutsky & Lo, 2000; Sloutsky, Lo, & Fisher, in press), they consistently relied on the label information, considering it more reliable predictor than appearance information. Hence, it seems that the tendency to rely on a single source increases with age,

independently of the increasing salience of inheritance information.

The second change points to a decrease in the importance of less predictive sources of information (i.e., appearance and labels) and an increase in the importance of a more predictive source (i.e., inheritance). Both developmental changes suggest that between 8 and 10 years of age children undergo a developmental shift from a feature-integration induction to a single-feature, knowledge-based induction.

Current experiments also raise questions about the nature of young children's induction. If children's induction is driven by their intuitive theories, they should be able to attend separately to each predictor, and then to integrate information from different predictors. On the other hand, if the reliance on multiple features stem from their inability to selectively attend to each of the source and the inability to separate sources, this would be indicative that induction is not based on intuitive theories. This is because intuitive theories are beliefs about the world, and, therefore, they could not be products of low-level pre-attentive mechanisms. Current results cannot conclusively distinguish between these possibilities. This issue, however, could be addressed in future research directly examining separability of inheritance, labeling, and perceptual information in children and preadolescents.

In sum, this research suggests that when compared stimuli comprise multiple sources of information, 4-5 year-olds tended to rely on several sources when performing induction, 7-8 year olds relied mostly, but not exclusively on inheritance information, whereas 10-11 year-olds relied solely on inheritance information. Therefore, in the course of development, children undergo a transition from performing induction relying on multiple sources of information to performing induction relying on a single, most predictive source.

Abstract

Theoretical accounts of the processing of inflectional morphology make implicit, untested assumptions about the activation of verb semantics from inflected verbs. This research used semantic priming to investigate the extent to which regular and irregular past tense forms activate verb semantics, in comparison to the verb stem. The results show that past tense forms activate verb semantics to the same extent as verb stems and without differences due to verb regularity. These results provide constraining data for models of inflectional morphology.

Introduction

Research on the mental representation and processing of inflected words has focused on the type of underlying processing system required to account for our ability to produce and comprehend regularly and irregularly inflected words. The English past tense in particular has formed an important test case for such research. It provides a sharp contrast between the productive regular past tense and a limited set of irregular forms. Theoretical accounts divide into those suggesting that all inflected forms, both regular and irregular, are stored using associative memory (e.g. Rumelhart and McClelland, 1986) and those proposing that the predictability of the regular past tense allows us to compute the inflected forms from their verb stems using symbolically based rules (e.g. Pinker, 1991).

Such accounts focus primarily on the processing and representation of the regular and irregular past tense as phonological forms, tending to neglect the important issue of how these forms contact their underlying semantic and syntactic content. Nonetheless, they incorporate assumptions, explicit or implicit, about how these inflected forms map on to their semantics. Pinker has suggested that the regular past tense is not stored in its own right but computed using symbolic rules, whereas the irregular past tense is stored independently of its stem (Pinker, 1991). Comprehension of the regular past tense is assumed to require rule-based decomposition into stem and inflection. This process may delay semantic activation relative to the irregular past tense, which is not assumed to require rule-based processing.

The related account proposed by Marslen-Wilson and Tyler (1998) explicitly postulates that the regular and irregular past tense activate the semantic representations of their verb stems through different routes. The morphophonologically complex regular past tense is parsed into its stem and affix in order to access stem semantics, whereas the irregular past is recognised as a full form, which must subsequently be mapped onto verb semantics assumed to be stored at the level of the lexical entry.

Strict full-listing accounts (Butterworth, 1983) suggest that all past tense forms are stored in memory, with semantic representations presumably stored independently of their verb stems. Activating such representations would not be delayed by rule-based processing, and would not be expected to differ according to morphological complexity or verb regularity.

Parallel-distributed processing models (Joanisse and Seidenberg, 1999; Plunkett and Marchman, 1993; Rumelhart and McClelland, 1986) have assumed that both the regular and irregular past tense activate semantic units associated with their verb stems. In common with strict full-listing accounts, the fact that the regular and irregular past tense have differing degrees of phonological and orthographic similarity to their stems is not assumed to entail differential processing. However, if a mapping is less consistent (as in irregular forms) this may lead to slower or less efficient activation.

It can be seen that although these accounts focus on the consequences of the variable predictability of past tense form from its associated verb stem, they inevitably make theoretical assumptions about the activation of verb semantics from inflected forms as well. Typically one would use semantic priming to test assumptions relating to the organisation of semantic representations or the time course of its activation. However, research using semantic priming has tended to use concrete nouns and/or uninflected verbs. This is because morphologically simple words are assumed to

be the paradigmatic forms associated with semantic information, and semantic priming is thought to reflect either activation spreading between their semantic representations or a reactivation of shared properties of these representations. Morphological priming, on the other hand, uses complex words as primes, targets or both, and is a form of repetition priming. It is thought to reflect the reactivation either of an underlying morpheme (Marslen-Wilson, Tyler, Waksler and Older, 1994) or of shared semantic and form units (Plaut and Gonnerman, 2000), depending on the theoretical account. As such, the task is used to explore lexical representation and access.

What would be expected if verbs in the past tense were used as semantic primes? Ultimately they must contact verb semantics since the presence of verb inflection is a normal part of language comprehension. However, all accounts, except perhaps strict full-listing theories, assume that verbs in the past tense are processed as modified forms of their stems, as inflectional morphology does not change word meaning or form class. The stem is viewed as the most basic form of a verb and assumed to be associated with its semantic representations. Inflected verbs are assumed to be phonological modifications of the verb stem.

So how do these modified forms map on to the verb semantics associated with their stems? How long does this process of mapping take? If semantic priming is the facilitation of responses due to a semantic relationship between morphologically simple words will there be any semantic priming from the past tense at all? Alternatively there might be priming when the modified form maps onto verb semantics, but the delay due to this processing might reduce the degree of facilitation in comparison to that from the verb stem. Perhaps the greater similarity of form between the regular past tense and associated verb stems will speed up mapping onto verb semantics via the stem. This could lead to more semantic priming from the regular past than the irregular.

These questions were addressed by the following experiments using verb stems and their past tense forms as semantic, rather than morphological, primes. The motivation for this research was not to adjudicate between theories postulating one or more processing routes for inflectional morphology. Rather the aim was to provide evidence about the activation of verb semantics from inflected forms, in order to constrain currently untested assumptions implicit in these theories.

Experiment 1: Intramodal auditory semantic priming.

Morphological priming with auditory presentation of both past tense primes and verb stem targets has shown facilitation of lexical decision responses to targets following regular and irregular past tense primes (Marslen-Wilson and Tyler, 1997). It seemed prudent to begin our investigation of semantic priming from the past tense with auditory presentation of both primes and targets.

Rather than simply using regular and irregular past tense forms as semantic primes, a within-item design was selected so that each verb prime would be used in both its stem and past tense form (i.e. both "blame ACCUSE" and "blamed ACCUSE"). This allows us to establish that the uninflected forms are sufficiently semantically related to their targets to cause priming. Also, if the past tense items do prime, this can be measured against the amount of priming from the associated stem, to ascertain the effects of mapping onto verb semantics from an inflected form.

52 regular and 52 irregular verb primes were paired with semantically related verb targets. Semantic relatedness was established empirically by asking participants to rate this on a nine-point scale (1 = extremely unrelated, 9 = extremely related). Separate ratings were collected for stem and past tense forms of each prime. Groups of 15 participants (native speakers of UK English, aged between 18 and 40, with no language disorders) rated the semantic relatedness of either the stem or past tense form of each verb prime paired with its target. Past tense prime-target pairs were rated slightly less related than their associated stem prime-target pairs (mean rating for stems = 7.34, sd .63, mean rating for the past tense = 7.12 sd .73, $F(1,96) = 13.54$, $p < .001$) with no effect of verb regularity.

Unrelated primes (e.g. "laugh ACCUSE" and "laughed ACCUSE") were selected by rotating test primes about their targets whilst maintaining tense and verb regularity. This ensured that there could be no systematic differences between test and control primes in each condition, other than semantic relatedness to targets. The semantic relatedness of control primes and their targets was pretested in the same way as the test primes. Past tense prime-target pairs were again rated as slightly less related than their associated stem prime-target pairs (mean rating for stem controls = 2.39, sd .84, mean rating for past tense controls = 2.07 sd .65, $F(1,96) = 13.16$, $p < .001$) with no effect of verb regularity. Related test primes had a mean rating of 7.23 (sd = .69) and unrelated controls had a mean rating of 2.2 (sd = .75). As our aim was to examine semantic rather than associative priming, all primes were selected to have a low associative strength to their targets.

To ensure that any differences in semantic priming between regular and irregular past tense primes were due to verb regularity we matched primes across verb regularity for semantic relatedness and associative strength to targets, familiarity, imageability, and surface and cumulative frequencies from the Celex Lexical

Database (Baayen, Piepenbroek and Gulikers, 1995). Number of syllables could not be matched, as the regular past tense tends to be longer than the irregular form. Targets were matched across conditions for surface and cumulative frequencies, familiarity, imageability and number of syllables. Since many English verbs can also be used as nouns, we ensured that all primes had higher surface and cumulative frequencies as verbs.

The listener's task was to make a lexical decision to each target, with instructions to respond as quickly and accurately as possible. A range of fillers was selected to ensure that semantic relationships, verbal primes or inflected verb primes could not be used to predict word targets. To this end we used 208 unrelated noun/adjective prime-target pairs, with half the nouns in the plural form and nonwords used for half the targets. We also used 104 verb-nonword pairs with the same proportions of regular and irregular, stem and past tense primes as the test items.

The materials were divided into four versions of the experiment. These were balanced so that all targets appeared once in each version. Each version had the same target preceded by either a semantically related stem or past tense or a control stem or past tense. All versions had 460 trials: 24 practice trials, 20 "warm-up" trials, 52 test trials (13 of each condition), 52 control trials (13 in each condition) and 312 filler trials. Semantically related verb pairs made up 25% of the word targets heard. These were pseudo-randomly distributed throughout the list, with the same order of test and filler items in each of the four versions. There were an equal number of word and nonword targets in each version.

All items were recorded by a female native speaker of English onto DAT tape. They were digitized at a sampling rate of 22kHz, and were played binaurally to the listeners over headphones under the control of DMDX experimental software (Forster and Forster, 1990).

There was a 200 millisecond interval between primes and targets and participants had up to 3 seconds to respond. After responding the next trial followed in 1500 milliseconds. Reaction times were measured from target onset. The experiment lasted approximately 50 minutes in total.

60 participants (native speakers of UK English, aged between 18 and 40, with no language disorders) took part in the experiment. 15 participants were randomly assigned to each version of the experiment.

Results

The data from four participants were discarded because of relatively high error rates and unusual, or variable reaction times. Six items were also removed, four because of experimenter error and two because of high error rates. This left a total of 56 participants and 98 items.

For the analysis of reaction times, all errors (2.5%) and extreme values (0.1%, defined as $\leq 500 \geq 2000$ msec) were removed from the data. Mean reaction times were then calculated over participants and items. These were entered into two analyses of variance on participant (F_1) and item (F_2) means, with the factors of prime type (test or control), verb regularity (regular or irregular), tense (stem or past tense) and version (1-4). Item means are shown in Table 1.

There was a main effect of prime type (F_1 (1,52) = 166.53, $p < .001$; F_2 (1,90) = 91.31, $p < .001$) due to faster reaction times following semantically related (mean RT = 826 msec, sd = 82 msec) compared to unrelated (mean RT = 875 msec, sd = 89 msec) primes.

There was also a main effect of tense (F_1 (1,52) = 14.37, $p < .001$; F_2 (1,90) = 15.69, $p < .001$) with reaction times following past tense items (mean RT = 857 msec, sd = 87 msec) being slower than those following verb stems (mean RT = 843 msec, sd = 90 msec). There was no main effect of verb regularity. There were no interactions between priming, tense and regularity. Planned comparisons confirmed that there was significant priming for every condition.

Discussion

This first experiment found that past tense primes significantly facilitated lexical decision responses to semantically related targets. With auditory presentation these inflected words were able to map onto their verb semantics sufficiently strongly and quickly to prime responses to related words presented 200 milliseconds later. Not only did the related past tense items facilitate responses but the main effect of priming and the absence of any interaction between priming and tense shows that they primed as much as their associated stems. This is surprising as semantic priming is

Table 1 Mean item reaction times and standard deviations for intramodal semantic priming.

	STEM PRIMES			PAST TENSE PRIMES		
	Test	Control	Diff	Test	Control	Diff
REGULAR	818 (82)	872 (85)	54 ***	840 (74)	883 (82)	43 ***
IRREGULAR	815 (86)	868 (94)	53 ***	830 (85)	876 (95)	46 ***

*** $p < .001$

generally thought to reflect semantic relationships between basic lexical forms. As the past tense is an inflected, or modified, form of its verb stem one might not have expected both to prime equally, especially as past tense prime-target pairs had been rated as being less related than their associated stem prime-target pairs in pretests.

The phonological form of the regular past tense is nearly identical to that of its stem so perhaps it is more predictable that this could map onto verb semantics as quickly as its stem. However, the phonology of words in the irregular past tense is less similar to their verb stems than the regular past tense, so we might have expected these to prime less. The lack of a significant interaction between priming, tense and regularity shows that this was not the case. Both the regular and irregular past tense primed as much as their stems and as much as each other.

There are several possible interpretations of these findings. If inflected verbs need to map on to the stem to activate verb semantics this mapping may occur so quickly and effectively that it does not interfere with priming. The degree of phonological similarity to the stem does not seem to affect the efficiency of this mapping. The irregular past tense has less phonological similarity to associated stems than the regular past tense yet this does not delay access to verb semantics. If the regular and irregular past tense are processed differently this does not seem to have consequences for semantic activation as measured in this experiment.

Another alternative is that inflected verbs do not need to map on to the stem in order to activate verb semantics. All forms might be equally associated with verb semantics. However, if the stem is not the most basic form associated with verb semantics, why should past tense inflections have led to slower responses? It is not the case that there was no effect of words being inflected in this experiment, just that this did not interact with semantic priming.

To summarize, this experiment found that past tense inflection, whether regular or irregular, did not affect semantic priming, although it did increase response latencies to targets.

Experiment 2: Cross-modal semantic priming.

It is already established that intramodal presentation of the regular and irregular past tense facilitates responses to associated verb stems (Marslen-Wilson and Tyler, 1997) and Experiment 1 established that they also facilitate responses to semantically related verbs. However, when primes and targets are presented in different modalities the irregular past tense no longer facilitates responses to associated stems (Marslen-Wilson, Hare and Older, 1993). This contrasts with the regular past tense, which continues to show morphological priming. As modality seems to affect morphological priming from the irregular past tense the second experiment tested whether it also affects semantic priming.

Cross-modal presentation also allows us to probe semantic activation earlier in its time course. The first experiment might have failed to detect effects of tense or verb regularity on semantic activation if these had dissipated in the 200 millisecond inter-stimulus interval between the prime and target. In addition, reducing available processing time allows us to assess whether the tense effect found in the first experiment reflected the impact of inflected words on initial semantic activation or a possible post-lexical effect arising in the interval between hearing primes and responding to targets.

The second experiment used the design and materials from Experiment 1 but this time a visual target presented for 500 milliseconds followed the immediate offset of the auditory prime. Reaction times were recorded from target onset as before. 51 participants took part (native speakers of UK English, aged between 18 and 40, with no language disorders). 12 to 14 participants were randomly assigned to each version of the experiment.

Results

The data from four participants were discarded due to unusual and/or variable reaction times. The items involving 5 target words were also removed because of high error rates. This left a total of 47 participants and 99 test items.

For the analysis of reaction times, all errors (2%) and extreme values (0.1%, defined as ≥ 1350 msec) were removed from the data. Mean reaction times were then calculated over participants and items. These were

Table 2 Mean item reaction times and standard deviations for cross-modal semantic priming.

	STEM PRIMES			PAST TENSE PRIMES		
	Test	Control	Diff	Test	Control	Diff
REGULAR	516 (51)	525 (54)	9	511 (46)	538 (63)	27 ***
IRREGULAR	517 (50)	536 (60)	19 **	512 (44)	531 (59)	19 *

* p < .05, ** p < .01, *** p < .001

entered into two analyses of variance on participant (F_1) and item (F_2) means, with the same factors as experiment 1. Item means are shown in Table 2.

There was a main effect of prime type (F_1 (1,43) = 28.62, $p < .001$; F_2 (1,91) = 24.59, $p < .001$), due to faster reaction times following related (mean RT = 514 msec, sd = 48 msec) compared to unrelated (mean RT = 532 msec, sd = 59 msec) primes. There were no main effects of verb tense or regularity and no interactions between priming, tense and regularity.

Planned comparisons on item means in individual conditions indicated that regular stems did not prime significantly (t (48) = -1.23, p = .225) due to an unexplained interaction between priming and version (F_2 (3,45) = 6.49, $p <.001$). One version showed reduced latencies following semantically unrelated regular stems. The remaining three versions showed a significant effect of priming (F_2 (1,33) = 9.62, p = .004) and no interaction with version (F_2 (2,33) = 2.39, p = .107) with semantically related regular stems (RT = 510 msec) facilitating responses by 21 msec relative to unrelated regular stems (RT = 531 msec). All other conditions produced significant priming across all four versions.

Discussion

This experiment confirmed the main effect of priming, with semantically related primes facilitating responses to targets as before. Priming did not interact with tense or verb regularity. The amount of priming shown by regular stems is smaller than the other conditions when all four versions are analyzed. The main effect of priming, however, indicates that regular stem priming is not significantly different to other conditions when version-related variance is partialled out.

Past tense primes facilitated semantically related targets despite cross-modal presentation and reduced processing time. As the irregular past tense fails to act as a morphological prime under these conditions, one might have expected to see an interaction between prime, tense and verb regularity, such that the irregular past tense failed to prime despite priming in all other conditions. This was not found. Again there seem to be no consequences for semantic activation, as indexed by semantic priming, of words being inflected or having different degrees of phonological similarity to their stems.

In addition, the lack of a tense effect, when processing time is reduced, suggests that the effect found in the earlier experiment did not reflect the impact of inflected words on initial semantic activation but a post-lexical effect arising in the interval between hearing primes and responding to targets. This might be a consequence of the irrelevance of the past tense inflection to the subsequent stem target.

Thus in this second experiment, once processing time was reduced, there was no effect of words having past tense inflections on semantic activation. This suggests that all forms of a verb access its semantic representations equally rapidly.

General discussion.

Research on the English past tense has concentrated on issues relating to phonological or orthographic form. A central question has been whether the predictable similarity in form between verb stems and the regular past tense engages specialized rule-based processes to compute the past tense rather than storing it in full. However, theoretical models answering this question have made implicit, largely untested assumptions about the activation of verb semantics from verbs in the past tense.

Most models assume that verbs in the past tense access the same semantic representations as their verb stems and are processed as modified forms of their verb stems. We assume that the form, not the semantics, of the verb is modified as a result of syntactic constraints. These assumptions lead us to expect some effect of this modification of form on the activation of verb semantics. Single route accounts suggest that inflected words will have patterns of phonological activation that are highly similar, but not identical, to those of their stems. Dual route accounts suggest that inflected words must map onto underlying morphemic representations, accessed via the verb stem. Therefore, we might expect not to see semantic priming from inflected forms, or to see reduced priming reflecting the time taken to map onto semantics via the verb stem. However, both the experiments reported here show that this is not the case. Activation of verb semantics did not show any effects of verb inflection. The only consequence of verbs being inflected, i.e. the increase in response latencies to auditory targets following past tense primes, did not interact with semantic priming and appeared to be a post-lexical integration effect, as it was not present when processing time was reduced in the second experiment.

It is also commonly assumed that the amount and predictability of phonological similarity between stems and past tense, which is greater in the regular past tense, will have processing consequences, and might even engage different types of processing. The results reported here, however, suggest that these factors have no effect on the activation of verb semantics in comprehension.

Thus both stem and past tense, regular and irregular verb primes all accessed verb semantics equally in the same time frame. Activation of verb semantics seems insensitive to morphological complexity and inflectional regularity. The surprising aspect of this is

that verb stems are assumed to be the most basic form of verbs and processing of the regular and irregular past tense has been found to dissociate in development (Berko, 1958) and to doubly dissociate following neurological damage (Marslen-Wilson and Tyler, 1997; Tyler, deMornay-Davis, Anokinah, Longworth, Randall, & Marslen-Wilson, in press; Ullman, Corkin, Coppola, Hicock, Growdon, Koroshetz, and Pinker, 1997).

In particular these results might seem surprising given the dissociations between processing the regular and irregular past tense even in the normal adult. Both the regular and irregular past tense act as morphological primes when presented intramodally but with cross-modal presentation the irregular past tense no longer primes stem targets (Marslen-Wilson, Hare and Older, 1993). However, the current results show that the irregular past tense does facilitate responses to semantically related verbs, both cross-modally and intra-modally. This is consistent with the complete equivalence of regular and irregular forms in terms of their linguistic and communicative function.

In summary, these experiments suggest that past tense forms activate the same semantic representations as their stems, priming related words to the same extent. There is no evidence that morphophonological processing delays semantic activation. There was no reduction in semantic priming to suggest a processing cost for inflected verbs and no regularity differences to suggest that degree of phonological modification affects the time course of access to semantics. This suggests a lexical architecture permitting either direct mapping of all verb forms onto semantics, or the mapping of all verb forms, regular and irregular, stem and past tense, onto an abstract root morpheme providing access to semantics. If, on either view, separate processing routes are indeed involved in the perceptual analysis of regular and irregular forms, then they deliver their output to higher-order interpretive systems with essentially the same time-course. Theoretical models explaining the processing of the regular and irregular past tense therefore need to bear in mind that access to verb semantics seems to be insensitive to both morphological complexity and inflectional regularity.

Towards a Theory of Semantic Space

Will Lowe (wlowe02@tufts.edu)
Center for Cognitive Studies
Tufts University; MA 21015 USA

Abstract

This paper adds some theory to the growing literature of semantic space models. We motivate semantic space models from the perspective of distributional linguistics and show how an explicit mathematical formulation can provide a better understanding of existing models and suggest changes and improvements. In addition to providing a theoretical framework for current models, we consider the implications of statistical aspects of language data that have not been addressed in the psychological modeling literature. Statistical approaches to language must deal principally with count data, and this data will typically have a highly skewed frequency distribution due to Zipf's law. We consider the consequences of these facts for the construction of semantic space models, and present methods for removing frequency biases from semantic space models.

Introduction

There is a growing literature on the empirical adequacy of semantic space models across a wide range of subject domains (Burgess et al., 1998; Landauer et al., 1998; Foltz et al., 1998; McDonald and Lowe, 1998; Lowe and McDonald, 2000). However, semantic space models are typically structured and parameterized differently by each researcher. Levy and Bullinaria (2000) have explored the implications of parameter changes empirically by running multiple simulations, but there has up until now been no work that places semantic space models in an overarching theoretical framework; consequently there there are few statements of how semantic spaces *ought* to be structured in the light of their intended purpose.

In this paper we attempt to develop a theoretical framework for semantic space models by synthesizing theoretical analyses from vector space information retrieval and categorical data analysis with new basic research.

The structure of the paper is as follows. The next section brie¤y motivates semantic space models using ideas from distributional linguistics. We then review Zipf's law and its consequences the distributional character of linguistic data. The £nal section presents a formal de£nition of semantic space models and considers what effects different choices of component have on the resulting models.

Motivating Semantic Space

Firth (1968) observed that "you shall know a word by the company it keeps". If we interpret company as *lexical* company, the words that occur near to it in text or speech, then two related claims are possible. The £rst is unexceptional: we come to know about the syntactic character of a word by examining the other words that may and may not occur around it in text. Syntactic theory then postulates latent variables e.g. parts of speech and branching structure, that control the distributional properties of words and restrictions on their contexts of occurrence. The second claim is that we come to know about the *semantic* character of a word by examining the other words that may and may not occur around it in text.

The intuition for this distributional characterization of semantics is that *whatever* makes words similar or dissimilar in meaning, it must show up distributionally, in the lexical company of the word. Otherwise the supposedly semantic difference is not available to hearers and it is not easy to see how it may be learned.

If words are similar to the extent that they occur in the similar contexts then we may de£ne a statistical replacement test (Finch, 1993) which tests the meaningfulness of the result of switching one word for another in a sentence. When a corpus of meaningful sentences is available the test may be reversed (Lowe, 2000a), and under a suitable representation of lexical context, we may hold each word constant and estimate its typical surrounding context. A semantic space model is a way of representing similarity of typical context in a Euclidean space with axes determined by local word co-occurrence counts. Counting the co-occurrence of a target word with a £xed set of D other words makes it possible to position the target in a space of dimension D. A target's position with respect to other words then expresses similarity of lexical context. Since the basic notion from distributional linguistics is 'intersubstitutability in context', a semantic space model is effective to the extent it realizes this idea accurately.

Zipf's Law

The frequency of a word is (approximately) proportional to the reciprocal of its rank in a frequency list (Zipf, 1949; Mandelbrot, 1954). This is Zipf's Law. Zipf's law ensures dramatically skewed distributions for almost

all statistics applied to language; the power scaling ensures that the majority of words occur very infrequently, creating a severe sparse data problem, and that the top few most frequent words constitute the majority of all tokens. For example, the 10 most frequent word stems, or lemmas, in the 100M word British National Corpus are 'the', 'be', 'of', 'and', 'to', 'a', 'in', 'have', 'that' and 'it', constituting slightly over one quarter of all tokens in the corpus (25974687 / 99985962 0.26). Also the most frequent words of English are grammatical functors or closed class words (Cann, 1996), which although vital to syntax, are typically uninformative with respect to word meaning. Much of the next sections will be devoted to dealing with the distributional effects of Zipf's law.

To introduce some notation, semantic space models typically represent the distributional context of each word t in terms of a set of representative 'context' words $b_1 \ldots b_D$. t's distributional pro£le is then represented by a vector of co-occurrences $\mathbf{v}$ where $\mathbf{v}_i$ is a function of $f^W(b_i,t)$, the number of times b_i occurs in a window W words either side of t in a corpus of N words. For future reference $f(t)$ is the occurrence frequency of t in the corpus, $p(t)$ is the probability of t, often estimated by t N, and $p^W(b_i,t)$ is the probability of seeing b_i and t together in a window of size W.

Semantic Space

A semantic space model is method of assigning each word in a language to a point in a real £nite dimensional vector space. Formally it is a quadruple $\mathtt{A},\mathtt{B},\mathtt{S},\mathtt{M}$:

$\mathtt{B}$ is a set $b_{1\ldots D}$ of basis elements that determine the dimensionality D of the space and the interpretation of each dimension. $\mathtt{B}$ is often a set of words (Lund et al., 1995, e.g.) although lemmas (Lowe and McDonald, 2000), encyclopedia articles (Landauer and Dumais, 1997) and whole documents have been used.

$\mathtt{A}$ speci£es the functional form of the mapping from co-occurrence frequencies between particular basis elements and each word in the language so that each word is represented by a vector $\mathbf{v} = \mathtt{A}(b_1,t), \mathtt{A}(b_2,t), \ldots, \mathtt{A}(b_D,t)$. $\mathtt{A}$ may be the identity function.

$\mathtt{S}$ is a similarity measure that maps pairs of vectors onto a continuous valued quantity that represents contextual similarity.

$\mathtt{M}$, is a transformation that takes one semantic space and maps it onto another, for example by reducing its dimensionality. Various choices for these elements are possible, and lead to rather different spaces. $\mathtt{M}$ may also be an 'identity' mapping that does not change the space. In the following sections we consider the implications of different choices of $\mathtt{A},\mathtt{B},\mathtt{S}$ and $\mathtt{M}$.

$\mathtt{A}$: Lexical Association Function

Zipf's law suggest that using vectors of co-occurrence counts directly may not be a good choice when constructing a semantic space. To see why, consider two words t_1 and b with probabilities $p(t_1)$ and $p(b)$. If t_1 and b have *no* semantic relation to each other, then they will be distributionally related to one another only through their syntactic properties e.g. by the fact that they are both nouns. For simplicity we ignore any residual syntactic dependence and model their empirical frequencies $f(t_1)$ and $f(b)$ as independent binomially distributed random variables

$$\begin{array}{ll} f(t_1) & B(p(t_1),N) \\ f(b) & B(p(b),N). \end{array}$$

In this idealization t_1 and b are perfectly distributionally independent so $f^W(b,t_i) = WN\,p(b,t_1) = WN\,p(t_1)p(b)$ (this is just the expected co-occurrence frequency summed over each possible position in the window).

The fact that the expected co-occurrence count under independence is linear in the probability of t_1 leads to a problem in any model that sets $\mathtt{A}((b,t_i) = f^W(b,t_i)$, e.g. the Hyperspace Analogue to Language (HAL; Lund et al., 1995). Even if t_1 and t_2 are unrelated, if $p(t_1)$ $p(t_2)$ then their vectors will contain elements with similar magnitudes. This implies that any similarity measure applied to the vectors will judge them to be similar. Conversely if they are related but $p(t_1)$ $p(t_2)$ then their vectors will contain elements with widely differing magnitudes, simply due to their differing occurrence probability. Zipf's Law threatens that any difference in distributional pro£le available in $f^W(b,t_i)$ may be swamped by the effect of a difference in occurrence probability.

The upshot for models such as the HAL that use vectors of counts that are not corrected for chance is that distances will have a frequency bias. That is, proximity on semantic space will be partly due to distributional similarity, and partly due to relative frequency; the larger the difference in occurrence probability, the larger association a context element must have to affect the similarity function.

Since it is unlikely that semantic similarity depends on relative frequency, we have a theoretical reason not to use raw co-occurrence counts as a lexical association function.

Researchers in information retrieval have also noted problems with raw co-occurrence counts and use various weighting schemes to counteract them. Latent Semantic Analysis (LSA; Landauer and Dumais, 1997; Rehder et al., 1997), a semantic space model derived from information retrieval research uses an entropy-weighted function: $\mathtt{A}(b,t) \propto \log(f^W(b,t)$ 1). The logged co-occurrence count is then divided by the entropy of the distribution of b over each documents. If b is evenly distributed across documents then it is probably not informative about any particular document. In contrast if it occurs in some but not others it may be more informative about their content.

LSA's lexical association function is designed to allow arbitrarily many basis elements into the similarity calculation by weighting them appropriately. However neither logging nor dividing by entropy is guaranteed to reverse the effects of chance co-occurrence since this is never explicitly estimated.

	Target	Non-target
Context	$f^W(b,t)$	$f^W(b,\ t)$
Non-context	$f^W(\ b,t)$	$f^W(\ b,\ t)$

Table 1: Co-occurrence frequency within a window of target, context and all other words. t represents a word that is not t.

Lowe and McDonald (2000) used a log-odds-ratio measure to explicitly factor out chance co-occurrences. The empirical counts necessary for computing the log-odds-ratio are shown in Table 1. t represents any word that is not t, b represents a word that is not the context word b and $f^W(\ b,t)$ is the number of times a word that is not the context word occurs among the W words surrounding t.

Computing the cell counts is straightforward because there exists a very close approximation that is a function only of $f^W(b,t)$ itself, $f(t)$, $f(b)$, W, and N:

$$\begin{aligned} f^W(b,\ t) &= Wf(b) \quad f^W(b,t) \\ f^W(\ b,t) &= Wf(t) \quad f^W(b,t) \\ f^W(\ b,\ t) &= WN \quad (f^W(b,\ t) \quad f^W(\ b,t) \\ &\qquad f^W(b,t)). \end{aligned}$$

To derive these expressions consider the limiting situation where $W = 1$ and $f(b,t)$ is the number of times the bigram b,t occurs. Since by de£nition $f(b) = f(b,t) \quad f(b,\ t)$, then $f(b,\ t) = f(b) \quad f(b,t)$, and the same reasoning applies to $f(\ b,t)$. Similarly the number of elements in the table, $f(b) \quad f(\ b)$, must be the number of bigrams in the corpus. For a large corpus this is essentially N, the number of words in the corpus. Therefore since $f(\ b,\ t)$ is the only cell undetermined it is obtained by subtracting the sum of the other cells from N. The W factors appear on quantities other than the co-occurrence count when the window size is more than one because only $f^W(\ b,\ t)$ already takes the window size into account[1].

We obtain probabilities from Table 1 by dividing each cell count by WN. Then the *odds* of seeing t rather than some other word when b is present are $p^W(b,t)\ \ p^W(b,\ t)$, and the odds of seeing t in the absence of b is $p^W(\ b,t)\ \ p^W(\ b,\ t)$. Therefore if the presence of b *increases* the probability of seeing t then the odds ratio (Agresti, 1990)

$$\begin{aligned} \theta(b,t) &= \frac{p^W(b,t)\ \ p^W(b,\ t)}{p^W(\ b,t)\ \ p^W(\ b,\ t)} \\ &= \frac{p^W(b,t)\,p^W(\ b,\ t)}{p^W(b,\ t)\,p^W(\ b,t)} \end{aligned}$$

[1]The derivation is reported elsewhere (Lowe, 2000a).

is greater than 1. When the presence of b makes no difference to the probability of seeing t then $\theta = 1$ and we can conclude that b and t are distributionally independent. Finally, if $\theta < 1$ the presence of t makes seeing b less probable.

We can estimate the odds ratio from Table 1:

$$\hat{\theta}(b,t) = \frac{f^W(b,t)\,f^W(\ b,\ t)}{f^W(b,\ t)\,f^W(\ b,t)}.$$

Where the WN factors have canceled. This measure is often logged so that then the magnitude of $\log\hat{\theta}(b,t)$ can be interpreted as a direct measure of the level of associative strength between t and b, with the effects of chance co-occurrence factored out. Positive values indicate greater than chance positive association.

Lexical Association in Lexicography

The *most* informative words for t are those that occur only in its context, e.g. t='sealed' and b='hermetically'. Instances of word pairs like this are concordances, or collocations, and are of interest to lexicographers. Consequently, the log-odds-ratio also provides a method of £nding collocations between words. Previous work in lexicography has used pointwise mutual information, log-likelihood ratios, and T-tests. Since by symmetry these alternative measures can also be lexical association functions, we review them brie¤y below.

Mutual Information The pointwise mutual information $I(b,t)$ between t and b Church and Hanks (1990) is

$$I(b,t) = \log\frac{p^W(b,t)}{Wp(b)p(t)}$$

and can be also be estimated using the frequencies in Table 1. $I(b,t)$ measures how much information an occurrence of b contains about t. If b occurs with t no more often than would be expected by chance then $p^W(b,t) = Wp(b)p(t)$ and $I(b,t) = 0$, so the mutual information measure effectively factors out random co-occurrences. However, if t and b always occur together then $p^W(b,t) = p(b)$ and $I(b,t) = \log 1 \ \ p(t)$, so the less frequent b and t are the larger their association is. In contrast, changing the marginal probabilities of t or b is equivalent to adding a constant value to rows or columns of the contingency tables above (Bishop et al., 1975). It is easy to con£rm that this change makes no difference to θ.

The G-score Dunning (1993) uses a log-likelihood ratio statistic (Agresti, 1990), which he calls the G-score, to discover collocations in text. This method compares two models of the relationship between t and b. In the £rst model (association) assumes that $p(b \quad t) = p(b \quad t)$, whereas the second model (no association) assumes that $p(b \quad t) = p(b \quad\ \ t)$. The statistic is the ratio of the maximized log-likelihoods for each model's parameters. This measure takes chance co-occurrence into account because it implicitly compares the observed co-

occurrence frequencies with the co-occurrence frequencies that would be expected by chance. For example, the expected value of the top left cell in Table 1 is $Wf(t)f(b)\ N$ under (no association) but $f^W(b,t)$ under (association). Empirically using log-likelihood ratios as vector elements in a semantic space generates similar results to using log-odds-ratios. This is to be expected since both measures take chance co-occurrences into account. Alternative measures include the χ^2 statistic and Fisher's exact test. However, Dunning shows that the distributional properties of the G-score are superior under normal lexicographic conditions, and the hypergeometric probabilities required in Fisher's test are intractable to compute for contingency tables containing very large counts (Agresti, 1990). For example, $f^W(\ b\ \ t)$ will typically exceed the number of words in the corpus.

Considering the lexicographic task emphasizes the 'second order' nature of semantic space measures of similarity: they re¤ect regularities across multiple '£rst order' association measures, one for each vector element. This interpretation is taken up again in discussing appropriate similarity functions below.

B : Choosing a Basis

When choosing basis elements for a semantic space there is a trade-off between choosing words that are representative of sentence content, but may not give reliable count statistics due to their low frequency, and choosing high frequency words that provide reliable statistics but appear in almost every sentence of the language. The trade-off is an instance of the bias-variance dilemma in statistical learning theory (Geman et al., 1992).

The Bias-Variance Dilemma Every statistical model is able to represent a subset of the class of possible hypotheses about data. The range of hypotheses is typically controlled by the model's structure and by a set of adjustable parameters. More ¤exible models can represent more hypotheses and are said to have less *bias*. In contrast, a very ¤exible model will require a large amount of data to determine accurate values for its parameters. When there is not enough data compared to the number of parameters, parameter estimates may be optimal for the particular data set the model was trained on, but will fail to generalize to new data. A model that 'over£ts' in this way is said to have high *variance*. Model variance can be decreased at the cost of adding bias e.g. by constraining or removing parameters. Bias can be decreased by making the model more ¤exible, at the cost of needing more data to cope with increased variance.

In a semantic space the vector elements, $\mathtt{A}(b,t)$ are parameters that estimate the amount of association between b and t on the basis of observed data $f^W(b,t)$. When choosing the basis elements $b_1 \ldots b_D$, we can de£ne a highly biased model by choosing only very high frequency words. Co-occurrence counts for high frequency words are very reliable because high frequency words appear in nearly all sentences. This biased model will have very low variance; each $\mathtt{A}(b,t)$ is a well-determined parameter because $f^W(b,t)$ is large enough to provide a reliable estimate of $p^W(b,t)$. However, every vector will be similar because all words in the language tend to occur with the high frequency words in the basis, irrespective of their distributional pro£le. Consequently, distances between words will be extremely similar and vectors in the biased model will fail to re¤ect important distributional differences.

Alternatively, if only low frequency content words are chosen as basis elements then vectors will be more highly informative and distances in the space will be able to re¤ect subtle distributional similarities. This model will have high variance because the co-occurrence counts needed to determine $\mathtt{A}(b,t)$ are unreliable. Variance can always be decreased by providing more data, but Zipf's law suggests a power relation between the amount of new text that would need to be found and the reduction in co-occurrence count variability.

In theory the fullest possible distributional pro£le for a word would include all words in the language, generating an infeasibly large vector. In practice this is not possible and some subset of words must be chosen.

The solution for LSA is to use as many words as possible with appropriate weighting for each vector element, and then use **M** to compress the original vectors into a smaller space with dimensions that are linear combinations of the original ones.

The Column Variance Method For HAL, elements of B are chosen by compiling a 70,000 70,000 matrix of word co-occurrences and discarding the columns of lowest variance[2]. Consistent with Zipf's law, column variance decreases sharply with the frequency of the word corresponding to the column (Lund et al., 1995). Then for each set of experimental stimuli, Burgess *et al.* compute variances over each vector element and retain only the most variant. We can refer to this as the column variance method of basis element choice.

The method is dif£cult to analyze because the basis is recomputed for each experiment, but we can show that it has a frequency bias. If b and t are unrelated then we can, again, model them as Binomially distributed. In the simple case where $W = 1$, the variance of the frequency count under independence is

$$\begin{aligned} \mathrm{Var}\, f^W(b,t) &= Np(t)p(b)(1 \quad p(t)p(b)) \\ &= Np(t)p(b) \quad Np(t)^2p(b)^2. \end{aligned}$$

so the expected variance of $f^W(b,t)$ is quadratic in $p(b)$. The expected variance of the elements of a *column* of such counts is the same as the variance of the column sum i.e. the sum of the individual variances. Figure 1 shows the expected variances for a 14 14 table of co-occurrence counts for perfectly unrelated words with occurrence probabilities ranging from 0.5 to 0.0667. Even completely unrelated words will show distinct structure

[2]Co-occurrences are also weighted by distance, but this does not affect the following argument.

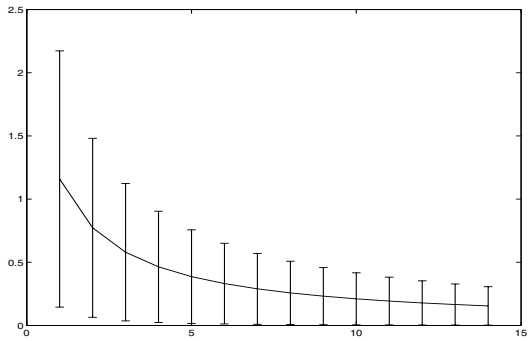

Figure 1: An example of column variance method. Expected column means based on expected co-occurrence counts between each of 14 hypothetical unrelated words. To estimate means and variances for a corpus of N words, multiply all quantities by N. Error bars represent expected column variances.

in their column variances, but this is entirely due to their baseline frequencies.

There are two possible causes for a high column variance. The £rst cause is simple frequency as shown in Figure 1. The second reason is that the words are in fact distributionally related. Then unexpectedly large variance can be a sign that the Binomial assumption has failed, and that two words are in fact related. However the size of the variance increase necessary is variable. In the column variance method, for a word that is distributionally related to some of the experimental materials to make it into the £nal basis set it must be strongly associated enough that its observed column variance moves it into the window of very high variance words at the upper end of the frequency table. In other words, it is not enough to be twice as variant as would be expected by chance, a word must be as many times more variant as it takes to have a variance that is absolutely high; lower frequency words have to work harder and unrelated but high frequency words will get chosen anyway.

This analysis of the column variance method predicts that, in the absence of strong association, the variance of a column corresponding to some candidate element will correlate strongly with that element's frequency.

This was tested by taking candidate lemmas of frequency rank 100 to 600 in the BNC, and experimental stimuli from McKoon and Ratcliff's graded priming study (see Lowe and McDonald, 2000). The analysis predicts that the levels of genuine association (corrected for frequency) between these candidates and the experimental stimuli will be be low because the words are so frequent that they provide little information about context. In fact for this data log-odds-ratios are mildly *negatively* correlated with column variance r=-.317 p<.001. In contrast candidate frequencies strongly positively correlated with column variance for co-occurrence counts, r=.8553 p<.001.

S : Similarity Measure

Two popular similarity measures are Euclidean distance and the cosine. For two vectors $\mathbf{v}$ and $\mathbf{w}$ in a D-dimensional basis, the squared Euclidean distance $\|\mathbf{v} - \mathbf{w}\|^2$ is simply related to the cosine $\rho_{\mathbf{vw}}$ of the angle between them:

$$\begin{aligned} \|\mathbf{v} - \mathbf{w}\|^2 &= \sum_{i=1}^{D} (v_i - w_i)^2 \\ &= \|\mathbf{v}\|^2 \; \|\mathbf{w}\|^2 \; 2\frac{\mathbf{vw}}{\|\mathbf{v}\| \; \|\mathbf{w}\|} \\ &= \|\mathbf{v}\|^2 \; \|\mathbf{w}\|^2 \; 2\rho_{\mathbf{vw}} \end{aligned}$$

where $\|\mathbf{w}\|^2 = \sum_i^D w_i^2$ is a squared vector length. From this equation it can be seen that $\|\mathbf{v} - \mathbf{w}\|^2 \propto \rho_{\mathbf{vw}}$ only when $\mathbf{v}$ and $\mathbf{w}$ are standardized in length. When $\mathbf{A}(b,t) = f^W(b,t)$ then vector element may have widely differing lengths depending on $p(b)$ and $p(t)$.

One advantage of the cosine is that it ranges between -1 and 1, and so removes any arbitrary scaling induced by the range of A and the number of elements in B. When A is simple co-occurrence the cosine is also less sensitive than Euclidean distance to extreme values induced by widely differing basis element frequencies, although a good choice of A should avoid this problem.

The interpretation of similarity as a 'second order' regularity can motivate yet another plausible similarity measure. We may take the correlation coef£cient (Pearson's r) as a measure of how well the elements of each word's vector match. The only difference between this and the cosine measure is that the mean of each vector is included in the similarity measure. This will not only offset the effect of different vector element magnitudes, but also place all calculations in a regular statistical framework. The statistical implications of taking correlation coef£cients over log-odds-ratios remain to be worked out. In addition, all the measures described here will bene£t from a characterization of their properties in small samples. This is future work.

M : Model

A semantic space is fully functional when a B, A and S have been speci£ed. However, it is possible to build a more structured mathematical or statistical model. In LSA the model consists of a projecting vectors into a linear subspace of B using singular value decomposition. This is equivalent to selecting the k orthogonal axes that account for most variance of words in semantic space. Each word is then projected into the the subspace, and point is then 're-in¤ated' back into the full dimensionality and cosine measures applied. Cosines can be taken in the linear subspace without subsequent re-in¤ation as suggested by Berry et al. (1995).

The theoretically important point about LSA's dimensionality reduction is that it is a simple instance of inferring latent structure in distributional data. Parts of speech, and grammatical structures are also examples of

latent structure in the sense that they are in-principle unobservable aspects of words that re¤ect their distributional properties. One important direction for semantic space research is to £nd an appropriate type of latent structure to explain the distributional regularities that are assumed to underly semantic similarity. Biologically motivated models using topographic mapping, and strictly random mappings have also been investigated (Lowe, 2000a,b).

Conclusion

In this paper we have put forward some theory for semantic space models. In addition to presenting a framework for thinking about current semantic space models we have examined the implications of various design choices, emphasized the importance of avoiding frequency biases, and presented methods for doing so. We have also connected semantic space theory to lexicographic methods and to standard problems of bias and variance discussed in the statistical literature.

Abstract

We examined the questions college students ask when everyday devices malfunction. Our investigation of the explanatory reasoning processes is organized around the central theme of question asking. PREG, a model of human question asking, predicts when and what types of questions are asked by humans while comprehending expository texts. PREG has two salient predictions. First, deep comprehenders should ask questions that converge on plausible faults. Second, eye movements should converge on those likely faults. An eye tracking study supported these predictions. The present research supports the claim that question asking and eye tracking are two excellent indicators of device comprehension in the context of breakdown scenarios.

Introduction

Deep comprehension of everyday devices can be manifested in a number of tasks and measures. For example, most colleagues would agree that the deep comprehenders construct coherent representations of functioning devices, draw appropriate inferences, answers explanation-based questions correctly (e.g., why, how, what-if, what-if-not), and solve transfer problems that apply their understanding (Gentner & Stevens, 1983; Graesser, Singer, & Trabasso, 1994). This study investigates the manifestations of deep comprehension of devices that are not as widely recognized. We believe that deep comprehension is required when devices breakdown, when eyes fixate on likely faults, and when questions are asked about likely faults. (Graesser, Olde, & Lu, in press; Graesser, Olde, Pomeroy, Whitten, Lu, & Craig, in press).

Question asking and its role in understanding texts and stories is well-documented (Graesser & McMahen, 1993; Kass, 1992; Schank, 1986, 1999; Ram, 1994). The literature has consistently suggested that the understanding of a story is achieved by identifying the questions raised by the story and then searching for the answers in the story. Question asking has many potential functions in reasoning and problem solving. For instance, question asking is often affiliated with searches, comparisons, explanations, predictions and several other cognitive processes. It is reasonable to say that comprehenders would have more questions as they reason through an expository text and that their questions would manifest comprehension depth. For example, it is very hard to imagine that a shallow comprehender could ask questions addressing the critical causal components of an event. In this article, we examine a model of question asking in the context of understanding technical texts. More specifically, we are interested in the model's predictions about deep versus shallow comprehension of everyday devices as revealed by question asking. It is suggested that question asking opens a window for viewing the sub-processes involved in understanding (Ram, 1994), such as the retrieval of explanations in long term memory and the search of information from a display. However, there has been very little empirical research that documents the relationships among comprehension, question asking, and information search (as reflected in eye tracking). Therefore, we conducted a study in which eye tracking was measured while college students generated questions when confronted with a breakdown scenario.

PREG: A Model of Question Asking

Several computational models of question asking have been constructed in the context of story understanding. These models were capable of generating questions with respect to the goals and sub-goals of a story. However, an adequate model of question asking should be capable of predicting when and what types of questions humans ask as they comprehend expository texts as well as other types of learning material. Otero and Graesser (in press) developed a PREG model of question asking that attempts to capture these question asking mechanisms in detail. The general assumption of the model is that clashes between text input and a reader's existing world knowledge trigger question generation (Graesser, Olde, Pomeroy, et al., in press; Otero et al., in press). Questions are constructed when readers come across information in a text that presents contradictions, anomalies, obstacles to goals, discrepancies, constrasts and other triggers of potential cognitive disequilibrium (Graesser et al., 1993; Graesser & Person, 1994).

The discrepancies between input and world knowledge can be associated with the different levels of representations, ranging from shallow to deep (Britton & Graesser, 1996; Gentner et al., 1983; Graesser, Millis, & Zwaan, 1997; Kieras & Bovair, 1984; Kintsch, 1998). The surface code, which is at the shallowest level, keeps the wording and syntax of a text in a verbatim form. As for the visual modality, it preserves the low-level lines, angles, sizes, shapes, and textures of the picture. The textbase, which is at the intermediate level, in essence is a propositional representation that maintains the meaning of the explicit text and the pictures. The mental model, which is at the deepest level, captures the referential content of the text. When applied to everyday devices, this would include:

1. the components of the electronic or mechanical system;
2. the spatial arrangement of components;
3. the causal chain of events when the system successfully unfolds;
4. the mechanisms that explain each causal step;
5. the functions of the device and device components;
6. the plans of agents who manipulate the system for various purposes.

Quite clearly, a rich set of knowledge structures needs to be constructed when an adult comprehends a device at a deep level.

According to the PREG model, conceptual graph structures are adopted to encode a chronology of events and states that happen during the course of device motion. The conceptual graph structure is not built arbitrarily, but is comprised of a set of categorized nodes which denote concepts and proposition-like descriptions in the text and corresponding visual-spatial information. These nodes are connected by arc categories such as ENABLE, CAUSE, PROPERTY, REASON and OUTCOME. In addition, most arcs are directed with a source node and an end node.

It is assumed that pictorial and textual information is incorporated in a single underlying representation. Empirical studies show that most readers are capable of alternating between picture and text and that the text dominates the reading process when illustrated texts are comprehended (Bagget & Graesser, 1995; Hegarty & Just 1993).

Individual Differences in Question Asking

The current study examines the questions that college students ask when an everyday device malfunctions. For example, consider a cylinder lock and the following breakdown scenario: the key turns, but the bolt does not move. According to PREG, understanding is manifested when a device breaks, not when it is running smoothly. Thus PREG predicts that deep comprehenders should ask good questions that converge on likely faults. More specifically, these questions should tap the nodes in the conceptual graph structure that are the plausible causes of the malfunction. To test this hypothesis, Graesser, Olde, Pomeroy et al. (in press) conducted a study in which 108 participants first read an illustrated text, then were provided a breakdown scenario, and then generated questions. After completing the question asking task, an objective comprehension test on the devices were administered. A battery of tests that measure cognitive abilities and personality were administered in the end.

The results confirmed the hypothesis: Good comprehenders generate high quality questions that focus on plausible faults of the breakdown. Follow-up multiple regression analysis further suggested that ASVAB (the Armed Services Vocational Aptitude Battery, Department of Defense, 1983) technical score was the primary predictor of both deep comprehension and question quality.

Given that technical scientific knowledge turned out to be a robust predictor of device comprehension, we conducted a qualitative analysis of the questions asked by participants with high (upper 33% of distribution) versus low technical knowledge (lower 33% of the distribution). The questions generated by participants with high technical scores tend to converge on the fault components and address the causal connections between parts, processes, and relations that are in the chain of breakdown. The questions asked by low technical participants tend to be diffuse. That is, most of the components in a system were addressed in the hope that it might turn out to be pertinent instead of converging on 1 or 2 parts. Their questions rarely were

elaborations on the causal links addressing the malfunction.

Since the above patterns emerged, we were curious to know whether there were systematic differences in the eye movement patterns between individuals with different levels of cognitive abilities. That is the focus of the present study.

Question Asking and Control of the Eye

Eye movements provide an important window for understanding the cognitive processes and representations that play a role in a particular cognitive task. However, no one has investigated the relationship between eye movements and the cognitive components in question asking. PREG predicts that eye movements should converge on the likely faults. As far as individual differences in the eye movement are concerned, the following hypotheses could be directly generated from the PREG model. First, deep comprehenders are expected to have a high density of eye fixations occur at words, objects, parts, and processes that are at the source of cognitive disequilibrium (e.g., anomalies, contradictions, broken parts, contrasts, missing components, and so on), while shallow comprehenders should indiscriminately scan the regions of the illustrated text. A sufficient amount of technical knowledge is necessary for identifying anomalies in a system. Thus, technical knowledge and other indices of deep comprehension should be positively correlated with measures of the fixations that assess the extent to which a comprehender focuses on fault areas.

Method

Participants

The participants were forty college students at the University of Memphis. The students participated for course credit in an introductory psychology class.

Illustrated Texts and Question Asking Tasks

The participants read 5 illustrated texts on everyday devices: a cylinder lock, an electronic bell, a car temperature gauge, a toaster, and a dishwasher. The illustrated texts were extracted from Macaulay's (1988) book, *The Way Things Work.* These were the same devices that were used in the Graesser, Olde, Pomeroy et al., (in press) study, except that the clutch was dropped from the current study; it was extremely difficult for participants to differentiate and label the individual teeth in the wheels of the clutch mechanism.

As in the Graesser, Olde, Pomeroy et al., (in press) study, there were five trials, each of which consisted of two phases. The participant first read an illustrated text for 3 minutes, which was displayed on a computer monitor. After the reading phase, the breakdown description was presented either above or to the left of the illustrated text and the participants began the question asking phase (while the illustrated text remained on the screen). The participants asked questions aloud for 90 seconds during this phase and the protocol was recorded. The previous study had participants generate questions in writing whereas the present study collected spoken questions. Each participant furnished question asking protocols for all 5 devices. The assignment of devices to test order was counterbalanced across the 40 participants with a Latin square.

Device Comprehension Test

The participants subsequently completed a 30-question test of device comprehension (5 devices x 6 three-alternative, forced-choice question per device). All 30 questions were generated from a theoretical framework in qualitative physics (Forbus, 1984). Suppose there are N components in a system and their states are delineated as either inhibitory, excitatory, or neutral as affected by other components in the causal network. The test questions are concerned with how tweaking one component A has an impact on another component B. An example question constructed according to the three possible states is as follows:

What happens to the pins when the key is turned to unlock the door?

(a) they rise
(b) they drop
(c) they remain stationary (correct answer)

It is not likely that participants will be able to answer such questions correctly without deep comprehension of the devices. It is reasonable to predict that deep comprehenders will be able to trace the causal antecedents and causal consequences of the events (Graesser & Bertus, 1998) and shallow comprehenders will lose track of causal connections. The device comprehension test was thus designated as the gold standard for deep comprehension. It is predicted that performance on the device comprehension test should positively correlate with the quality of the questions that get asked and also with fixations on the faults of a breakdown scenario. The device comprehension score could vary from 0 to 30. A score of 10 would be chance performance if there were no sophisticated guessing or background knowledge.

Battery of tests of individual differences

The participants completed assessments of the following measures of individual differences: four scales of technical knowledge (mechanical comprehension, electronics, general science, auto & shop) extracted from ASVAB (Department of Defense, 1983), and additional tests of spatial reasoning (Bennet,

Seashore, & Wesman, 1972) and openness (Costa & McCrae, 1991). These were included, as they were the statistically significant predictors of deep comprehension and question asking in the Graesser, Olde, and Pomeroy et al. (in press) study.

Recording of eye tracking and question asking

Eye movements were recorded by a Model 501 Applied Science Laboratory eye tracker. There was a magnetic head tracker so the participants could move the head during data collection. The participants were calibrated before they started the experimental session of reading the illustrated texts and asking questions. During calibration, the participants viewed 9 points on the computer display and a computer recorded the x-y coordinates. The calibration process took 10-15 minutes. Participants were dismissed if they wore glasses, but the equipment could accommodate contact lenses.

The experimental session was videotaped and audio recorded. The VCR camera focused on a scene monitor screen, on which the illustrated text being viewed by the participant and the trace of the participant's eye movements were mirrored. The VCR recorded both the illustrated text and a superimposed image of what the left eye was focusing on. The superimposed image showed the locus of (a) the focus of the eye and (b) an X-Y axis with the 0-0 point at the center of the focus. The voice of the participant was recorded on the VCR so that the spoken questions could be transcribed. This set-up allowed us to record and review (a) the contents of the computer display, (b) the focus of the left eye, and (c) the voice of the student asking questions.

Computer software was available to record eye movements at a fine-grained level. The software produces area plots for specific areas of interest. In particular, we were interested in the portions of eye fixations focusing on the areas of interest associated with faults. These faults were sometimes in the text and sometimes in the picture.

The following measures were scored on the think aloud protocols collected in the question asking task.

Volume of questions: The number of questions that were asked in the question asking task.
Question Quality: The number or proportion of questions that referred to a plausible explanation of the breakdown.

Trained judges coded the verbal protocols with an acceptable level of reliability.

Results and Discussion

Descriptive Statistics

Table 1 presents means and standard deviations for the measures collected in this study. The ASVAB measures were comparable to normal college student populations. Scores of spatial reasoning were not significantly different from the scores for college students reported in Bennet et al. study (1972).

Table 1: Descriptive Statistics on Measures of Individual Differences

Measures	Mean	SD
Mechanical	13.9	6.0
Electronics	9.3	4.3
Auto & Shop	10.0	5.3
General Science	16.9	4.7
Spatial	23.8	15.2
Openness	52.1	9.2
Gender	1.25	.44

The Coordination between Question Asking and Eye Movements

It is important to examine the device comprehension scores first. The mean device comprehension score was 18.6 (SD = 4.6), which is 62% of the questions being answered correctly. As would be expected, device comprehension was significantly correlated with the number of fault questions asked ($r = .45$, $p < .01$). In addition, device comprehension showed a high positive correlation with all the ASVAB measures, in particular, ASVAB technical knowledge ($r = .54$) and general science ($r = .60$).

The data supported PREG's predictions. There were 29.5 fixations (SD = 11.1) on plausible faults per device, or 9.3 seconds (SD = 3.9) out of 90 seconds. 11.5% of the eye fixations and 10.4% of the time focused on the fault areas. The index of deep comprehension, i.e., device comprehension score, was significantly correlated with the eye tracking measure of number of fixations on faults ($r = .43$).

We examined the role of question asking in eye tracking at this point. The data showed strong evidence that there was consistent coordination between question asking and eye movements. Furthermore, there were significant differences in the measures of eye tracking between participants who had a relatively high number of fault questions and those who had a low number of questions, e.g., number of fixations on faults (167.6 with SD = 42.2 versus 127.5 with SD = 61.0, for high versus low).

Given the importance of cognitive abilities during device comprehension, we explored which measures of cognitive ability are more capable of discriminating deep comprehension versus shallow comprehension as measured by question asking and eye movements. General science turned out to be a significant predictor of the eye tracking measure and the number of fault questions asked. The participants who scored higher on general science had more questions on faults (7.7 with

SD = 2.7 versus 6.0 with SD = 3.0, for high versus low), and had bigger number of fault fixations (173.1 with SD = 48.7 versus 122.0 with SD = 50.9).

Openness is one of the "big five" personality factors: neuroticism, extroversion, openness, agreeableness, and conscientiousness (Costa et al., 1991). The subscale of openness attempts to capture creativity. A t-test on the eye tracking measure and question asking measure showed that there were significant differences between participants with high openness scores versus those with low openness scores: number of fixations on faults (167.8 with SD = 49.6 versus 127.3 with SD = 55.0, for high versus low), and number of fault questions (8.2 with SD = 2.9 versus 5.5 with SD = 2.4). The data suggested that openness was a robust predictor of question asking and subsequently affected the patterns of eye movements.

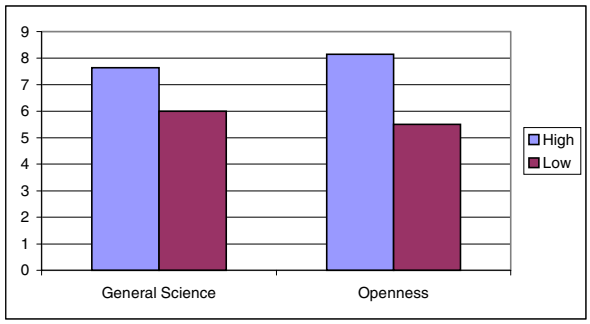

Figure 1: The number of questions on faults by high versus low on general science and openness scales.

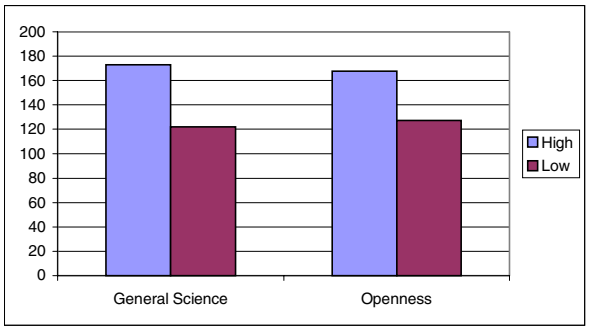

Figure 2: The number of fixations addressing faults by high versus low on general science and openness scales.

There have been two different views concerning the relationships between eye movements and ongoing cognitive processes (Rayner, Reichle, & Pollatsek, 1998). One is that eye movements are mainly driven by oculomotor processes; the other is that there is a correspondence between eye movements and cognitive processes. The data quite clearly suggested the coordination between question asking and eye movements. The question at this point was to what extent question asking was in control of eye movements. The ideal method of addressing this question would be structural equation modeling. However, given the number of participants in the present study, we could only conduct a partial correlation analysis.

If our PREG model is correct, there should not be a significant correlation between the number of questions addressing faults and readers' technical knowledge after partitioning out the variance of question asking. Subsequent data analysis supported the hypothesis that question asking is in control of eye movements rather than eye tracking guiding question asking. When the variable (number of fault questions) was controlled, the correlation between technical knowledge and the number of fixations on faults approached 0 ($r = .14$, $p < .05$). However, controlling the variance of eye movements did not affect the correlation between technical knowledge and the number of fault questions. They remained significantly correlated ($r = .39$, $p < .05$). The results are consistent with some recent findings which suggest that some cognitive processes are fast enough to affect eye movements (Rayner et al., 1998).

In short, it appears that individuals with high scores on general science and openness are most capable of asking questions about the anomalous information in a system. Subsequently these individuals move their eyes to the plausible fault areas and verify their reasoning about the breakdown scenario. On the other hand, individuals, who are low on the general science and openness scales, tend to be less sensitive to the contradictions when they arise. Thus they resort to the strategy of scanning all the regions of a text in the hope of hitting the target.

Conclusion

The current research has demonstrated the usefulness of the eye tracking data for studying the cognitive components in question asking. The analysis of eye fixations provides an account of how people with different levels of cognitive ability and different types of personality reason through the device malfunction and how their explanatory reasoning processes center around anomaly detection and question asking.

Modeling Forms of Surprise in an Artificial Agent

Abstract

Mainly rooted in the cognitive-psychoevolutionary model of surprise proposed by the research group of the University of Bielefeld (Meyer, Reisenzein, Schützwohl, etc.), the computational model of surprise described in this paper relies on the assumption that surprise-eliciting events initiate a series of mental processes that begin with the appraisal of unexpectedness, continue with the interruption of ongoing activity and the focusing of attention on the unexpected event, and end with the analysis and evaluation of that event plus revision of beliefs. With respect to the computation of unexpectedness, the model also incorporates suggestions by Ortony and Partridge. This model of surprise is implemented in an artificial agent called S-EUNE, whose task is to explore uncertain and unknown environments. The accuracy of our surprise model was evaluated in a series of experimental tests that focused on the comparison of surprise intensity values generated by the artificial agent with ratings by humans under similar circumstances.

Introduction

Roughly speaking, artificial and biological agents accept percepts from the environment and generate actions. Since different actions may lead to different states of the world, in order to perform well (to execute the "right" action), some kinds of artificial agents make use of a mathematical function that maps a state of the world onto a real number - the utility value. Thus, in those agents, decision-making is performed by selecting the action that leads to the state of the world with the highest utility (Russell & Norvig, 1995; Shafer & Pearl, 1990).

Although research in Artificial Intelligence has all but ignored the significant role of emotions in reasoning/decision-making (e.g., Damásio, 1994), several computational models for emotions have been proposed in the past years, based in part on research in psychology and neuroscience (for a detailed review of those models see e.g., Pfeifer, 1988; Picard, 1997).

Considered by many authors as a biologically fundamental emotion (e.g., Ekman, 1992; Izard, 1977), *surprise* may play an important role in cognitive activities, especially in attention focusing and learning (e.g., Izard, 1977; Meyer, Reisenzein, & Schützwohl, 1997; Ortony & Partridge, 1987; Reisenzein, 2000b) (note however, that some authors, like Ortony, Clore, and Collins, 1988, do not consider surprise an emotion). According to the research group of the University of Bielefeld, Germany (e.g., Meyer et al., 1997), surprise has two main functions, informational and motivational, that together promote both immediate adaptive actions to the surprising event and the prediction, control and effective dealings with future occurrences of the event. Ortony and Partridge's view of surprise shares aspects with this model, especially in that both assume that surprise is elicited by unexpected events. The same is also true for Peters' (1998) computational model of surprise, implemented in a computer vision system, that focuses on the detection of unexpected movements.

In this paper, we propose a computational model for surprise that is an adaptation (although with several simplifications) of the models proposed by the German research group of the University of Bielefeld and by Ortony and Partridge.

The following section presents an overview of the overall agent's architecture into which the surprise model is integrated. Subsequently, we explain this model in detail. Finally, we describe experimental tests carried out to evaluate the accuracy of the surprise model.

Overview of the Agent's Architecture

EUNE (Emotional-based Exploration of UNcertain and UNknown Environments) is an artificial agent whose goal is the exploration of uncertain and unknown environments comprising a variety of objects, and whose behavior is controlled by emotions, drives and other motivations. Besides desiring to know or be aware of the objects belonging to the environment, EUNE is also able to "feel" the emotions (including surprise)

those objects cause. In fact, these "felt emotions" guide the exploratory behavior of EUNE: roughly speaking, at any given time, among several objects available in the environment, EUNE selects that object for study and analysis that causes more positive emotion and less negative emotion (Izard, 1977) (see Reisenzein, 1996, for related theories of emotional action generation, and Barnes & Thagard, 1996, for an alternative approach to emotional decision-making). This process is repeated until all objects in the environment have become known.

In this article, we describe S-EUNE, a simplified version of EUNE whose emotional makeup is confined to the emotion of surprise. As many other agents, S-EUNE has percepts, actions, goals, memory, emotions/drives, and deliberative reasoning/decision-making (Figure 1) (for more details on this architecture see Macedo & Cardoso, 2001).

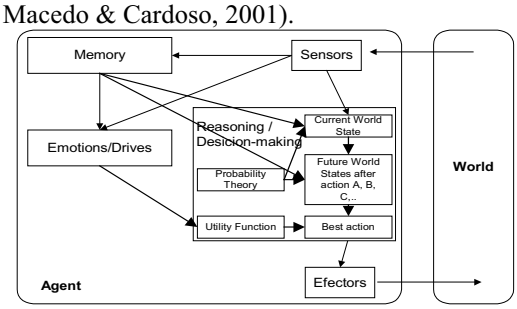

Figure 1: S-EUNE's architecture.

Previously defined by the user, the environment comprises a variety of objects located at specific positions. In the present article, these objects are confined to buildings. Each object comprises three distinct, fundamental components: *structure*, *function* and *behavior* (Goel, 1992). For the sake of simplicity, the *structure* (the visible part of the object), is restricted to the shape of the object (e.g., triangular, rectangular, etc.); however, any object may comprise several sub-objects. The *function* of the object concerns its role in the environment (e.g., house, church, hotel, etc.). The *behavior* of the object concerns its activity (actions and reactions) in response to particular features of external or internal stimuli (e.g., static, mobile).

The perceptual system of the agent (two simulated sensors) provides information related to the *structure*, the *function*, and the *behavior* of the objects, as well as the distance of the objects. Note that the *function* of the objects is not accessible (i.e., cannot be inferred from visual information) unless the agent is at the same place as the object.

As a knowledge-based agent, S-EUNE stores all the information acquired through the sensors in its memory unit. The agent's knowledge base is of an episodic kind: each object is stored, in the form of a graph, as a separate case in episodic memory. In addition, each object representation is associated with a number that expresses its absolute frequency (Figure 2).

Field \ Case	C_1	C_2	C_3	C_4
Structure				
Function	House	House	Church	Hotel
Behavior	Static	Static	Static	Static
Abs. Freq.	50	40	5	5

Figure 2: Example of the episodic memory of S-EUNE after exploring an environment.

When information from the environment is sampled, the *surprise generation module* compares that information to the information stored in memory and outputs the intensity of the elicited surprise. A corresponding facial expression is also produced. The model of surprise is described in more detail in a later section. Note that, in the more general EUNE agent, this component - in this case called the *emotion, drives and other motivations module* - may also comprise other emotions apart from surprise, such as anger, sadness, etc., as well as drives and other motivations.

The *reasoning/decision-making module* of S-EUNE receives the information from the simulated external world and outputs the action that has been selected for execution. This module comprises several subprocesses: (i) taking the information of the world provided by the sensors (which may be incomplete) as input, the current state of the world (the agent's current position, the position of the objects, etc.) is computed; (ii) taking the current state of the world, probability theory and memory-stored information as input, possible future world states and respective probabilities are computed for the actions that the agent can perform; (iii) from these actions, a single one (presumably the best one) is selected. This is the action that maximizes the Utility Function (Russell & Norvig, 1995; Shafer & Pearl, 1990), which in the case of S-EUNE relies heavily on the anticipated intensity of surprise elicited by the future state of the world. Thus, the preferences of S-EUNE are reflections of its anticipated surprise. In order to achieve this goal of maximizing anticipated surprise, the *reasoning/decision-making module* makes use of an Utility Function, abbreviated *U(W)*, which is based on the surprise function (defined in the next section) as follows:

$$U(W) = f(U_{surprise}(W)) = f(SURPRISE(Agt, Obj(W)))$$

This Utility Function means that the utility of a world state W is given by the surprise that the state W causes the agent to "feel". In this article, a world state is defined as "being close to or seeing an object" (the object that is currently the focus of attention of the agent's sensors), and f is taken to be the identity function, implying that *U(W)* increases monotonically

with the intensity of surprise. As a consequence of this, the agent always selects for approach the object that actually elicits and/or promises to elicit maximum surprise.

Surprise Model

As mentioned before, our model of surprise is mainly based on Ortony and Partridge's proposals and on the University of Bielefeld model. We will now give an overview of these models and then explain our computational model by comparing it with these two models.

Background Models

Ortony and Partridge (1987) proposed that there is a difference between surprisingness and expectation failure. They suggest that, although surprise sometimes results from expectation failure, it is frequently also caused by events for which expectations were never computed. In other words, one can be surprised by something one didn't expect without having to expect something else. Ortony and Partridge also proposed that surprisingness is an important variable in artificial intelligence systems, particularly for attention and learning.

The following assumptions were made in their model: the system (or agent) receives an input proposition; the system has an episodic and semantic memory; elements of the memory may be immutable (propositions that are believed to be always true) or typical (those that are believed to be sometimes true); and, some elements of the memory are activated when an input proposition is received.

Ortony and Partridge further distinguish between *practically deducible propositions* and *practically non-deducible propositions*. *Practically deducible propositions* comprises the propositions that are explicitly represented in memory, as well as those that can be inferred from them by few and simple deductions. Hence, *practically deducible propositions* are that subset of formally deducible propositions that don't require many and complex inferences. Furthermore, *practically deducible propositions* may be actively or passively deduced in a particular context. In the former case, their content corresponds to *actively expected* or *predicted* events; in the latter case, to *passively expected* (*assumed*) events.

Based on these assumptions, Ortony and Partridge proposed that surprise may result from three situations (Table 1 presents the correspondent range of values): (i) *active expectation failure*: here, surprise results from a conflict or inconsistency between the input proposition and an *active prediction* or *expectation*; (ii) *passive expectation failure* (or *assumption failure*): here, surprise results from a conflict or inconsistency between the input proposition and what the agent implicitly knows or believes (*passive expectations* or *assumptions*); and (iii) *unanticipated incongruities* or deviations from norms: here, surprise results from a conflict or inconsistency between the input proposition (which in this case is a *practically non-deducible proposition*) and what, after the fact, may be judged to be normal or usual (cf. Kahneman & Miller, 1986), that is, *practically deducible propositions* (immutable or typical) that are suggested by the unexpected fact. Note that, in this case, at least prior to the unexpected event, there are no expectations (passive or active) with which the input proposition could conflict.

Table 1: Three different sources of surprise and correspondent range of values (adapted from Ortony & Partridge, 1987).

Confronted proposition	Related Cognition	
	Active	Passive
Immutable	[1]; $S_A=1$; *Prediction*	[2]; $S_P=1$; *Assumption*
Typical	[3]; $0< S_A<1$; *Prediction*	[4]; $S_P<S_A$; *Assumption*
Immutable	[5]; ∅	[6]; $S_P=1$; *none*
Typical	[7]; ∅	[8]; $0< S_P<1$; *none*

In their cognitive-psychoevolutionary model, the research group of the University of Bielefeld has made similar assumptions as Ortony and Partridge, namely that surprise (considered by them as an emotion) is elicited by the appraisal of unexpectedness. More precisely, it is proposed that surprise-eliciting events give rise to the following series of mental processes: (i) the appraisal of a cognized event as exceeding some threshold value of unexpectedness (schema-discrepancy) - according to Reisenzein (1999), this is achieved by a specialized comparator mechanism, the unexpectedness function, that computes the degree of discrepancy between "new" and "old" beliefs or schemas; (ii) interruption of ongoing information processing and reallocation of processing resources to the investigation of the unexpected event; (iii) analysis/evaluation of that event; (iv) possibly, immediate reactions to that event and/or updating or revision of the "old" schemas or beliefs.

Our Computational Model of Surprise

We have implemented a computational model of surprise, in the context of S-EUNE, that is an adaptation (although with some simplifications) of the University of Bielefeld's model and in which the above-mentioned four mental processes elicited by surprising events are present. The suggestions by Ortony and Partridge are mainly concerned with the first of these steps, and are compatible with the Bielefeld model (see Reisenzein, 1999). Accordingly, we drew on these assumptions for the implementation of the appraisal of unexpectedness and the computation of the intensity of surprise, as well as the selection of knowledge structures in our model.

Within our model, knowledge is of an episodic kind, rather than being both semantic and episodic (although this will be part of our future work) as in Ortony and Partridge's model. Therefore, the knowledge structure of our model differs also from the schema-theoretic framework of the University of Bielefeld's model, that also assumes both episodic and semantic knowledge. In our model an input proposition (or new belief) is related to a visual object or parts of an object (for instance the visual effect of an object with squared windows, rectangular door, etc.). Besides, the agent has in its episodic memory explicit representations of similar propositions. Following Ortony and Partridge, we also distinguish between *deducible* and *non-deducible*, *active* and *passive*, *immutable* and *typical* propositions as well as between different possible sources of surprise (see Table 1). The immutability of a proposition can be extracted from the absolute frequency values associated with the cases (see Figure 2 above). For instance, the proposition "houses have squared facades" is immutable (since all the houses in memory have squared facades), whereas "houses have squared windows" is a typical proposition with a probability (immutability) value of .55 (as implied by Ortony and Partridge's model, in our model immutability is a continuous variable).

The usual activity of the agent is moving through the environment hoping to find buildings that deserve to be investigated. When one or more buildings are perceived, the agent computes expectations for their *functions* (for instance, "it is a house with 67% of probability", "it is a hotel with 45% of probability", etc.). Note that the *function* of a building is available to the agent only when its position and that of the building are the same. On the basis of this information (the *structure* of the object and predictions for its *function*), the agent then computes the surprise intensity that the building causes through the computation of its degree of unexpectedness (described below). Then, the building with the maximum estimated surprise is selected to be visited and investigated. This corresponds to the "interruption of ongoing activity" assumed in the Bielefeld model of surprise. The previously estimated value of surprise may now be updated with the additional information concerning the *function* of the building. The object is then stored in memory and the absolute frequencies of the affected episodes in memory are updated. This is a simplification of the fourth step of the University of Bielefeld's model (for alternative approaches to belief revision, see, for instance, Gärdenfors, 1988). Note that the experience of surprise is also accompanied by a correspondent facial expression (raised eyebrows, widened eyes, open mouth) (Ekman, 1992).

To see how the first step, the appraisal of unexpectedness, is performed, we now describe how the degree of unexpectedness is computed in the three surprise-eliciting situations distinguished by Ortony and Partridge.

As said above, when the agent sees the structure of a building it computes expectations (*deducible*, *active expectations*) for its *function* (e.g., "it is a hotel with 45% of probability", etc.). If, after visiting that building, the agent finds out that it is a post office, it would be surprised, because its *active expectations* conflict with the input proposition (note that, in our model, belief conflicts may be partial rather as well as total). This is thus an example of the first source of surprise distinguished by Ortony and Partridge. In contrast, when the agent sees a building with a window (or roof, etc.) of a particular shape (for instance, circular), although it may not have made an *active prediction* for its shape, it is able to infer that it expected a rectangular shape with, for instance, 45% probability, a squared shape with 67%, etc. This is an example of a *deducible*, *passive expectation*: although not made before the agent perceived the building, it could easily infer an expectation for the shape of the window after it was perceived. This case is therefore an example of the second source of surprise because the input proposition "has a circular window" conflicts with the agent's *passive expectations*. Finally, when the agent sees a building with no facade, it has neither an *active* nor a *passive expectation* available, because there are no buildings with no facade in its memory and therefore the agent could not predict that. Thus, "the house has no facade" is an example of a *non-deducible proposition*. This is an example of the third source of surprise: there is a conflict between the input proposition "the house has no facade" and what after the fact is judged to be normal or usual ("buildings have a facade").

Let us now describe how the intensity of surprise is computed. There is experimental evidence supporting that the intensity of felt surprise increases monotonically, and is closely correlated with the degree of unexpectedness (see Reisenzein, 2000b, for a review of these experiments). This suggests that unexpectedness is the proximate cognitive cause of the surprise experience. On the basis of this evidence, we propose that the surprise felt by an agent *Agt* elicited by an object Obj_k is proportional to the degree of unexpectedness of Obj_k, considering the set of objects present in the memory of the agent. According to probability theory (e.g., Shafer & Pearl, 1990), the degree of expecting that an event X occurs is given by its probability P(X). Accordingly, the improbability of X, denoted by 1-P(X), defines the degree of not expecting X, and the intensity of surprise can, for simplicity, be equated with unexpectedness:

$$SURPRISE(Agt, Obj_k) =$$
$$= DegreeOfUnexpectedness(Obj_k, Agt(Memory)) = 1 - P(Obj_k)$$

Although other probabilistic methods might be used to compute P(X), in the case of objects comprising several components we propose to compute the probability of the whole object Obj_k as the mean of the conditional probabilities of their n constituent parts, which are individually computed using Bayes's formula (Shafer & Pearl, 1990) (note that each one of those conditional probabilities individually gives the degree of unexpectedness of a specific piece of the object, given as evidence the rest of the object):

$$P(Obj_k) = \frac{\sum_{l=1}^{n} P(Obj_k^l \mid Obj_k^1, Obj_k^2, ..., Obj_k^{l-1}, Obj_k^{l+1}, ..., Obj_k^n)}{n}$$

Experimental Tests

Although our model is consistent with the experimental evidence reported, we performed two new experiments to test the following issues: (i) whether the intensity values generated by the artificial agent match those of humans under similar circumstances; (ii) the role of the amount of previous knowledge on the surprise intensity; (iii) whether the surprise intensity values generated by the artificial agent fall within the range of the surprise intensity values proposed in Ortony and Partridge's model. In both experiments, the participants (S-EUNE and 60 humans with mean age of 20.5 years) were presented with 40 quiz-like items. Experiment 1 was performed in an abstract domain with hedonically neutral events (see Stiensmeier-Pelster, Martini, & Reisenzein, 1995, for a similar experiment with humans). Each "quiz item" consisted of several sequences of symbols. Some of the "quiz items" contained a single sequence in which one symbol was missing. Experiment 2 was performed in the domain of buildings. In this case, each "quiz item" consisted of the presentation of a building, and some items did not include information about its *function* (see Reisenzein, 2000a, for a conceptually similar experiment with humans). In those cases where a symbol of the sequence (Experiment 1) or information about the *function* of the building (Experiment 2) was missing, the participants had to state their expectations for the missing symbol or the missing *function*. Subsequently, the "solution" (the missing information) of the "quiz item" was presented and the participants were asked to rate the intensity of felt surprise about the "solution", as well as for the whole sequence/building. For "quiz items" ending with complete sequences or complete buildings, the participants had to rate the intensity of felt surprise about a specified element of the sequence or a specified piece of the building. Subsequently, they also indicated their *passive expectations* for that element/piece. The "quiz items" used in both experiments were selected on the basis of a previous questionnaire study. They were equally distributed among the three sources of surprise described earlier, as well as among different intensities of surprise ranging from low to high.

Figure 3 presents the results of Experiment 1. It can be seen that the intensity of surprise computed for an element of a sequence by the agent (labeled *S-EUNE-Piece* in Figure 3) is close (average difference = .065, i.e., 6.5%) to the corresponding average intensity given by the human judges (*Humans Average-Piece*). Even better results (average difference = .022) were obtained for the surprise values computed for the whole sequence (*S-EUNE-Whole* and *Humans Average-Whole*). Figure 3 also shows that the standard deviations of the surprise intensities given by the 60 humans (*S.D.-Humans-Piece*, *S.D.-Humans-Whole*) were less than .23 (for an element) and .18 (for the whole sequence).

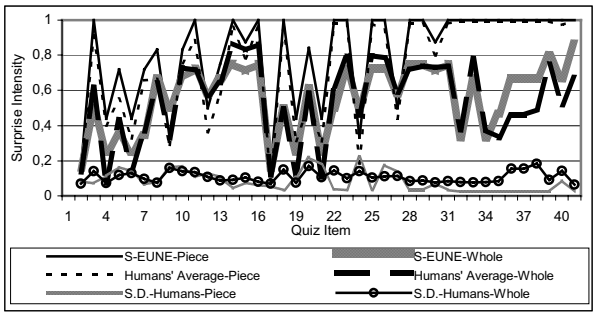

Figure 3: Results of Experiment 1.

Figure 4 presents the results of Experiment 2. In this experiment, S-EUNE answered the "quiz items" several times, each time with a different episodic memory. Due to the lack of space, we reported only the results of three sessions, denoted by S-EUNE-I, IV and V (with I, IV and V denoting an increasingly large memory). It can be seen that the surprise values of the agent are not as close to the human judgments as in the previous domain. For instance, the average differences for S-EUNE-V were .47 (for a piece of a building) and .05 (for the whole building). This happened most likely because, in contrast to the previous, hedonically neutral domain, in the domain of buildings the knowledge of humans and of the agent is different. However, the results suggest that the larger the episodic memory, and the closer its probability distribution corresponds to the real world, the closer are the surprise values given by the agent and by the humans. For instance, S-EUNE-V (*S-EUNE-V-Piece* and *S-EUNE-V-Whole*) showed the best correspondence to the human ratings. This experiment also confirms to some extent the dependence of surprise on the contents and developmental stage of memory, suggested by studies that compared the surprise reactions of adults with those of children (Schützwohl & Reisenzein, 1999).

Both experiments also confirmed that the values of surprise fall in the ranges predicted by Ortony and Partridge, with the exception that, in the case of the source of surprise corresponding to cell [8] of Table 1, the values are always 1, and, in the case of cell [4], $S_P=S_A$.

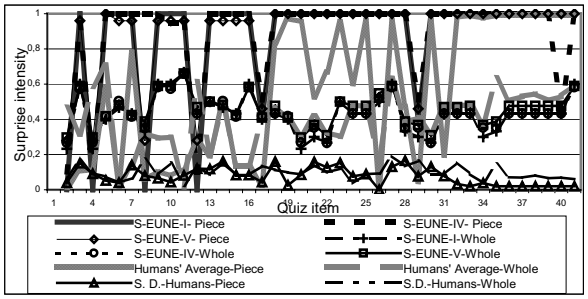

Figure 4: Results of Experiment 2.

Conclusions

The results of the reported experiments suggest that the described computational model is a possible model of surprise. However, alternative surprise functions are conceivable, such as, $SURP(O)=\ln_2(1/P(O))$ (as suggested by information theoretic accounts) or $SURP(O)=1-P(O) \Leftarrow P(O)<.5$; $SURP(O)=0 \Leftarrow P(O)\geq .5$ (as suggested to us by Rainer Reisenzein). We are currently exploring these and other alternatives.

Acknowledgments

We would like to thank Andrew Ortony and Rainer Reisenzein for their helpful comments, and the participants of our experiments for their cooperation.

Abstract

The goal of this research is to create general computational models of the interplay between affect, cognition and behavior. These models are being designed to support characters that act in virtual environments, make decisions, but whose behavior also suggests an underlying emotional current. We attempt to capture both the cognitive and behavioral aspects of emotion, circumscribed to the role emotions play in the performance of concrete physical tasks. We address how emotions arise from an evaluation of the relationship between environmental events and an agent's plans and goals, as well as the impact of emotions on behavior, in particular the impact on the physical expressions of emotional state through suitable choice of gestures and body language. The approach is illustrated within a virtual reality training environment.

Introduction

Emotions play a central role in our lives. A wealth of empirical research has revealed a complex interplay between emotions, cognition and behavior. Emotional state may impact decision-making, actions, memory, attention, voluntary muscles, etc., which, conversely, may influence emotional state (e.g., see Berkowitz, 2000). Teasing apart and understanding these complex relationships is not an easy undertaking.

Not surprisingly, given this complexity, there are also a wealth of emotional models, with starkly differing views concerning the relation between cognition and emotion. While some theories have argued that cognition has a central role in evoking emotions (Lazarus, 1991), others have argued for a more minor role (Zajonc, 1984). With regards to the effects of emotions, theories of emotion have historically posited them as a problem for cognition, an impediment to effective cognitive function. On the other hand, more modern theories view emotions as more helpful than problematic, for example, a mechanism that facilitates human adaptation (e.g. Lazarus 1991, Simon, 1967).

We come to this conundrum from a certain perspective. The focus of our work is on general software agents that model human performance in rich simulated worlds. In particular, we focus on virtual training environments where intelligent agents interact with a human participant to facilitate the training objectives.

Emotions play an important role in such environments by enhancing believability and realism, increasing a sense of empathy and attachment to synthetic characters, and adding to the suspense of the simulation. For example, one of our environments, Carmen's Bright IDEAS, is designed to teach mothers of pediatric cancer patients better problem solving skills (Marsella et al., 2000). The mother learns by interacting with agents in a simulated world that mirrors her own. In particular, emotional models are used to help the mother identify with a human-like agent who faces various social problems due to her child's cancer. Another example is the Mission Rehearsal Exercise, a training environment designed to teach decision-making skills in highly evocative situations (Swartout, et al., 2001). The system provides an immersive learning environment where participants can experience the sights, sounds and circumstances they will encounter in real-world scenarios while performing mission-oriented training (Figure 1). Emotional models are used to enhance the intensity of the experience by creating characters that can respond emotionally to the student's decisions.

These simulations are set apart by the complexity of the environments and, more importantly, the detailed cognitive, emotional and behavioral modeling required. The agents face a variety of social and physical challenges, requiring the generation and execution of complex multi-agent plans. Overall, this complexity distinguishes this effort from more abstract simulation environments designed to study long term interactions of simpler agents (e.g., Nicholson et al., 1998) or believable, non-human agents in games (Neal Reilly, 1996).

Although complex, these realistic simulation environments offer a unique opportunity to explore and evaluate issues that arise by virtue of the complexity and fidelity of the modeling. For example, the agents must be able to generate complex plans with multiple goals and sub-goals. These plans may need to evolve or be replaced over time. Therefore, a key issue arises as to how the dynamics of this process and the structure of

Figure 1: A scene from the Mission Rehearsal Exercise

the resulting plan relate to overall emotional state and its dynamics. Another key issue concerns the agents' behaviors. They must interact with human participants across a range of modalities in a way that appropriately conveys their underlying emotional state. The wide repertoire of human nonverbal behaviors must be modeled, both subtle and extreme behaviors, consistent with emotional state. Fundamental questions arise as to what behaviors are exhibited and how various cognitive and emotional factors mediate between alternative behaviors. Finally, the realism of these simulations affords a unique, albeit weak, form of evaluation. The realism here supports more direct comparison with human behavior under matching conditions.

In essence, we are suggesting that it can be useful to attack the emotion conundrum head on via comprehensive, realistic simulations. Such simulations raise interesting research questions for cognitive science. Indeed the relation is synergistic since research on human cognition and emotion drives the design of our models.

In this paper, we demonstrate how some of the daunting subtlety in human behavior can be modeled by intelligent agents, from the perception of events in the world, to the appraisal of their emotional significance, through to their outward impact on agent behavior. We put forth a domain-independent solution that focuses on the problem of modeling "task-oriented" emotions – emotions that arise from performance of a concrete task. We then go on to illustrate the application of this model to virtual training environments.

Plans, Emotion & Behavior

The agents we design must provide convincing portrayals of humans facing difficult, dangerous problems. In particular, they must exhibit emotionally revealing nonverbal behaviors and expressions consistent with deeply evocative/disturbing situations. These behaviors must also change in concert with the emotional state of the agents; obviously people express themselves differently when sad, happy or angry.

Of course, one cannot realistically convey emotions without realistically modeling the genesis of those emotions. Because planning is central to our agent's behavior, we first needed to address how agents' plans/goals lead to their emotions. Then, we needed to address the impact of emotion on behavior. The driving force behind our modeling efforts was psychological research on the relation of cognition, emotion and behavior. However, the development of the models also raised significant research issues.

Plans and Emotional Appraisal

Many psychological theories of emotion emphasize the tight relationship between emotions and cognition. Emotions clearly influence our decision-making (Clore et al., 1994; Fiedler & Bless, 2000). What is less recognized is the strong influence cognition has over emotion. For example, the same event could evoke a variety of emotional responses depending on our mental state: getting a flat tire could evoke anger or joy depending on if we want to reach or avoid our destination. Such events derive their emotion charge, not from some intrinsic emotion evoking properties, but from our interpretation of their significance. Much of the recent theorizing on emotion builds on this observation, arguing that emotions arise from a cognitive appraisal of how events impact our plans and goals (Ortony et al, 1988; Lazarus, 1991).

Such psychological findings are problematic for building realistic models of human emotion. Just as fans of different teams will respond differently to the score of a goal, intelligent agents must respond differently to events in the simulation, and in a way that appears coherent to a human observer. For an agent developer, however, psychological findings and theories are seldom cast in a way that easily translates to general computational models.

Fortunately, there has been a nice convergence between cognitive appraisal models of emotion and the technologies underlying intelligent agents. Thus, while appraisal theories are vague on how events relate to goals, artificial intelligence planning methods now provide elaborate "mental" structures and inference techniques to assess this relationship (see Weld, 1999). While cognition cannot be reduced merely to planning, such algorithms can provide a cornerstone for making appraisal theories more concrete. By maintaining an explicit representation of an agent's plans, they can easily reason about future possible outcomes – a key requirement for handling emotions like hope and fear that involve future expectations. Planning techniques also detect interactions between plans, for example, as

when the plans of one agent are incompatible with those of another – a key requirement for handling emotions like anger or reproach which typically involve multiple actors.

Modern planning techniques also support a rich model of how cognition influences one's emotional state. We can model some of the dynamic ebb and flow of human emotion by relating emotional appraisals to the current state of plans in an agent's memory. As plans grow and change through the planning process, so too the emotional state will change as a reflection of this process – in a sense providing a window into an agent's mental processes.

Finally, by providing an explicit and rich reasoning infrastructure, plan-based approaches facilitate models of how emotions impact decision-making. Emotional state can act as search control, focusing cognitive resources on specific goals or threats. It can also alter the overall character of problem solving. For example, negative emotions seem to lead to narrow focused problem solving while positive emotions lead to broader problem solving that attempts to achieve multiple goals simultaneously (Sloman, 1987).

Emotional State and Physical Behavior

Psychological research on emotion reveals its pervasive impact on physical behavior such as facial expressions, gaze and gestures (Argyle & Cook, 1976; Ekman & Friesen, 1969, 1971). These behaviors communicate considerable information about an individual's emotional state. This may be intentional, as in shaking a fist. On the other hand, behaviors such as rubbing one's thigh, averting gaze and raised eyebrows may have no explicitly intended role in communication, but they suggest considerable information about emotional arousal, attitudes and attention. Indeed, observers can reliably infer a person's emotions and attitudes from nonverbal behaviors (Ekman & Friesen, 1969). For example, depressed individuals may avert gaze and direct gestures inward towards their bodies. An angry person's nonverbal behavior tends, if unsuppressed, to align itself with the object of the anger (e.g., by confrontational stares or obvious avoidance of eye contact).

Such movements also serve to mediate the information available to the individual. For example, if a depressed individual's head is lowered, this also regulates the information available to the individual. Orienting on an object of fear or anger brings the object to the focus of perceptual mechanisms, which may have indirect influences on cognition and cognitive appraisal by influencing the content of working memory. Even a soothing behavior like rubbing an arm may serve to manage what a person attends to (Freedman, 1972).

These findings provide a wealth of data to inform agent design but such sources are descriptive, not proscriptive, often leaving open many details as to how alternative behaviors are mediated. Contemporary agent technology allows one to create rich physical bodies for intelligent characters with many degrees of physical movement. This forces one to directly confront the problem of emotional consistency. For example, an "emotionally depressed" agent might avert gaze, be inattentive, perhaps hug themselves. However, if in subsequent dialog the agent used strong communicative gestures such as beats (McNeill, 1992), then the behavior might not "read" correctly. Similarly, people don t tend to nonchalantly use deictic gesture while simultaneously averting their gaze due to mild feelings of anger or guilt. Such behavior may look un-natural, inconsistent, or may convey a different shade of meaning depending on context. Which is not to say that the overall mix of behaviors should always be monolithic. People do say one thing while expressing another. At the least, the mix of nonverbal behaviors often shade the meaning of what is said or communicated nonverbally. Returning to the previous example, if an agent does combine deictic gesture with gaze aversion, it may shade the interpretation dramatically, towards an expression of extreme emotion and a desire to control that emotion. For example, the agent is so disgusted with the "listener", they can t bear to look at them .

Implicit in these various concerns is that the agent has what amounts to a resource allocation problem . The agent has limited physical assets, e.g., two hands, one body, etc. At any point in time, the agent must allocate these assets according to a variety of demands, such as performing a task, communicating, or emotionally soothing themselves. For instance, the agent's dialog may be suggestive of a specific gesture for the agent's arms and hands while the emotional state is suggestive of another. The agent must mediate between these alternative demands in a fashion consistent with their goals and their emotional state.

Implementation

Implementations demand compromise. In our work we limit the scope of models by what agent technology currently does well, rather than trying to develop comprehensive but less general solutions. Thus, we focus on emotions arising from plan generation and execution, and ignore a number of potential sources of emotion, such as ego conflict. Similarly we focus on physical behavior, expressing emotion through body gestures and facial expressions, ignoring the myriad ways people communicate emotion through speech (and instead rely on pre-recorded voice clips for verbal communication).

An agent consists of three main components. The planner/executor maintains a representation of the world state, and develops, executes and repairs plans that achieve the agent's goals. STEVE (Rickel & Johnson, 1998) plays the role of the planner/executor in the

application described below, but variety of AI planning methods could serve this role. The other components implement the cognitive appraisal of emotions and manage their physical manifestation.

Cognitive Appraisal

As we alluded above, we focus on cognitive appraisals as they relate to an agent's plans and draw on the strengths of modern artificial intelligence planning techniques. Specifically, we build on Émile, a computational realization of Ortony et al.'s cognitive appraisal theory (Gratch, 2000). The approach assesses the relationship between events and an agent's disposition (described by its goals, social standards). Unlike most computational accounts, Émile explicitly considers the role plans play in mediating the relationship between events and the agent's disposition. Rather than appraising events directly, Émile appraises the state of plans in memory, as inferred and elaborated by a general-purpose planning algorithm. This allows Émile to avoid the large number of domain-specific appraisal rules needed by prior computational approaches (e.g., Elliott, 1992). Domain-specific information, for the most part, is restricted to the operator descriptions (the domain theory) from which plans are built, and which an intelligent agent needs anyway to inform planning and action selection.

Émile also draws heavily on the explicit plan representation to derive the intensity of emotional response. Émile incorporates the view of Oatley and Johnson-Laird (1987) and Neal Reilly (1996) that emotions are related to changes in the perceived probability of goal attainment. Intensity is broken down into the probability of the event in question (e.g. the probability of goal achievement or the probability of a threat) and the importance (utility) of the event to the agent, both of which are derived from the current plan structure. As intensity is based on the current plans, the assessment is a reflection of their current state and changes with further planning. Individual assessments are aggregated into a set of "leaky buckets" associated with each emotion, where these buckets represent the current intensity of different emotions.

Physical Focus

The key challenge of the behavior component is to manage the flexibility in an agent's physical presence in a way that conveys a consistent emotional state. Agents are represented by rich bodies with fully articulated limbs, facial expressions, and sensory apparatus. The implementation must control the degrees of freedom provided by the agent's body in a way that satisfies the constraints imposed by psychological findings

To address this problem we rely on the Physical Focus model (Marsella et al. 2000), a computational technique inspired by work on nonverbal behavior in clinical settings (Freedman, 1972) and Lazarus's (1991) delineation of emotion-directed versus problem-directed coping strategies. The Physical Focus model bases an agent's physical behavior in terms of what the character attends to, how they relate to themselves and the world around them, specifically whether they are focusing on themselves and thereby withdrawing from the world or whether they are focusing on the world, engaging it.

The model organizes possible behaviors around a set of modes. Behaviors can be initiated via requests from the planner/executor or started spontaneously when the body is not otherwise engaged. At any point in time, the agent will be in a unique mode based on the current emotional state. This mode predisposes the agent to use particular nonverbal behavior in a particular fashion. Each behavior available to an agent is categorized according to which subset of these modes it is consistent with. Any specific nonverbal behavior, such as a particular nod of the head, may exist in more than one mode and conversely a type of behavior, such as head nods in general, may be realized differently in different modes. Transitions between modes are based on emotional state.

Modes also influence an agent's sensitivity to external stimuli, currently in a simplistic fashion. Rather than modeling the full flexibility of how people can focus their perception and attention (Wells & Matthews, 1994), we provide a domain specific mechanism for ranking stimuli by their intensity and filtering certain stimuli depending on if the focus mode is inner or outer directed.

Grouping behaviors into modes attempts to mediate competing demands on an agents physical resources, especially gesturing and gaze, in a fashion consistent with emotional state. This grouping model is designed with the intent that it be general across agents. However, realism also requires that specific behaviors within each mode incorporate individual differences, as in human behavior. For example, we would not expect a mother's repertoire of gestures to be identical to that of an army sergeant.

In the current work, we model three modes of physical focus: body-focus, transitional and communicative (as opposed to the five modes discussed in Marsella et al., 2000). Body focus is marked by a self-focused attention, away from the conversation and the problem-solving behavior. Emotionally, it is associated with considerable depression or guilt. Physically, it is associated with the tendencies of gaze aversion, paused or inhibited verbal activity and hand to body stimulation that is either soothing (e.g., rhythmic stroking of forearm) or self-punitive (e.g., squeezing or scratching of forearm). The agent exhibits minimal communicative gestures such as deictic or beat gestures (McNeil 1992,

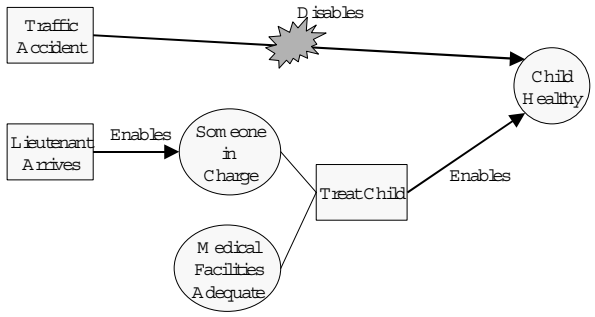

Figure 2: An example of the mother's plan

Cassell & Stone 1999) when in this mode. Transitional indicates an even less divided attention, less depression, a burgeoning willingness to take part in the conversation, milder conflicts with the problem solving and a closer relation to the listener. Physically, it is marked by hand to hand gestures (such as rubbing hands or hand fidgetiness) and hand to object gestures, such as playing with a pen. There are more communicative gestures in this mode but they are still muted or stilted. Finally, communicative indicates a full willingness to engage in the dialog and problem solving. Physically, it is marked by the agent's full range of communicative gestures, use of gaze in turn taking, etc.

Illustration

We illustrate the model by walking through an example of the system's behavior in the context of a virtual environment for familiarizing soldiers with the demands of peacekeeping operations. The Mission Rehearsal Exercise attempts to create an immersive learning environment through the integration of high-fidelity real-time graphics, intelligent agents, 3D audio and an interactive story whose outcome depends on the decisions and actions that participants take during the simulation.

In our working scenario, the system models a mix of three interactive and about forty pre-scripted virtual humans that play the parts of characters in the peacekeeping exercise. A human trainee commands a platoon of soldiers that have become involved in an automobile accident while driving to meet another platoon in need of reinforcement. The student must decide how best to allocate his forces between the conflicting goals of assisting an injured child and completing his mission, all under the watchful eyes of a "ZNN" cameraman.

Currently, only the character portraying the injured child's mother incorporates our emotional model. Figure 2 illustrates a simplified representation of the mother's plan at the opening scene in the scenario. The mother is waiting for the lieutenant (the student) to arrive, which she views as a precondition for her child to be treated. She is somewhat angry with the lieutenant, perceiving him as responsible for the accident (the domain-theory hard-codes an attribution that the lieutenant is responsible for "accident" task). This appraisal is moderated by the importance of the goal (high) and the likelihood of the threat cannot be overcome (moderate). Initially she believes the medical facilities are adequate to treat the child on scene, meaning she has the simple plan in memory that the lieutenant should arrive and her child will be treated, neither task being under her direct control. Since her child is hurt, a threat to an important goal, she has high levels of distress. The likelihood the treatment will be successful even if applied is relatively low (implying that there are many non-specific threats to its success) so she is also extremely anxious. The sense of hopelessness (and anxiety) leads her to have an inner-directed Physical Focus. Her body gestures are directed inward and she will not attend to most stimuli.

When the lieutenant arrives, the mother perceives that the sub-goal that someone is in charge is now attained and all non-specific threats associated with its attainment disappear. The probability that the child will be treated grows, and the mother's distress diminishes enough to transition her into transitional focus. Her gestures become more outward directed and she attends to more perceptual stimuli and her child.

Later in the scenario, the lieutenant orders one or two squads forward to reinforce the platoon downtown. The mother interprets this as disabling her sub-goal that the troops help her child. The strength of this interpretation is influenced by the number of squads the student orders forward (implemented by domain-specific rules that infer the probability of the disablement based on the number of moving units). The appraisal model treats this as a blameworthy event, causing the mother to become angrier at the troops. This anger is sufficient to transition her into communicative mode. The planner repairs the mother's current plan, deciding that imploring the troops to stay is a way of redirecting their behavior. Her body language in performing this action is colored by her body focus and anger level, either remaining seated and gesturing mildly or raising to a standing position and gesturing strongly (see Figure 1).

Discussion

This project is still in its early stages (the initial prototype was completed at the end of September 2000). From a research perspective the biggest limitation is the lack of evaluation. Is it a viable learning environment? Does the addition of emotional models increase the realism of the scenario? Do people find the character's reactions plausible? How do emotional models impact the learning experience? Our plan is to begin formal evaluations in the coming year in conjunction with other research groups in the psychology and communications departments at the University of Southern California. Our anecdotal feedback has been encouraging.

We have demonstrated the system to a number of military personal and those who served in Bosnia or Kosova seemed strongly affected by the experience. One U.S. Army Colonel began relating a related incident after seeing the demo, became quite emotional, and concluded by saying, "this system makes people feel, and we need that." In another anecdote, someone playing the role of the lieutenant became agitated when the mother character began yelling at him and when she wouldn't respond to his reassurances (she cannot be mollified when her anger exceeds some threshold).

Finally, there are a number of limitations in how the system infers emotional state that need adjustment or re-thinking in light of this application. As mentioned, cognitive appraisal only addresses emotions that arise from a concrete representation of plans of goals. We only weakly address the influence of emotion on perception and completely ignore the influence emotions hold over beliefs. Another key issue is the notion of responsibility. For example, whom should the mother blame for the accident? The troops? Herself? Our sense is she should have a shared sense of responsibility and that this sense should change dynamically, influenced by her emotional state and subsequent actions of the troops. Our treatment of anger is also too simplistic. Anger seems influenced by the extent to which we decide someone intended the offending action and the extent to which they show remorse or attempt to redress the offence. We suspect the explicit use of plans can assist in forming such assessments, but we are still sorting out how.

These limitations notwithstanding, the integration of plan-based appraisal of emotional state with the Physical Focus model provides a great deal of architectural support for emotional modeling. Furthermore, anecdotal evidence suggests that people find the agent's emotions to be plausible, and, to our surprise, people occasionally responded emotionally to our agents.

Elementary School Children's Understanding of Experimental Error

Amy M. Masnick (masnick@andrew.cmu.edu)
David Klahr (klahr@cmu.edu)
Department of Psychology
Carnegie Mellon University
Pittsburgh, PA 15213

Abstract

Understanding data variability and potential error sources is essential to a full understanding of experimental science. We propose a typology of error that considers not only the nature of the error, but also the phase in the experiment in which it occurs. We looked at second- and fourth-grade children's understanding of error, their use of evidence in guiding this understanding, and the role of context in reasoning about error. We found that children could name and recognize sources of error even when they were unable to design controlled experiments. Children used evidence to guide their reasoning, making predictions and drawing conclusions based on the design of their experiments. Children were also sensitive to the context of reasoning: they differentiated the role of random error in relative and absolute measurements. These findings suggest that children understand a wide variety of potential error sources several years before they have acquired the systematic procedures necessary to control and interpret such error

A student in a fourth grade science laboratory is attempting to determine the effect of different factors on how far a ball rolls down a ramp. The ramp is adjustable for length, height, and surface smoothness, and there are two types of balls. Distance is measured by counting the number of discrete "steps" the ball travels up a sloped staircase at the end of the ramp. The teacher's primary instructional goal is to have the child learn how to design unconfounded experiments, in which experimental contrasts differing on only one attribute support logically grounded causal inferences.

In an ideal world, the student could demonstrate an understanding of experimental design by setting up two ramps such that they differed only with respect to surface type, releasing two identical balls, and observing that the ball on the smoother ramp went faster.

But the world is not ideal, and many unanticipated, unknown, and unintended events could influence the outcome of this experiment. Perhaps the student does not fully understand the logic of unconfounded experimentation, and so varies more than one factor at a time. Perhaps one ball is pushed slightly at the start of its roll or hits the side of the ramp on the way down. Perhaps one ball rolls back a few steps at the end of the run and the true distance it rolled is lost. Perhaps none of these "obvious" things occur, but, upon repeating the experiment several times, the student discovers that the balls travel different distances on each replication. What is the student to conclude?

Each of these events can be considered as a different type of experimental error. Among philosophers of science the question of how to best classify different types of experimental error remains controversial. The "conventional" view is that there is a true value and an error term that is part of the observed measurement, and it is distinguishing the magnitude of each that is the difficult part (cf., Hon, 1989). Quite a different perspective – and the one adopted in our analysis – is a process-based view that recognizes the inevitability of errors and that classifies them according to when in the overall cycle of experimental investigation they occur. Hon (1989) has proposed such a taxonomy and used it to organize a wide range of historical cases in which error played an important role in the scientific discovery process. We have adapted his approach by combining it with an earlier, psychologically oriented, classification of error (Toth & Klahr, 1999) to produce a similar taxonomy with which to organize some of the psychological literature on children's understanding of error, and to motivate our own investigations. In our taxonomy, there are five relatively distinct stages to the experimentation process (design, set-up, execution, measurement, and analysis of results), and each stage is associated with a category of error.

Types of Error in Designing and Executing Experiments

Design error This type of error occurs during the earliest conceptual phase of an experiment when some variables not being tested are not controlled and a confounded design is produced. For example, if the goal is to determine the effect of different ramp surfaces, then an experiment that compares a high smooth ramp with a low rough ramp contains a design error. No matter what the outcome of the test, it will be unclear whether any differences in the distance the balls rolled are due to the different steepnesses or different surfaces. Design errors occur "in the head" rather than "in the world" because they result from cognitive failures: either from a failure to fully understand the logic of unconfounded contrasts, or from inadequate domain knowledge.

Execution error These errors occur when something not considered or planned for in the design influences the outcome. Execution error can be random (such that replications can average out its effects) or biased (such that the direction of influence is the same on repeated trials), and it may be obvious (such as hitting the side of the ramp) or unobserved (such as an imperfection in the ball).

Measurement error This type of error overlaps the set-up and the measurement phases, because measurement is involved in setting up the apparatus and calibrating instruments as well as in assessing outcomes.

Interpretation error Interpretation errors can occur at any phase in the experiment. If an error occurs in any of the phases and is not recognized as such, it can influence the interpretation. The analysis phase involves both statistical analysis and theoretical inference, both of which are subject to a wide variety of statistical and cognitive errors. Errors that involve ascribing effects when in fact there are none, or claiming a null effect when one actually exists fall into this category.

Children's Understanding of Experimental Error

Although there is only a small philosophical literature on experimental error, there is an even smaller literature on the psychology of experimental error, i.e., empirical investigations of how people understand and interpret various kinds of experimental error. In this section we briefly summarize what is known about children's understanding of error. The terminology and methods of investigation in these developmental studies are quite varied, making it difficult to compare their results, but we summarize them in terms of the classificatory scheme presented earlier.

Several of the studies of grade school children's error understanding have focused on how children reason about repeated measurements and data variability. Varelas (1997) looked at third and fourth grade children's reasoning about repeated measurements when they carried out experiments in groups. She found that most children expected some variability in measurements, though why they expected this variability was not always clear.

Avoiding an error in the interpretation phase involves assessing when an error is sizeable enough to affect conclusions. Schauble (1996) looked at fifth and sixth graders, and non-college adults. One difficulty many children (and some adults) had was in distinguishing variation due to errors in measuring the results from variation due to true differences between the conditions (i.e., between intended contrasts and measurement phase errors). When in doubt, participants tended to fall back on their prior theories. If they expected a variable to have an effect, they interpreted variability as a true effect; otherwise, they were more likely to interpret the variability as due to error.

Lubben and Millar (1996) found that some high school children still have considerable difficulty understanding data variability, at least in situations in which they are given the data but are not performing the experiments themselves.

Error is a difficult concept to understand, and it seems likely that there are several levels of understanding (Lubben & Millar, 1996). There is evidence that first and second grade children can recognize a good experiment, even when they cannot yet generate one (Sodian, Zaitchik, & Carey, 1991). This finding suggests that children who are unable to generate error-related reasons for data variability may still have a basic understanding of error and therefore be able to recognize error-based explanations as plausible.

Causal Reasoning and Error Understanding

One way to clarify this literature about error is to reconceptualize error as a subset of the more fundamental topic of causal reasoning. Whether we recognize it as error or not, error is always caused by something. As suggested by the taxonomy proposed here, the nature of that something may be different for each phase of the experimental cycle. From this perspective, before one can reason about error in science experiments, it is necessary to be able to reason about causes (Koslowski & Masnick, in press).

In the current study, we set out to explore several aspects of children's understanding of error: their understanding and recognition of different types of error; consistency of reasoning about experimental design and conclusions, the ability to differentiate between the importance of error when comparing relative and absolute measurements; and the use of theory and evidence in justifications for confidence.

We know that children often have difficulty designing controlled experiments (e.g., Chen & Klahr, 1999). However, it is unclear how much they do understand and whether they can reason consistently based on their incorrect designs. If when children design confounded experiments, they make predictions about the outcome based on variables other than the target variable, it would suggest that although they do not fully understand the goals of the experiment, they use background knowledge to reason correctly based on the experiment they have designed.

Another measure of understanding is children's confidence about conclusions. If they understand the importance of a good design, we would expect them to be more confident of conclusions based on the results of an unconfounded experiment than a confounded one. At a more sophisticated level, if children understand the role of random error, they may still not be completely confident of outcomes after just one or two runs of an unconfounded test. They may consider that there are often uncontrollable factors that can affect a result and, by extension, the conclusions drawn.

The question of when error is important enough to alter conclusions is a difficult one. When looking at simple mechanics problems, the question also depends on the experimental context. If the goal is to determine the exact distance a ball will roll down a ramp under certain conditions, even the slightest unintended intrusion can raise questions about the result. But when the goal is to compare the relative distance a ball rolls given two levels of a particular variable, if the difference is sizeable, error is less important.

We designed a study to address several aspects of children's understanding of error throughout all phases of an experiment, to examine what elementary school children know about different types of error. First, we looked at whether children can design unconfounded experiments, make predictions consistent with their designs, and differentiate the role of error in absolute and relative measurements? Next, we looked at whether children generate alternative reasons for variation in repeated measurements, considering the roles of execution and measurement errors. Finally, we looked at whether children recognize potential sources of error.

Method

Participants Participants were 29 second-grade (mean age = 8.1) and 20 fourth-grade (mean age = 10.1) children from a private elementary school in southwestern Pennsylvania.

Materials Materials included two wooden ramps, each with an adjustable downhill track connected at its lower end to a slightly uphill, "staircase" surface. Children could set three binary variables to configure each ramp: the height (high or low), by using wooden blocks that fit under the ramps; the surface (rough or smooth), by placing inserts on the downhill tracks; and the length of the downhill ramp (long or short), by placing gates at either of two starting positions. Finally, children could choose either a rubber ball or a golf ball to roll down either ramp.

In addition, a laminated copy of a scale for indicating confidence (see below) and a stopwatch were used.

Procedure

Children were interviewed individually. All interviews were videotaped for later coding and analysis. During a brief familiarization phase, children were introduced to the ramp materials and the confidence scale (called a "sureness" scale, with levels of totally sure, pretty sure, kind of sure, and not so sure) and were asked a few questions to ensure that they understood how to use all of the materials.

Part One The purpose of Part One was to determine the extent to which children could design unconfounded experiments with these materials, and to assess their ability to differentiate between absolute and relative measurements. Each child was asked to design four experiments to determine the effect of different settings for specific variables that might affect how far a ball rolls down a ramp. In the first two experiments, children were asked to set up the ramps to test whether the steepness of the ramp made a difference in the outcome; in the third and fourth experiments, they were asked to test the effect of surface.

After the child set up the ramps, the experimenter asked why the ramps had been set up that way and also asked which ball was expected to go farther and why. Next, the experimenter asked the child to release both gates at the same time to see how far the balls rolled.

After the balls had stopped rolling, the experimenter asked the child what he/she had learned and why. Next, the experimenter asked the child whether the target variable (steepness or surface) made a difference. The child used the sureness scale to indicate confidence that the particular variable did make a difference, and to explain why.

Next, the experimenter asked a series of questions about relative and absolute values of the outcome variable. The experimenter asked the child to imagine, if the identical experiment were to be repeated, whether the same ball would go farther, and then whether the two balls would be expected to land on the exact same steps. The children were then asked to rate their sureness about each answer and explain why.

After each experiment and question series, the ramps were disassembled and the child was asked to set up the next experiment.

Part Two The purpose of this part was to explore the child's understanding of data variability in replicated experiments. A single ramp was set up with a high steepness, smooth surface, long run, and a golf ball. For each of five trials, the child was instructed to release the ball by lifting the gate on the experimenter's signal, while the experimenter simultaneously started a stopwatch. When the ball reached the bottom of the ramp (but before it began to roll up the steps), the experimenter stopped the stopwatch and read out a time for the child to record by writing it down. To ensure that all children were presented with the same range of data, the experimenter reported a fixed, predetermined set of times to each child, regardless of the actual time on the stopwatch[1].

At the completion of the five trials, the experimenter noted that it appeared to take a different amount of time for each roll and asked the child to generate reasons to explain these differences. Each child was encouraged to give as many reasons as he or she could think of, and then was asked for a summary explanation he or she would provide the teacher if she asked how long it took.

The experimenter then changed the surface of the ramp to a rough surface, and the ball was again rolled down five times. Again, the experimenter read each child an identical list of run durations. In this second round of numbers, there was a noticeable outlier among the numbers given[2]. After the five trials were completed, the experimenter again asked the child for reasons why the numbers would come out differently and a summary for the teacher.

Part Three Whereas Part Two required children to generate potential sources of error, in Part Three a few such sources were provided, to see how well children

[1] Times: 1.08, 1.20. 1.15, 1.02, 1.17; mean = 1.12, sd = 0.07

[2] Times: 1.90, 2.48, 1.88, 1.95, 1.85; mean = 2.01, sd = 0.26

could reason about their possible influence. Questions about both relative and absolute differences were asked.

The experimenter explained that she had been working with some children at another school who were trying to figure out whether run length made a difference. She demonstrated their situation by presenting the two ramps set up as an unconfounded experiment comparing the short and long run length, with both ramps having high steepness, smooth surfaces, and rubber balls.

The experimenter then asked about three scenarios the students had encountered: 1) one ball hit the side of the ramp on the way down; 2) the two balls were released at different times instead of simultaneously; 3) one ball rolled back a few steps before anyone could record how far it went. Note that scenarios 1 and 3 might be expected to affect both relative and absolute outcomes, while scenario 2 was designed as a control question because it should not effect on the outcome. For each, the experimenter asked the child whether the event described could affect how far the ball went, and whether it could change which ball went farther.

Results

Experimental Design Skills

Children's experimental design skills were assessed by looking at the number of correct (unconfounded) experiments designed. A correct design contrasted the target variable while holding the other three variables constant. This assessed their ability to avoid design phase errors, and to demonstrate knowledge of the Control of Variables Strategy (CVS). We categorized two types of incorrect designs: confounded (contrast of the target factor and one or more other factors), or non-contrastive (no contrast of the target factor). There was a significant effect of grade on CVS performance, with second graders averaging 16% unconfounded experiments, and fourth graders averaging 40% ($t(47) = 2.89$; $p = 0.006$).

Predicting Experimental Outcomes

Children's predictions about which ball would go farther were coded as correct or incorrect. (If the two balls traveled the same number of steps, children were coded as predicting incorrectly, unless they predicted a tie.)

Overall, children were extremely good at predicting the outcomes of unconfounded experiments and significantly less accurate when predicting the outcomes of non-contrastive designs, as measured by Fisher's exact tests of association. [3] For all but the first experiment, there was a strong relationship between predictive accuracy and type of design (unconfounded, confounded, or non-contrastive). (See Table 1.) Children's predictions were most accurate when they designed unconfounded experiments, next most accurate when they designed confounded experiments, and least accurate when they designed non-contrastive experiments. The relationship was stronger for fourth graders than for second graders.

Table 1: Prediction accuracy, by type of experiment

Number Accurate	Uncon-founded	Con-founded	Non - contrastive
Expt. 1	10/10	28/32	5/7
Expt. 2**	9/9	20/27	5/13
Expt. 3*	12/18	16/21	3/10
Expt. 4**	14/14	14/21	6/14

*$p < 0.05$; **$p < 0.01$

Explanations for Predictions

Children's explanations for their predictions were coded for mention of the target variable (steepness or surface), non-target variables, and any prior outcomes.

To assess the consistency of responses, we examined the relationship between children's reasons for their predictions and the type of experiment they designed (unconfounded, confounded, or non-contrastive), using Fisher's exact tests of association. For all four experiments, there was a significant relationship between mention of the target variable and the type of experiment designed. Overall, children mentioned the target variable as an explanation for 92% of their unconfounded experiments, 61% of their confounded experiments and 14% of their non-contrastive experiments. When broken down by grade, there is still a significant relationship at both grade levels. Similarly, there was a significant relationship between type of experiment and mention of the non-target variable. Children said they based their prediction on one or more of the non-target variables 6% of the time when they designed unconfounded experiments, 56% of the time when they designed confounded experiments, and 61% of the time when they designed non-contrastive experiments.

Confidence

Children's responses to the questions, "Can you tell if X makes a difference?" were coded as yes/no responses. Children noted how sure they were of this answer by using the four-level confidence scale. Finally, children explained why they chose the sureness value they did.

Nearly all of the children were "kind of sure," "pretty sure," or "totally sure" about whether steepness makes a difference on the first two experiments (98% and 86%) and whether surface makes a difference on the third and fourth experiments (90% and 86%). Confidence was unrelated to whether the test was unconfounded, as assessed by Fisher's exact tests of association ($p > 0.10$ for each of the four experiments), but there is some evidence that it is related to the accuracy of prediction. Four Fisher's exact tests were performed to assess the relationship between accuracy of prediction and

[3] Six times children designed correct experiments but inaccurately predicted the outcome. These six comparisons all occurred during the third experiment, a comparison of the surfaces, in which either the two balls tied or the ball on the rough surface actually rolled farther than the ball on the smooth surface.

confidence in conclusions. The trend was significant in the third and fourth experiments. In the first experiment, not enough children were unsure to allow for a strong comparison. Children who correctly predicted the outcome were more likely to be sure than those who predicted incorrectly (See Table 2 for details).

Table 2: Percent sure of target variable's effect, by prediction accuracy

Percent sure	Correct prediction	Incorrect prediction	P-value
Expt. 1	98% (42/43)	100% (6/6)	1.000
Expt. 2	91% (31/34)	73% (11/15)	0.179
Expt. 3	97% (30/31)	78% (14/18)	0.054
Expt. 4	94% (32/34)	67% (10/15)	0.022

Comparing Relative/Absolute Replications

For each question about whether the same ball would go farther if the experiment were to be repeated, children first answered yes or no, and then rated their confidence. These two responses – yes/no and confidence level – were combined into a single 7-point ordinal variable, ranging from totally sure the same ball would not go farther to totally sure it would go farther, with not so sure as the midpoint. An analogous coding scheme was used for the questions about whether the balls would land in the exact same positions.

The reasons given for why children expected the same or a different outcome were coded for mention of any of a list of common responses, including the fact that nothing had changed, and the effect of the target variable (e.g., "This one is the steeper ramp so that will make it go farther").

When asked whether the same ball would go farther were the experiment repeated without changes, over 90% of the time children thought it would (i.e., they said that they were kind of sure, pretty sure, or totally sure that it would). This figure excludes cases in which the balls traveled the same distance. The expectations about whether the balls would land in the exact same position were more varied. About 50% of the time, children thought the two balls would not land in the same positions again, about 40% of the time children thought they would, and the remaining times they were unsure.

To test whether children had different expectations for replication of relative and absolute outcomes, scores from the 7-point confidence code for absolute replication were subtracted from the corresponding scores for relative replication. For each child, we computed the mean of this difference score over the four experiments. Children were significantly more confident that the same ball would go farther than that the two balls would land in exactly the same place (mean difference = 2.46; sd = 1.76; t (48) = 9.8; $p < 0.001$). A t-test indicated a marginally significant effect of grade (mean for 2nd grade = 2.1, 4th grade = 3.0, t (47) = 1.95, p = 0.057). Children had different ideas about the importance of variation in the data depending on whether the judgments were about relative or absolute measurements.

Children's reasons for confidence about relative replication were nearly evenly divided: 40% were evidence-based (e.g., "this ball went farther last time"), and 45% theory-based (e.g., "this one will go farther because it's on the steeper ramp").

Accounting for Variability in Replications

Children's explanations for why the timing was different for each of the five trials were coded for mention of several factors, such as the child releasing the gate before or after the experimenter said "go," the experimenter stopping or starting the stopwatch too early or late, or the ball hitting the side of the ramp. Coding agreement over ten participants ranged from 85-100% on each code.

The average number of error sources named on the two sets of trials was 1.48 by second-graders and 2.15 by fourth-graders, a significant difference (t(46) = 2.73; p = 0.009). General linear models examining whether ability to design unconfounded experiments (as assessed by CVS score) is related to ability to name error sources in this second part indicate no relationship once grade is controlled in the model (F (1, 45) = 1. 79, p = 0.19).

Hypothetical Scenarios

Responses to the questions about hypothetical scenarios were classified into one of three categories: (1) yes, with mechanism explanation; (2) yes, without mechanism explanation; (3) no.

All participants correctly said that the ball hitting the side and that the ball rolling back a few steps could influence how far a ball went and whether the same ball would go farther. Eighty-eight percent were able to offer a reason for the former, and 72% were able to offer a reason for the latter. For the question about whether the timing of gate release would affect the distances traveled, 68% said that it would not and 4% offered a plausible mechanism for why it might make a difference (e.g., the vibration of the ramp might be different when a ball is simultaneously rolling down a ramp right next to it).

Overall, 34% of children completely and accurately answered all 6 questions. Fifty percent of the fourth graders and 22% of the second graders answered all the questions correctly.

Generating Error Sources

At several points throughout the interview, children were asked to think of reasons why experiments did not or might not have the same results when repeated (e.g., explaining why the balls would not land in the same place or why a ball rolled down the same ramp five times took a different amount of time for each run). The responses were coded for mention of possible sources of error, such as the ball hitting the side, or wind blowing, or the gates being lifted different ways, as a reason for the variation in results. Eighty-eight percent of children were able to

name at least one source of error. All six children who did not name any sources of error were second-graders.

Discussion

We set out to examine children's knowledge of different error sources. Our results indicate that despite children's difficulty in designing unconfounded experiments, they do understand a lot about error and its importance.

As found in earlier studies (Chen & Klahr, 1999; Toth, et al., 2000), children frequently made design errors (that is., they had difficulty designing unconfounded experiments). However, children showed consistency in their reasoning by referring to their design in justifying their predictions, regardless of whether it was a good experiment.

This evidence of consistency in justifications and conclusions also indicates some causal reasoning abilities. In the majority of cases, children recognized the link between the design and the outcome by considering their design to determine which factors would affect the outcome, and which factors they could draw conclusions about with confidence.

In addition, children's prior theoretical knowledge guided their reasoning. They were more likely to be confident about their conclusions when the evidence matched their prior beliefs (their predictions), though they were still confident more often than not, regardless of their predictions. Children also justified most predictions based on expected effects of the target and non-target variables (though this reliance varied based on design).

Children also demonstrated some understanding of the role of error in interpretation. Even by the second grade, children differentiated the importance of error in different situations, recognizing that errors are much more likely to affect measurements of exact positions than of relative positions. This finding may suggest a nascent understanding of the difference between main effects and specific examples. Children's confidence that the relative ordering would remain the same suggests they expect main effects to be robust, whereas their lack of confidence in absolute outcomes remaining the same suggests their understanding of variability in each sample.

When reasoning about experiments with ramps, children can use several different kinds of information. They can use their domain knowledge, i.e., what they know of the mechanics of friction and gravity, and of other factors that might affect how a specific instrument works. They can also use any formal experimental knowledge they have about what kinds of factors make for a good experiment, such as how to avoid errors in all phases of the experiment. Domain-specific knowledge enables them to name potential sources of error that could affect the outcome, while domain-general knowledge about experimental design encourages them to search for these specific examples.

The fact that most children are able to name at least one possible source of random error indicates that they do have at least a rudimentary idea about how unpredictable and uncontrolled factors can influence an experiment's outcome. At the same time, the observation that most of these same children are not consistently able to design unconfounded experiments suggests that the understanding is not complete at this age. Knowledge about this gap in understanding can lay the foundation for future research about children's knowledge of science experimentation and about the most effective means to aid science educators teaching children these skills.

Interactive Models of Collaborative Communication

Michael Matessa (mmatessa@arc.nasa.gov)
NASA Ames Research Center, Mail Stop 262-4
Moffett Field, CA 94035 USA

Abstract

The collaborative nature of communication has been demonstrated by research on the increased efficiency (Hupet & Chantraine, 1992) and the adaptive behavior (Giles, Mulac, Bradac, & Johnson, 1987) of interacting pairs, but these two lines of research have never been explicitly related. This paper reports empirical results showing that adaptively matching word use can increase communication efficiency and also gives an ACT-R (Anderson & Lebiere, 1998) modeling account of the processes involved.

Efficient Communication

Imagine that two people have to communicate a number of times about abstract figures that are difficult to name. Typically, the pair will initially use a long referential phrase and with subsequent references shorten that phrase to one or two words (Clark & Wilkes-Gibbs, 1986; Krauss & Fussell, 1991; Krauss & Weinheimer, 1966). For example, in an experiment run by Krauss and Fussell (1991), a pair shown the figure in Figure 1 referred to it over five trials as

a Martini glass with legs on either side
Martini glass with the legs
Martini glass shaped thing
Martini glass
Martini

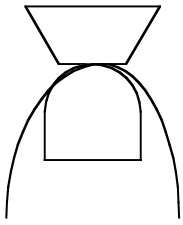

Figure 1: An abstract figure

This process is evidence of the collaborative nature of communication since subsequent phrases tend to make reference to previous phrases and since the phrase eventually agreed on to describe the object would not likely be able to describe the object without the benefit of the prior history of the evolution of the phrase.

Several partner-related factors have been shown to influence the number of words used in the referential communication task. If subjects are asked to create referential phrases for an imagined partner who will later read the phrases, the phrases tend not to decrease over time (Hupet & Chantraine, 1992). If a partner is present but not allowed to give feedback, the rate of decrease is slowed (Krauss & Weinheimer, 1966).

Accommodating Communication

In this discussion, accommodation is the matching of partner behavior in a conversational setting. These behaviors can include lexical choice (Fais, 1998; Garrod & Anderson, 1987; Garrod & Doherty, 1994) and syntactic choice (Bock, 1986; Fais, 1994) as well as speech styles, dialect, non-verbal behavior, vocal intensity, prosody, speech rate and duration and pause length (Giles, Mulac, Bradac, & Johnson, 1987).

Examples of accommodation can be seen in the maze game of Garrod and Doherty (1994), where subjects must decide how to describe their positions in a two-dimensional maze. Some subjects came to describe their positions in a line notation, giving first the line and then their location in that line:

A: Third row two along.
B: Second row three along.

Other subjects developed a matrix notation, giving horizontal and vertical locations:

A: Correct, I'm presently at C5.
B: E1.

Most research on accommodation has focused on dependent measures of converging/diverging behavior or recipient evaluations of that behavior. One hypothesis of this paper is that diverging behavior (non-accommodation) can not only influence the evaluation of behavior, but can also reduce the efficiency of referential communication. Support for this hypothesis would be shorter messages for subjects interacting with accommodating partners as compared to subjects interacting with non-accommodating partners. To do this manipulation with human partners, either confederate partners or partners motivated with positive and negative social group pressures would need to converge or diverge to communication behavior. Either choice would introduce extraneous social complications

into a question about informational processing. Ideally, the decision to diverge or converge should be independent of other communication processing in the partner. One solution is to use computational agents as partners. Two agents could be created that would either converge to or diverge from word choice of a human partner, with other communication processing being exactly the same. If both agents accommodated to the message length used by the human partner, then message length could be used as a dependent measure of efficiency. This would then test the effect of lexical accommodation on message length. The generality of the results would be greater if the behavior of the agents were psychologically plausible. One line of research involving computational theory of human cognition is ACT-R.

ACT-R & Communication

ACT-R (Anderson & Lebiere, 1998) is a computational theory of human cognition incorporating both declarative knowledge (e.g., addition facts) and procedural knowledge (e.g., the process of solving a multi-column addition problem) into a production system where procedural rules act on declarative chunks. At a subsymbolic level, facts have an activation attribute which influences their probability of retrieval and the time it takes to retrieve them. Rules have a reliability attribute which influences their probability of being used.

Support for this declarative/procedural viewpoint has been found in many ACT-R language projects. One project emphasizing declarative representation is Boyland and Anderson's (1997) model of syntactic priming. Research has shown that the use of a specific syntax can be primed in experimental settings if a subject repeats presented sentences (Bock, 1986). Boyland and Anderson created a model that explained this phenomenon as priming of declarative structures built from the comprehension of sentences.

With a procedural representation, Matessa and Anderson (2000) showed that the ACT-R rule reliability learning mechanism predicts a blocking effect in cue learning where the use of highly available cues can block the learning of more reliable cues, since the sequential nature of productions allows only one cue to be chosen at a time. This prediction was supported by experimental evidence of blocking for linguistic actor choice cues such as word order, case marking, and verb/noun matching. Taatgen and Anderson (2000) used a model that combined both declarative and procedural learning to explain the U-shaped learning of irregular verbs, and Lewis (1998) created a parsing model with retroactive and proactive interference of declarative knowledge and procedural attachment processes.

Any interactive model of communication must be able to establish mutual knowledge, interpret the communicative intent of a partner, follow basic communicative obligations, and use communication to further some goal. These abilities have been the focus of a number of lines of research in the communication literature (Clark & Schaefer, 1989; Core & Allen, 1997; Poesio & Traum, 1998; Traum & Allen, 1994) and the ACT-R model of communication presented in this paper is guided by theories in this literature. ACT-R itself is a method for describing human cognition in terms of facts and rules, but the content of the facts and rules used in communication must be guided by current theories of communication. This model of communication was used to test the effect of accommodation (the matching of partner vocabulary) on communication efficiency by having two ACT-R models created from the basic communication model, one accommodating to word use and one non-accommodating.

Experiment

Communication is usually motivated by the desire to complete a certain task. Subjects were given parts of a graph with the goal of creating a whole graph. The graphs are colored objects connect by lines (similar to those used by Levelt (1982) to study communicative reference) and are designed so that similarly colored objects on the parts can overlap and form a larger graph.

Communication using text is more conducive to modeling, so the subjects send messages by way of a chat window from two different computers. In addition to creating a whole graph from two parts, subjects also have the goal of confirming each of the circles. This is done by each subject selecting one circle at a time -- if the circles are the same, their score is increased, but if the circles are different, the score is decreased. This confirmation goal gives an objective measure of task performance in terms of a score, and it allows for the use of more complicated dialogue acts such as requesting that the other person confirm a circle or committing to confirming a circle.

In a similar spirit to the COLLAGEN project (Rich & Sidner, 1998), this modeling effort is not aimed towards the processing of unrestricted English syntax but in modeling the higher-level communicative acts accomplished with English. So like the COLLAGEN project the models interact with people with a restricted set of English phrases. This restricted interface need not drastically hinder the communication process or task performance. In a study comparing a restricted interface to an unrestricted interface for students solving physics problems, Baker and Lund (1997) showed that the restricted communication interface did not interfere with task performance. In fact, it promoted a more task-

focused and reflective interaction.[1] Still, for the current task, unrestricted and restricted communication were compared to see if the restricted interface had any effect on task performance. The restricted interface allows the composition of a text message by first choosing a topic of discussion and dialogue act to address the topic. The topics of conversation are paired connections (how one circle relates to another), multiple connections (rows or columns of circles), numbers (how many of a specific kind of circle there are), correspondences (what circle in one person s graph corresponds to in the other person s graph), confirmations (talking about mutually confirming a circle), and experiment phases.

Also, to allow more problems to be solved in a single experimental session which would allow the development of communication over time, the problems were simplified to have six total objects with one marked as common. From previous research (Clark & Wilkes-Gibbs, 1986; Krauss & Fussell, 1991; Krauss & Weinheimer, 1966) it was expected that the message length would decrease over time. To facilitate this decrease in the restricted interface, the manner of composing messages in the template was changed from choosing words from a pull-down menu to typing words that were displayed in a menu. The menu for the word choice could be skipped over with the Tab key, and in this way shorter messages could be produced. This new method permits a closer correspondence to the unrestricted interface (unrestricted typing) and gives a time benefit to skipping words by not having to spend time in typing them. Additional dimensions of size and shape were added to the color dimension of the circles in order to provide more redundant information in the problem that could later be left out of messages, resulting in a shorter message length. These dimensions were redundant, so that red objects were always small and thin, green objects were always medium and round, and blue objects were always large and fat.

Subjects

One hundred Carnegie Mellon University undergraduates attempted the graph completion task. Twenty-two were paired and used the unrestricted interface, thirty-two were paired and used the restricted interface, twenty-two were paired with an accommodating ACT-R model, and twenty-four were paired with a non-accommodating ACT-R model. This created eleven pairs in the unrestricted interface condition, sixteen pairs in the restricted interface condition, twenty-two pairs in the accommodating model condition (pairs consisting of a subject and a model), and twenty-four pairs in the non-accommodating model condition.

[1] For an alternate viewpoint, see Suchman (1997).

Method

Each pair was told that they would each be given part of a graph and their goal was first to create a whole graph as a result of circles overlapping from each part of the graph, and then to confirm each circle in the whole graph. They were told they would be sitting in different rooms and would be using a chat window to talk to each other. They were shown a drawing pad which contained an example graph part consisting of connected colored circles, and were shown how to add and erase circles representing circles from the partner s graph. They were also shown a chat window which could send eighty-character messages and only displayed the partner s last message. In the restricted interface condition, subjects were told that messages were composed in a communication window that allowed the creation of restricted sentences and were led through the creation of each kind of message. After making sure subjects understood the task, they were then given individual practice problems which used the adding, erasing, and confirming functions of the drawing pad. Finally, the subjects were given their graph parts and were told there were no time constraints in solving the problem.

Results

Figure 2 shows the average time that pairs in each condition took to solve problems. Error bars in this and subsequent figures represent standard error. Results are averaged for the first three problems, the second three, third, and fourth. Since there were an unequal number of pairs in each condition for any particular problem, statistics are performed on each group of three problems.

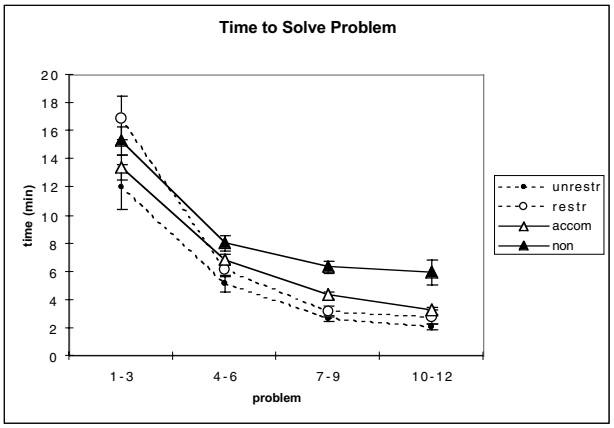

Figure 2: Time to solve problem

There was no significant effect of condition on time to solve problems in the first two groups of three problems ($F(3,65)=2.12$; $F(3,56)=1.72$), but there was an effect in the last two groups of three problems ($F(3,37)=8.58$, $p<.0005$; $F(3,28)=5.76$, $p<.005$). This effect is driven

by slower times in the non-accommodation condition, which was significantly slower than the accommodation condition in the last two groups of three problems ($t(24)=3.71$, $p<.001$; $t(18)=2.61$, $p<.05$). Since the results were similar between the restricted and unrestricted conditions for errors and time to solve problems, the unrestricted condition will not be included in subsequent discussions.

Figure 3 shows how many words were typed, or message length, for sentences concerning connections of objects. Message length tended to decrease with time, for example, a message such as The small thin red object is above our large fat blue object in the first problem could be reduced to messages such as red above blue by the twelfth problem.

Messages in the non-accommodation condition tended to be longer than those in the accommodation condition, not significantly in the first two groups of three problems ($t(43)=0.55$; $t(39)=0.83$) but significantly in the second two groups of three problems ($t(24)=1.97$, $p<.05$; $t(18)=1.81$, $p<.05$).

Human Model

The accommodating and non-accommodating models are able to solve the communication task, but cannot by themselves explain the effect of accommodation. This is because they are "passive" in that they are not the first to decide to skip words in messages descriptions or to skip messages describing confirmation actions. Instead, they follow the lead of their partner and skip words when their partner skips words and skip messages when their partner skips messages. What is needed is an "assertive" "human" model that can decide to skip words and messages first. This model should also be able to account for differences found when subjects interact with accommodating and non-accommodating models.

This "human" model was created by extending the accommodation model with extra rules for actively skipping words. Since time is saved by not typing, these rules make solving the problem more efficient. This effect is achieved in the current situation by having the efficiency rules be sensitive to cooperative actions of the partner (with accommodative word matching signaling cooperative behavior). Two of the rules, skip-word-match-eff and skip-confirm-match-eff, attempt to retrieve memories of their partner matching their own word use. This gives these rules a sensitivity to whether their partner is accommodating or non-accommodating. The other rules do not attempt to retrieve matching memories. The rationale behind these rules is that the decision to skip a word or confirmation message will more likely lead to success if the partner has been cooperative in their behavior, and memories of word matching by the partner give evidence of this cooperation. Rules that find this evidence have a higher reliability because the evidence increases the probability that skipping will lead to success. The rule to continue confirmation

These rules have a subsymbolic value, reliability, associated with them that affects the probability with which they will be used -- rules with higher reliabilities have a higher probability of being used. The efficiency rules added to the accommodation model were skip-word-match-eff (skips a nonessential word if partner matches word) with a reliability of .735 and skip-word-nomatch-eff (skips a nonessential word) with a reliability of .730. The reliability values were set with regard to subject performance with the accommodating and non-accommodating models. These values were then used in runs of the human model with another human model to make zero-parameter predictions of subject performance with other subjects in the restricted interface condition.

Looking at message length, Figure 3 shows results of twenty runs of the "human" model (shown as a dashed line) interacting with the accommodating model, the non-accommodating model, and another human model compared to the results of subjects interacting with the accommodating model, the non-accommodating model, and another human subject.

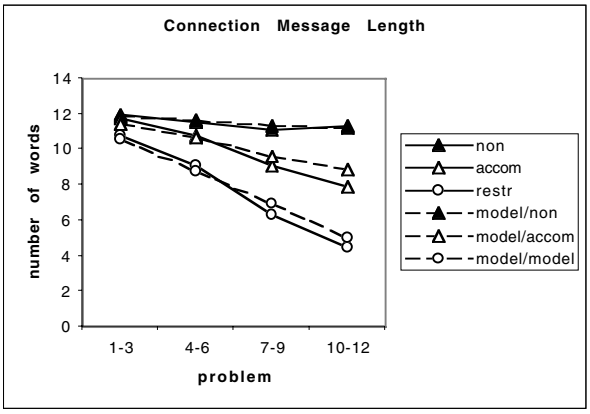

Figure 3: Connection message length

Conclusions

Data from the main experiment show that subjects interacting with accommodating models that match their word choice can solve problems faster than subjects interacting with non-accommodating partners. This result ties together results from the referential communication literature showing partner-based effects on efficiency with results from the accommodation literature showing accommodating behavior motivated by efficiency.

Having a theory of communication in a computational form allowed testing of the theory by having it directly interact with subjects. In terms of errors and time to solve problems, subjects generally

reacted to the accommodating model incorporating the theory much like any other human. In fact, in a post-experiment questionnaire subjects guessed they were interacting with a human 43% of the time they were interacting with the accommodating model (subjects guessed the non-accommodating model was human 48% of the time, but the difference is not significant). There is still room for improvement however, since only 10% of subjects interacting with human partners thought their partners were computers.

The computational nature of the theory also allowed predictions to be made without the use of human subjects. The reliability of the efficiency rules for the human model were set based on human performance with the accommodation and non-accommodating models, but the results of the human model communicating with another human model represent a zero-parameter prediction that closely matched human performance in the restricted interface condition.

Abstract

Distributional information has recently been implicated as playing an important role in several aspects of language ability. Learning the meaning of a word is thought to be dependent, at least in part, on exposure to the word in its linguistic contexts of use. In two experiments, we manipulated subjects' contextual experience with marginally familiar and nonce words. Results showed that similarity judgements involving these words were affected by the distributional properties of the contexts in which they were read. The accrual of contextual experience was simulated in a semantic space model, by successively adding larger amounts of experience in the form of item-in-context exemplars sampled from the British National Corpus. The experiments and the simulation provide support for the role of distributional information in developing representations of word meaning.

The Distributional Hypothesis

The basic human ability of language understanding – making sense of another person's utterances – does not develop in isolation from the environment. There is a growing body of research suggesting that *distributional information* plays a more powerful role than previously thought in a number of aspects of language processing. The exploitation of statistical regularities in the linguistic environment has been put forward to explain how language learners accomplish tasks from segmenting speech to bootstrapping word meaning. For example, Saffran, Aslin and Newport (1996) have demonstrated that infants are highly sensitive to simple conditional probability statistics, indicating how the ability to segment the speech stream into words may be realised. Adults, when faced with the task of identifying the word boundaries in an artificial language, also appear able to readily exploit such statistics (Saffran, Newport & Aslin, 1996). Redington, Chater and Finch (1998) have proposed that distributional information may contribute to the acquisition of syntactic knowledge by children. Useful information about the similarities and differences in the meaning of words has also been shown to be present in simple distributional statistics (e.g., Landauer & Dumais, 1997; McDonald, 2000).

Based on the convergence of these recent studies into a cognitive role for distributional information in explaining language ability, we call the general principle under exploration the *Distributional Hypothesis*. The purpose of the present paper is to further test the distributional hypothesis, by examining the influence of context on similarity judgements involving marginally familiar and novel words. Our investigations are framed under the 'semantic space' approach to representing word meaning, to which we turn next.

Distributional Models of Word Meaning

The distributional hypothesis has provided the motivation for a class of objective statistical methods for representing meaning. Although the surge of interest in the approach arose in the fields of computational linguistics and information retrieval (e.g., Schutze, 1998; Grefenstette, 1994), where large-scale models of lexical semantics are crucial for tasks such as word sense disambiguation, high-dimensional 'semantic space' models are also useful tools for investigating how the brain represents the meaning of words.

Word meaning can be considered to vary along many dimensions; semantic space models attempt to capture this variation in a coherent way, by positioning words in a geometric space. How to determine what the crucial dimensions are has been a long-standing problem; a recent and fruitful approach to this issue has been to label the dimensions of semantic space with *words*. A word is located in the space according to the degree to which it *co-occurs* with each of the words labelling the dimensions of the space. Co-occurrence frequency information is extracted from a record of language experience – a large corpus of natural language. Using this approach, two words that tend to occur in similar linguistic contexts – that is, they are *distributionally* similar – will be positioned closer together in semantic space than two words which are not as distributionally similar. Such simple distributional knowledge has been implicated in a variety of language processing behaviours, such as lexical priming (e.g., Lowe & McDonald, 2000; Lund, Burgess & Atchley, 1995; McDonald & Lowe, 1998), synonym selection (Landauer & Dumais, 1997), retrieval in analogical reasoning (Ramscar & Yarlett, 2000) and judgements of semantic similarity (McDonald, 2000).

Contextual co-occurrence, the fundamental relationship underlying the success of the semantic space approach to representing word meaning, can be defined in a number of ways. Perhaps the simplest (and the approach taken in the majority of the studies cited above) is to define co-occurrence in terms of a 'context window': the co-occur-

rence frequency of w_1 with w_2 is defined as the number of times that w_2 (the 'context word') occurs in the window of n words surrounding w_1, summed over all instances of w_1 in the corpus. Given a set of k context words, any word in the vocabulary can be represented as a k-dimensional vector of co-occurrence frequencies. The best fit to psychological data is typically achieved with word vectors constructed using context window sizes between ±2 and ±10 words (see, e.g., Patel, Bullinaria & Levy, 1998).

Besides its emphasis on identifying a potential source of information useful for the development of semantic representations, the distributional hypothesis also accommodates predictions about the consequences of *manipulating* the learning environment. By modifying the degree of distributional similarity holding between two words in a person's language experience, a particular word's location in semantic space can be adjusted (i.e., a word vector can be 'pushed' in a given direction). In Experiments 1 and 2 we test whether manipulating contextual co-occurrence has behavioural consequences, by eliciting judgements of semantic similarity involving marginally familiar and nonce words embedded in biasing contexts.

Learning Word Meaning from Context

It is well-established that the context in which an unfamiliar word occurs is an important determinant of how much is learned about the word, and it is apparent that context often provides the sole means for establishing its meaning (e.g., Carnine, Kameenui & Coyle, 1994; Fischer, 1994). In order to interpret an unknown word, the context provides cues, in the form of some combination of: (1) the identity of the words in the context surrounding the unknown word and the relationships between these words and the unknown word (i.e., distributional information); (2) world knowledge retrieved from long-term memory associated with these words; and (3) the cognitive model of the discourse (or situation) currently being built. But it seems that distributional information on its own, if suitably constraining, could be sufficient for determining the meaning of an unfamiliar word. Consider the occurrence of the neologism *broamed* in the following context:

Because the capsule was hermetically broamed, its contents were in perfect condition after more than a hundred years under water.

In this example, knowledge about the distributional behaviour of *hermetically* certainly guides the inference that the meaning of *broamed* is similar to the meaning of *sealed*, because *hermetically* nearly always co-occurs with *sealed*. Further support for this inference is contributed by knowledge about capsules and the conditions required in order for something to remain in perfect condition in adverse circumstances.

Contextual cues also play an important role in consolidating the meaning of newly-learned words. The more exemplars of a word in its context of use that are encountered, the more its meaning can be refined and delimited, especially if one has some prior knowledge of the discourse or passage topic. We assume that a close correspondence exists between a word's subjective familiarity and the amount of experience one has with the word. The less experience, the less familiar the word and the less established its semantic representation in the brain.

In the experiments reported below, we attempt to manipulate the distributional knowledge associated with sets of marginally familiar and completely novel words in order to test a basic prediction of semantic space models in particular and the distributional hypothesis in general. Distributional information is the only variable manipulated; for each item we constructed two different paragraph contexts, each containing only four exemplars of the item. By judicious selection of the words in the context surrounding each instance of the word of interest, co-occurrence patterns can be created that resemble the patterns of other, more familiar words. Using semantic space model terminology, a word vector can be 'pushed' towards another vector by bringing dimensions of the space into alignment. The question we addressed was whether this manipulation of distributional information was sufficient to influence subjects' ratings of semantic similarity.

Experiment 1

Experiment 1 focuses on marginally familiar words. These are words that one is likely to have encountered, but not with sufficient frequency to have a firm grasp of their meaning. For instance, one might know that a *samovar* is some kind of utensil associated with hot drinks, but be unsure about whether it is used for making the drink or for serving it. So one might be equally willing to accept that *samovar* signifies something like a kettle or an urn. By exposing subjects to paragraphs containing exemplars of *samovar* together with contextual cues lexically associated with each of these possible interpretations (i.e., *urn* vs. *kettle*), subjects' representations of the meaning of *samovar* may be nudged towards the meaning of the word associated with the contextual cues. Thus the dependent variable we would like to measure is the similarity of the two words' semantic representations.

While such a measurement is not directly possible, psychologists have developed a number of indirect methods that purport to tap into the semantic representations of words. We needed a task that would allow similarity in meaning to be reliably measured, while at the same time remain sensitive to the hypothesised changes in semantic representations due to the context manipulation. Similarity ratings meet these criteria, having a long history of use in psychological investigations of word meaning (e.g., Osgoode, Suci & Tannenbaum, 1957), and importantly, similarity judgements have been shown to be affected by context. For instance, Barsalou (1982) demonstrated that in a 'pets' context, the concepts *snake* and *raccoon* were judged to be more similar than if no context was provided. Medin, Goldstone and Gentner (1993) also observed context-dependent similarity effects: *black* was rated as more similar to *white* when also compared to *red* than when *black*⇔*white* was the only comparison required. We expected that subjects' ratings of between-word similarity, such as *samovar*⇔*kettle*, would be

Context A: 'urn'

On his recent holiday in Ghazistan, Joe slipped easily into the customs of the locals. In the hotel restaurant there was a samovar dispensing tea at every table. Guests simply served themselves from the samovar whenever they liked. Joe's table had an elaborately crafted samovar. It was the first earthenware samovar that he had seen.

Context B: 'kettle'

On his recent holiday in Ghazistan, Joe slipped easily into the customs of the locals. His hotel room featured a samovar and a single hob. Each morning Joe boiled water in the samovar for tea. Like others he had seen on his holiday, Joe's samovar was blackened from years of use. He imagined that at some point it would be replaced with an electric samovar.

Figure 1. The *urn*-biased and *kettle*-biased paragraph contexts created for *samovar*.

similarly influenced by the properties of the paragraph context which they had just read.

Method

Participants Forty-eight subjects, mostly undergraduate Psychology students at the University of Edinburgh, were recruited. All participants were native speakers of British English.

Materials and Design A list of 20 marginally familiar words (ten nouns and ten verbs) was compiled. Sixteen items were selected from the pre-tested materials used by Chaffin (1997) in his study examining free associations made to high- and low-familiarity words, and the remaining four were chosen by the authors. Items ranged in frequency from 0.13 to 2.92 occurrences per million (median: 0.64), according to a lemma frequency list created from the 100 million word British National Corpus (BNC).

For each item, we generated two 'target meanings' which we felt were plausible interpretations of the items. Then, for each of these target meanings we composed a short paragraph containing exactly four exemplars of the item. (See Figure 1 for a representative item with its paragraph contexts). Text passages were homogenous in structure, with the first sentence setting the scene; the marginally familiar words were embedded in the following three or four sentences. Passages ranged in length from 50 to 96 words (median length of 62). We attempted to bias the interpretation of the item in the paragraph by seeding the immediate context of each exemplar with strong lexical associates of the selected target meaning. For example, the meaning of *samovar* in Context B is 'pushed' towards *kettle* through the words *boiled*, *blackened* and *electric*, which are all more indicative of kettles than urns.

The strong lexical associates were generated in turn using a statistical technique commonly employed in computational linguistics for discovering collocations (e.g., Church & Hanks, 1990; Manning & Schütze, 1999); this procedure involved, for each target meaning (e.g., *urn*, *kettle*), collecting the co-occurrence frequencies of all words found in a ±5 word window around it in the BNC, converting these counts using the log-transformed odds ratio statistic (Agresti, 1990), and then sorting the resulting list. Strong associates – roughly, words that co-occur more often than expected by chance – tend to appear at the top of the ranking. We then selected suitable words for use as contextual cues from the topmost part of the list.

Paragraph contexts were randomly assigned to one of the two levels of the Context factor (A, B). This design is now sufficient to test for an effect of Context when subjects are asked to rate the similarity between e.g., *samovar* and *urn* after reading either Context A or Context B. In order to complete a factorial design, Context was crossed with a second factor, Target Meaning, with the same two levels, varying the word to which the marginally familiar item is compared.

The materials were next divided into four versions of 20 paragraphs each. Counterbalancing ensured that no participant saw the same item more than once.

Procedure Subjects were divided randomly amongst each of the four versions. The experiment was administered in the form of a questionnaire, with one paragraph context per page. Located below each paragraph was a numbered seven-point scale, and subjects were instructed to rate how similar the item was to the target meaning, where 'a 1 means "not at all similar" and a 7 means "highly similar"'; e.g., "How similar is a *samovar* to an *urn*?". The verb items were presented in present participle form; e.g., "How similar is *absconding* to *escaping?*". Order of presentation of the 20 items was randomised individually for each participant.

After completing the 20 items, subjects were required to rate a list of 28 words for familiarity, also using a 7-point scale, where 'a 1 means "very unfamiliar" and a 7 means "very familiar"'. This list comprised the 20 designated items plus eight filler words of moderate to high familiarity. The purpose of the familiarity ratings task was to allow a more detailed examination of the similarity data, in order to take into consideration the inherent variability in individuals' experience with the items.

Results

We conducted two-way repeated measures analyses of variance (ANOVAs) on the similarity judgements, treating both subjects and items as random factors.

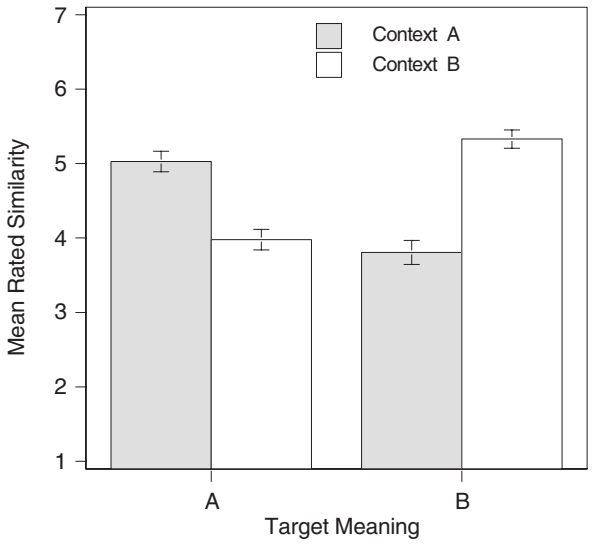

Figure 2. Mean semantic similarity as a function of Context and Target Meaning in Experiment 1.

There were no reliable main effects of either Target Meaning, $F_1(1,47)=4.02$, $MSE=0.667$, $p>0.05$; $F_2(1,19)=1.59$, $MSE=0.694$, $p>0.2$, or Context, $F_1(1,47)<1$; $F_2(1,19)<1$. The lack of a Target Meaning main effect indicates that, collapsing over the paragraph contexts in which the marginally familiar items were embedded, there was no bias between the 'A' and 'B' meanings in terms of their rated similarity to the item. The lack of a main effect of Context indicates an analogous absence of bias for the paragraph contexts.

There was a highly significant Context × Target Meaning interaction: $F_1(1,47)=60.04$, $MSE=1.323$, $p<0.001$; $F_2(1,19)=35.73$, $MSE=0.924$, $p<0.001$). As indicated by Figure 2, the interaction was due to Context effects at each level of Target Meaning. The mean similarity rating between a marginally familiar word and its 'A' meaning was higher when the item was embedded in the context biasing that meaning than when it appeared in the passage biasing the 'B' meaning.

Discussion

These results indicate that the distributional information contained in the paragraph contexts are sufficient to influence participants' similarity judgements. In the terminology of semantic space models, vectors were successfully 'pushed' towards other vectors in the representational space. Thus a strong prediction of the semantic space theory of meaning representation is supported: by selecting appropriate contextual cues and positioning them in the immediate linguistic context of a marginally familiar word, behavioural measures assumed to tap the word's meaningful properties can be influenced.

The results also provide support for the distributional hypothesis. Adding instances of a word in its environment of use to one's language experience – even as few as four exemplars – appears to be adequate to affect one's perception of its similarity in meaning to other words.

Although the items were chosen to be on the frontiers of familiarity for the subject population, the familiarity of a particular word can vary substantially between participants. For example, *samovar* may be a familiar word to someone who has travelled in Russia. According to the distributional hypothesis, this individual should be less influenced by the context when rating the similarity of *samovar* to *kettle* or to *urn*.

As we had collected familiarity ratings for each of the targets from each subject, we were able to address this question by dividing the ratings data points into low-familiarity (LoFam) and high-familiarity (HiFam) groups around the median familiarity score. The LoFam partition included data points with a self-rated familiarity score of three or less, and the HiFam group contained data for items rated as five or more.

The critical Context × Target Meaning interaction was present in the LoFam partition: $F_1(1,29)=59.24$, $MSE=1.80$, $p<0.001$; $F_2(1,17)=21.61$, $MSE=1.82$, $p<0.001$. The HiFam partition also displayed the interaction: $F_1(1,36)=21.55$, $MSE=1.80$, $p<0.001$; $F_2(1,17)= 30.28$, $MSE=0.92$, $p<0.001$.

It seems, then, that subjects' interpretations of marginally familiar words could be guided by the distributional properties of the contexts in which they were encountered, at least to the extent necessary to influence an immediately executed similarity rating. This effect was observed both for words with which subjects considered themselves reasonably familiar and for less familiar words.

The results of Experiment 1 raise two interesting questions with regard to our subjects' mental representations of the meanings of the stimuli: Were subjects actively using the distributional information in the contexts to actively augment (or even construct) their representation of the meaning of *samovar*? Or were the paragraph contexts activating particular features of their existing knowledge about samovars, causing the attendant shift in similarity ratings? In the latter case it could be argued that subjects' sensitivity to the distributional properties of words demonstrated in Experiment 1 is merely an epiphenomenon, a reflection of the fact that certain concepts share certain semantic features. On this account, the distributional properties associated with words arise *because* the concepts underlying the words possess certain features, and it is sensitivity to similarities between these concepts that subjects are actually manifesting. To examine these competing explanations, Experiment 2 controlled for the influence of any such prior conceptual knowledge by replacing Experiment 1's items with nonce words. Subjects were essentially starting from a 'tabula rasa' with respect to the meaning of nonce words, so evidence that the context was truly exerting an independent influence on subjects' judgements in Experiment 1 would be provided if similar effects of context are observed using nonce words.

Experiment 2

Experiment 2 controlled for the potential influence of participants' existing conceptual knowledge about the meaning of the target items by replacing the marginally

familiar items used in Experiment 1 with nonce words. (Thus the task now closely resembles the situation where an unknown word is encountered during reading, and its meaning has to be inferred from the context.)

Method

Participants Twenty subjects from the same population as Experiment 1 volunteered to take part.

Materials and Design The materials were identical to those used in Experiment 1, with the exception that the 20 marginally familiar items were replaced with orthographically-legal and pronounceable nonwords. For instance, all occurrences of *samovar* in the text passages were replaced with the nonce word *balak*. Care was taken that each nonce replacement did not phonologically resemble the original item or its two associated 'target meanings'.

Procedure The procedure was the same as for Experiment 1, except there was no familiarity ratings task.

Results and Discussion

Similarity ratings data were submitted to repeated measures ANOVAs. The Target Meaning × Context interaction was significant both by subjects: $F_1(1,19)=159.83$, $MSE=0.469$, $p<0.001$; and by items: $F_2(1,19)=40.23$, $MSE=1.863$, $p<0.001$. There were no main effects of either Target Meaning: $F_1(1,19)=1.09$, $MSE=0.385$, $p>0.3$; $F_2(1,19)<1$ or Context: $F_1(1,19)<1$; $F_2(1,19)<1$.

Thus these results are consistent with the findings of Experiment 1. It appears that any objections regarding the possible role and influence of prior knowledge about the meanings of Experiment 1's marginally familiar items are unfounded. Similarity comparisons involving unknown (nonce) words were also susceptible to manipulation of the same contextual cues that gave rise to the interaction in Experiment 1.

Simulating the Accumulation of Contextual Experience

Experiments 1 and 2 have shown that a very small amount of experience with a word in context is capable of influencing similarity judgements involving that word. The items in Experiment 1 were selected to represent the sorts of words to which subjects would be expected to have a low level of prior exposure. If it were possible to *increase* the amount of one's prior contextual experience with a given item, the influence of subsequent exposure (i.e., the four-exemplar paragraphs in Experiment 1) should be reduced. We simulated this effect of previous experience using a semantic space model derived from distributional statistics. We predicted that the size of the simulated context effect would diminish as the ratio of previous experience to the experience provided by the paragraphs increased. We varied the amount of contextual exposure given to the model by varying the size of the corpus used to construct co-occurrence vector representations for the 20 marginally familiar items.

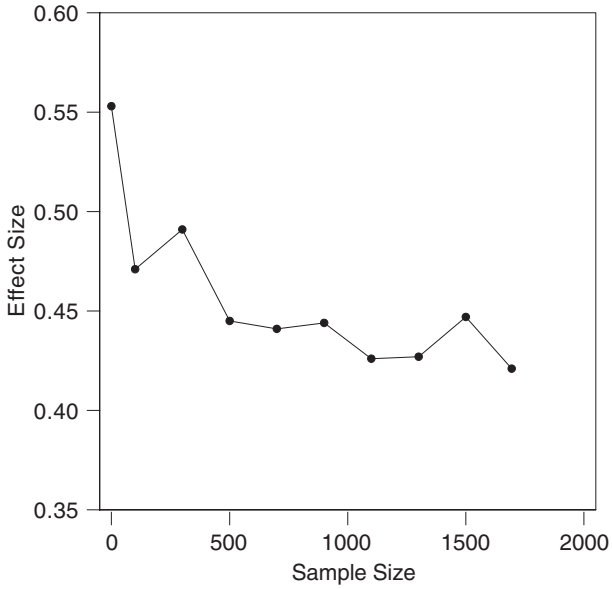

Figure 3. The size of the Consistency effect as a function of the amount of contextual experience.

Method

From the BNC, we extracted the ±5 word contexts surrounding every occurrence of all 20 items (a total of 1,694). We then took random samples (with replacement) of various sizes from this item-in-context 'corpus', appending them to both an analogous corpus formed by the 'A' passages and the corpus formed by the 'B' paragraphs, resulting in separate 'A' and 'B' corpora for each sample size.

From each 'corpus', we extracted co-occurrence vectors for the 20 items using a window size of ±5 words and the 20,000 most frequent content words as context words. The resulting item vectors thus directly reflect the ratio of previous experience to subsequent experience (vectors created from the passages only simulate a complete lack of previous experience with the word). Vectors for the 40 'target meanings' (e.g., *urn*, *kettle*) were constructed using the entire BNC.

Results and Discussion

We collapsed the 2 × 2 design of Experiment 1 into a single factor, Consistency, in order to compare the vector similarity of an item with each of its 'target meanings', between the case where the paragraph context is consistent with (or biases) the target meaning (e.g., *samovar*⇔*urn* for Context 'A'; see Figure 1) and the case where it is inconsistent (*samovar*⇔*urn* for Context 'B'). Similarity was computed as the cosine of the angle between vectors, and a paired-*t* test was conducted on the cosine measurements. Consistent comparisons should return a larger cosine than Inconsistent comparisons. At the $\alpha=0.01$ level of significance, reliable Consistency effects were observed for all sample sizes but one (the effect for the 1100-exemplar sample was significant at $\alpha=0.05$).

In order to illustrate the effect of increasing the amount of previous experience, Figure 3 displays the Consistency effect size (Cohen's *d*) as the sample size varies. As expected, the effect is largest for vectors created from the passages only, and diminishes as more contextual experience is added. Both Experiment 1's results and the anticipated effect of variable amounts of prior exposure were simulated in a semantic space model drawing only upon distributional information.

General Discussion

To summarise, manipulating the contextual cues present in short text passages was sufficient to influence adults' similarity judgements involving marginally familiar and nonce words embedded in these passages. Our results suggest that readers' interpretations of these items were 'pushed' towards the meanings of other words. Analogous to the way that the meaning of unknown words can be determined while reading, contextual information is also an influential factor when consolidating the meaning of words on the frontiers of familiarity.

The experimental results also suggest that a remarkably small amount of exposure to a word in a meaningful context is sufficient to influence similarity ratings. However, the relative recency of this experience is likely an important factor; the context effect may well diminish as a function of the length of time between reading the paragraph and making the similarity judgement.

Though a simple model of word learning, the semantic space simulation illustrated the decrease in susceptibility to contextual manipulation expected as one's prior experience with a word increases. Of course, we do not claim that human semantic space has 20,000 dimensions; rather, what is important is the inferences that can be drawn about a word's meaning simply by taking note of the words in its immediate context. It is notable that the simulated Consistency effect was still reliable even after all the contextual experience in the BNC was added; in as much as the BNC can be considered to represent the average person's language exposure, it seems that very little extra contextual experience is needed to affect the perception of a word's similarity in meaning to other words.

Abstract

Verbs are a major component of theories of language processing, partly because they exhibit systematic restrictions on their arguments. However, verbs follow their arguments in many constructions (particularly in verb-final languages), making it inefficient to defer processing until the verb. Computational modeling suggests that during sentence processing, nouns may activate information about subsequent lexical items, including verbs. We investigated this prediction using short stimulus onset asynchrony (SOA, the time between the onsets of the prime and target) priming. Robust priming obtained when verbs were named aloud following typical agents (nun - praying), patients (dice - rolled), instruments (shovel - digging), and locations (arena - skating). This research is the first to investigate systematically the priming of verbs from nouns. It suggests that event memory is organized so that entities and objects activate the class of events in which they typically play a role (Lancaster & Barsalou, 1997). These computations may be an important component of expectancy generation in sentence processing.

Introduction

Expectancy generation is a central construct in many theories of language comprehension, although the term has been used in a variety of ways. In the current work, we use it to refer not to explicit generation of expectancies (as in Becker's, 1980, verification model) but rather to the implicit expectancy generation that is a natural by-product of language comprehension processes (as exemplified, for example, by simple recurrent networks and other types of networks that implement processing through time, or by incremental parsing models with a predictive component). Consistent with the notion that comprehenders implicitly generate expectations, a number of computational models and human experiments have shown that both local and global context can narrow expectations for upcoming words in a sentence (e.g. Elman, 1990; Schwanenflugel & Shoben, 1985).

Expectancy generation in theories of sentence processing has focused primarily on verbs. This is reasonable because verbs, as predicating functions, tend to exhibit regular and systematic restrictions on the arguments with which they co-occur. In line with this notion, researchers have concentrated on the ways in which people's knowledge of verb argument structure and of the thematic roles associated with verbs constrains what may follow. It has been shown, for example, that a verb can restrict the range of syntactic structures or broad classes of words that are likely to follow it. One clear example of this is the influence of verb subcategorization preferences on resolving the direct-object/sentence complement ambiguity (Garnsey et al., 1997).

Thematic Roles

Verbs and their associated thematic roles are a major component of most linguistic and psycholinguistic theories of language processing, and many psycholinguistic experiments have focused on thematic role assignment. One reason for this is that thematic roles are hypothesized to be an important locus of semantic/syntactic interaction (Tanenhaus & Carlson, 1989). Recently, McRae, Ferretti, and Amyote (1997) incorporated and extended the important work of Carlson and Tanenhaus (1988), Dowty (1991), and others to construct a theory of thematic roles that incorporates event-specific information. On this account, thematic roles are viewed as including verb-specific concepts, and this conceptual/world knowledge is computed and used immediately in on-line language

processing (see Altmann & Kamide, 1999, for supportive evidence from head-mounted eyetracking). As part of this research, Ferretti, McRae, and Hatherell (2001; Experiments 1 and 2) showed that verbs in isolation prime typical agents, patients, and instruments. Their Experiment 4 showed further that priming was limited to the appropriate role when active versus passive sentence fragments were used to cue roles. Given these conjoint effects of semantic and syntactic cues, they concluded that verbs activate event schemas and that this knowledge should be considered as part of thematic roles.

Expectancies from Nouns to Verbs

Because of the emphasis on verbs in the sentence processing literature, one often finds characterizations in which processing is dependent to a high degree on the verb, implying that processing may be held in abeyance until the verb is heard or read. However, in verb-final languages such as German, deferring any hypothesis about structure and meaning until the end of the sentence or clause would be an inefficient processing strategy (Frazier, 1987). Furthermore, a number of recent articles have addressed incremental syntactic processing in verb-final constructions in German and Japanese (e.g., Kamide & Mitchell, 1999).

There are reasons to believe that under many circumstances, words from major syntactic categories other than verbs may exert powerful constraining forces on expectancy generation. For example, nouns can possess valence restrictions, although they do so to a lesser degree than do verbs. In addition, our work with modeling suggests that network dynamics will encode the degree to which elements other than the verb restrict the range of what may follow. Therefore, non-verbs may generate powerful expectations about what might follow, including expectations about possible verbs.

Strong candidates for driving expectations for semantic classes of verbs are typical fillers of their thematic roles: that is, the agents, patients, and instruments that often are involved in specific types of events, as well as locations at which specific events typically occur. The present research was designed to test this possibility. The logic underlying the experiment is that certain nouns may produce expectations for certain semantic classes of verbs during normal on-line sentence comprehension by activating event schema knowledge. If nouns do activate event knowledge associated with verbs, then those nouns should prime corresponding verbs in a short SOA single-word priming task. Note that we are not claiming that expectancy generation necessarily drives performance in a short SOA priming task. Instead, the claim is that nouns activate event schemas, and this drives the priming. The implication is that this knowledge, once activated, can then serve as a source for expectancy generation during on-line comprehension of full sentences in natural language.

Before describing the experiment itself, we briefly outline another aspect of the theoretical motivation, based on recent work on event memory.

Autobiographical Event Memory

In much the same way that language researchers have focused on knowledge computed from verbs, theories of autobiographical memory often have focused on activity as a primary organizing principle of event representations. Some researchers have characterized this as the strong activity view, whereby events are organized and accessed by activity only. Thus in parallel with the emphasis on verbs in the psycholinguistic literature, much of the literature on the organization of autobiographical memory emphasizes the centrality of events, which often are realized linguistically as verbs. The Ferretti et al. (2001) results showing that some verbs provide strong expectations for classes of noun concepts to fill specific thematic roles could be viewed as on-line support for this position.

At the same time, the literature on the organization of event memory also suggests that nouns may produce expectations for specific classes of verbs. Lancaster and Barsalou (1997) found that people are adept at organizing short narratives in terms of multiple components of events, including activity (i.e., by verb), time, participants (i.e., agents and patients), and location. They argued that contrary to the strong activity view, memory is organized to allow access from multiple components of events.

Our argument assumes that people's knowledge of a generalized event such as skating is constructed over time from individual event instances, and can be computed in multiple ways. If this is correct, nouns should quickly activate well-learned event knowledge, so that typical agents, patients, instruments and locations should prime verbs denoting the event.

Experiment

The present research tested this prediction using short SOA priming from nouns to verbs. The noun primes referred to entities, objects, and locations that are typically involved in the events denoted by the target verbs. We predicted shorter naming latencies for verbs primed by their common thematic role fillers than for verbs primed by unrelated nouns because a related noun will activate the schema corresponding to the type of event in which it typically participates, thus activating a verb denoting that type of event.

Method

Participants. Forty University of Western Ontario undergraduates participated for course credit. All participants were native speakers of English and had normal or corrected-to-normal visual acuity.

Materials. To tap into people's knowledge of the types of events in which certain entities and objects play a specific role, we used what we will refer to as thematic-based event generation norms. These norms are designed to estimate the conditional probability of a generalized event given an entity or object playing a specific role. Participants were asked to generate verbs in response to typical agents, patients, instruments, and locations. In the agent norms, participants were given nouns such as nun and were asked to "List the things that these people commonly do." In the patient norms, participants were given nouns such as dice and asked to "List the things that these objects/people commonly have done to them." In the instrument norms, participants were given nouns such as shovel and asked to "List the things that people commonly use each of the following to do." Finally, in the location norms, participants were given nouns such as arena and asked to "List the things that people commonly do at/in each of these locations." both For each item, ten blank lines were provided for responses. No time limit was imposed. Participants were undergraduate students from Bowling Green State University. Each participant completed only one list; there were approximately 25 items per list. In total, 20 participants responded to each item.

Responses were scored based on their rank order within a participant, and on their response frequency. That is, each response was scored in terms of the number of participants listing it first, second, third, through to tenth. A weighted score was calculated for each response by multiplying the frequency with which it was produced first times 10, second times 9, and so on, and then summing those products. Wherever possible, noun-verb pairs were chosen for the priming experiment by taking the verb with the highest weighted score. In a few cases, the response with the highest weighted score could not be used because it was a multi-word phrase, such as work out for gymnasium, and the constraints of the naming task demanded a single-word verb target. In a few other cases, the same verb was the best response for more than one item (e.g., cut for both chainsaw and knife). In both of these cases, the verb chosen for the priming experiment was either the next-best response, or a synonym or near synonym of the best response. For example, because cutting was used as the target for chainsaw, slicing was used instead of cutting as the target for knife.

From these norms, we chose 30 agents paired with the present participle of a verb such as nun - praying, waiter - serving, and lawyer - defending, 30 patients paired with the past participle form of a verb, such as teeth - brushed, dice - rolled, and tax - paid, 32 instrument-present participle pairs such as shovel - digging, pen - writing, and chainsaw - cutting, and 24 location-present participle pairs such as cafeteria - eating, bedroom - sleeping, and bathroom - showering. The weighted scores for the verbs for each thematic role were (maximum of 200): agents, $M = 91$, $SE = 10$; patients, $M = 111$, $SE = 10$; instruments, $M = 134$, $SE = 8$; and locations, $M = 114$, $SE = 11$.

Target verbs were presented in present participle form with the agent, instrument, and location primes. Verb targets paired with typical patients, however, were presented in their past participle forms to avoid including prime-target pairs that formed coherent familiar phrases, such as cigar smoking.

Lists. Two lists were created for each type of noun (i.e., agents, patients, instruments, and locations). Each list contained half of the related and the opposing half of the unrelated items. Unrelated items were created by re-pairing the nouns and verbs from the related trials in the opposite list. Filler trials consisted of unrelated noun-verb pairs such as stapler vacuuming. Each list contained four times as many unrelated filler trials as related target items (relatedness proportion was .17). Thirty-five unrelated practice trials were used for the practice session for every participant. No participant saw any word twice.

Procedure. For each trial, the participant was instructed to read silently the first word presented on the computer screen and to pronounce aloud the second word as quickly and accurately as possible into the microphone. Stimuli were presented on a 14-inch Sony Trinitron monitor connected to a Macintosh LC630 using PsyScope (Cohen et al., 1993). A microphone connected to a CMU button box measured naming latency (in ms) as the time between the onset of the target and the participant's pronunciation of it. Each trial consisted of: a focal point (*) for 250 ms; the prime for 200 ms; a mask (&&&&&&&&&) for 50 ms; and the target until the participant named it. The intertrial interval was 1500 ms, and a break was given every 40 trials. Testing sessions began with the practice trials and lasted approximately 20 minutes. The experimenter recorded trials in which the participant mispronounced a word (a pronunciation error), extraneous noise caused the voice key to trigger (a machine error), or the voice key failed to trigger (a machine error). Participants were assigned randomly to be tested on either the agents and locations, or on the patients and instruments. The order of the two lists was counter balanced across participants (i.e., ten participants were tested on agents then locations, and another ten on locations then agents, and the same for the patients and instruments).

Design. Naming latencies and the square root of the number of pronunciation errors (Myers, 1979) were analyzed by separate two-way analyses of variance for each thematic role (agents, patients, instruments, and locations). The factor of interest was relatedness (related vs. unrelated), which was within both participants (F_1) and items (F_2). List was included as a

Table 1: Mean Verb Naming Latencies (ms) and Percentage Pronunciation Errors

	Agents		Patients		Instruments		Locations	
Dependent Measure	M	SE	M	SE	M	SE	M	SE
Response Latency								
Unrelated	592	21	583	20	565	20	578	16
Related	574	19	561	18	549	17	560	19

Percentage Errors								
Unrelated	1.9	0.8	3.2	1.4	1.4	0.7	2.5	1.2
Related	1.9	0.9	1.9	0.8	1.1	0.6	1.5	0.8
Facilitation	0		1.3		0.3		1.0	

* Significant by participants and items

between-participants dummy variable and item rotation group as a between-items dummy variable to stabilize variance that may result from rotating participants and items over the two lists (Pollatsek & Well, 1995).

Results

Naming latencies greater than three standard deviations above or below the grand mean were replaced by that value (1% of trials). Two participants were dropped because their soft speaking style resulted in an extreme number of trials in which the voice key was not activated. Machine errors, the majority of which were caused by the microphone failing to register the participant's response, occurred on 4% of the trials, were excluded from all analyses. Pronunciation errors were excluded from the latency analyses. Mean naming latency and percent pronunciation errors are presented for each condition in Table 1. Verbs were named more quickly when preceded by a related versus an unrelated noun for each of the four thematic roles: agents: $F_1(1,18) = 6.19$, $p < .05$, $F_2(1,28) = 4.12$, $p < .06$; patients: $F_1(1,18) = 7.54$, $p < .05$, $F_2(1,28) = 11.98$, $p < .001$; instruments: $F_1(1,18) = 5.66$, $p < .05$, $F_2(1,30) = 7.64$, $p < .01$; and locations: $F_1(1,18) = 5.33$, $p < .05$, $F_2(1,22) = 10.41$, $p < .01$. There were no reliable differences in pronunciation error rates, all F's < 1.

Discussion

Noun-verb pairs were chosen using thematic-based event generation norms designed to tap into people's knowledge of the conditional probability of a generalized event given an agent, patient, instrument, or location. Significant noun-verb priming was found in all four cases. To our knowledge, this is the first experiment to investigate systematically the priming of verbs from nouns.

This experiment shows that nouns make available information about events in which they typically play a role. One plausible explanation of these results is that, as in the weak activity view of event memory (Lancaster & Barsalou, 1997), event schemas are organized so that they are accessible from common agents, patients, instruments and locations. That is, mental representations of generalized events are structured so that they can be computed quickly when a noun that refers to a typical component of a specific type of event is read or heard. When this generalized event knowledge is computed, the verb corresponding to this type of event is partially activated, thus resulting in the priming effects found in the Experiment. In other words, language and event memory are organized so that event knowledge can be accessed quickly from nouns, as well as from verbs. This explanation is consistent with Moss et al. (1995) who found priming using functionally-related items such as broom-floor. Moss et al. concluded that priming in their experiment occurred through representations of generalized events.

The fact that nouns can activate information about corresponding verbs suggests that, at least in some circumstances, nouns may be a strong source of expectancy generation for ensuing verbs. This may be particularly important for languages such as German and Japanese, which contain numerous verb-final constructions, but it may also play a key role in sentence comprehension (and production) in English. At least one noun phrase precedes the verb in the vast majority of English utterances, and in many constructions the verb appears late in the clause, as in questions (Which customer did he serve?) and it-clefts (It was vase on the coffee table that she broke.).

One question that might be asked of the present results is why priming was found from locations to verbs, whereas Ferretti et al. (2001) failed to find

priming from verbs to locations. The most likely explanation concerns the type of norming used in the two experiments. The present study used thematic-based event generation norms designed to tap people's knowledge of the conditional probability of an event given (in this case) a location. In contrast, Ferretti et al. used role/filler typicality norms in which participants were asked to provide ratings for questions such as "How common is it for someone to draw in each of the following locations?" This may not be the best way to measure the conditional probability of the location given the event. For example, although the mean role/filler typicality rating for draw-studio was 6.5 out of 7, there are numerous locations where drawing can occur, and a studio might not rank as the best.

To test this possibility, we conducted a further set of norms, parallel to the event generation norms used in the current study. Participants listed locations at which some event might occur, providing an estimate of the conditional probability. In these norms, the mean weighted score for Ferretti et al.'s (2001) verb-location items was only 44 (maximum of 200). In contrast, the mean weighted score of the location-verb items used in the present research was 114. This difference between the conditional probabilities in the relevant directions may account for the discrepancy between studies.

Note, however, that the Ferretti et al. (2001) study did find robust priming in the other three verb-noun conditions (i.e., verbs primed agents, patients, and instruments), raising the possibility that our results may be due to backward priming from the verb. If this was the case, it would seriously reduce the theoretical import of our results. In response to this potential criticism, we note that Kahan, Neely, and Forsythe (1999) and Peterson and Simpson (1989) have shown that backward priming occurs in a naming task at a short SOA, but not at an SOA of 500 ms. Therefore, we currently are replicating this experiment using a 500 ms SOA. If verbs are primed, which we expect they will be given the conditional probabilities as evidenced by our norms, then we can be positive that backward priming is not responsible for our results.

Spreading Activation Networks. A common explanation of word-word priming results focuses on spreading activation in a semantic network. Therefore, an interesting question concerns whether spreading activation networks would predict priming of verbs from agents, patients, instruments, and locations. Although the first semantic networks focused solely on noun representations (Collins & Quillian, 1969), relatively early extensions incorporated verbs (Gentner, 1975; Rumelhart & Levin, 1975). Verb representation included core meaning plus thematic links to nodes that stood as placeholders for possible noun phrases that fill those roles in sentences. Note that these links could be bi-directional, so that activation could spread from the thematic role nodes to the verb node. However, these thematic links and nodes included minimal semantic content that was restricted to general selectional restriction information. For example, a thematic link between a verb and an agent node might specify that the filler of that node must be animate. Thus, spreading activation models of this type predict no priming because the experiment reported herein controlled for general selectional restrictions in that the related and unrelated trials were equivalent in terms of this factor.

If current semantic networks were expanded, it could be assumed that noun nodes representing common agents, patients, instruments, and locations become linked to specific verb nodes over time. These links might be formed because of people's experience with events (via noticing that chainsaws are used for cutting), and/or linguistic descriptions of events (e.g., via word co-occurrence in speech and text). In this view, when participants read the noun prime in our experiment, activation might spread to the verb node and priming might result. Thus spreading activation networks could predict priming of verbs from typical thematic role fillers, but only by incorporating ad hoc assumptions well outside the scope of current versions of the theory.

Undifferentiated links encoding associative relatedness provide a possible second way in which spreading activation networks might predict priming from typical thematic role fillers to verbs. If the representations of words and/or concepts that often co-occur in events and language become linked in one or more of semantics, orthography, and phonology via an unspecified associative relation, then those links could serve as the basis for priming from nouns referring to typical components of events to verbs. Theoretically, however, it is a step backward to treat this knowledge as an undifferentiated associative relation because it is known to be thematic-driven knowledge concerning the relationship between generalized events and their common components.

Finally, a recent experiment, part of this line of research, produced results that are extremely difficult for a spreading activation network to account for, even given the additional ad hoc assumptions described above. Ferretti (2000) manipulated verb aspect to reference various components of the temporal structure of events. In one condition, he presented a verb prime in its imperfective aspect (e.g., was skating), which references an event as ongoing. Ferretti reasoned that if an event is in the process of occurring, then the location at which the event is taking place should be salient. In the second condition, the verb prime was presented in its past perfect form (e.g., had skated), which references the event as completed. That is, perfect aspect focuses on the resultant states of an event. Ferretti reasoned that if the event is referred to as completed, the location at which that type of event typically occurs should not be as salient. Thus, if priming is due to event knowledge and aspect references various components of the

temporal structure of events, priming should be found with imperfective aspect (where location is salient) but not with perfect aspect (where it is not). In a spreading activation network account, there should be no influence of aspect. In a short SOA priming task, typical locations were significantly primed by verbs presented in their imperfective aspect, whereas no priming obtained when perfect aspect was used. These results follow naturally from an account in which priming occurs via event schemas. However, accounting for them in a spreading activation network requires incorporating some mechanism by which aspect can modulate the flow of activation.

Conclusions

Event memory is organized in multiple ways, making it accessible from nouns as well as from verbs. Because of this, agents, patients, instruments, and locations prime verbs denoting events in which they typically play a specific role. These results suggest that nouns can be a basis for generating expectancies for upcoming verbs during on-line sentence comprehension.

Spatial Experience, Sensory Qualities, and the Visual Field

Douglas B. Meehan (dbmeehan@yahoo.com)
Department of Philosophy, CUNY Graduate Center

New York, NY 10016-4309 USA

Abstract

An explanation of the qualitative nature of visual experience must account for the spatial character of visual sensations. We need mental locations and a mental visual field to explain how visual sensations enable us to perceive physical entities as located, to explain the differences in the spatial characters of sensations revealed in introspection, and to explain the spatial character of visual anomalies such as nonillusory afterimages. But mental locations are properties of mental states, not objects, so they must not be spatial locations. I argue that the homomorphism view of sensory qualities, pioneered by Wilfrid Sellars (1956, 1959, 1960, 1967) can best explain the nature of mental space. This view explains mental locations as nonspatial mental counterparts of physical locations. Austen Clark (1996, 2000) rejects mental location, claiming that the spatial character of sensory experience can be explained in terms of the spatial properties of distal stimuli and of sensory receptors. I argue that Clark's theory fails in two respects: 1) it fails to explain how it is that we individuate our sensory experiences with respect to apparent spatial differences, and 2) we cannot make the psychophysical identifications needed to get Clark's theory off the ground without first picking out the sensations by their mental properties.

Introduction

The current philosophical literature on visual experience is rife with debate on the issue of the qualitative character of sensory experience. The debate focuses largely on the topic of color and color qualia. But an explanation of color qualia will not exhaust a philosophical account of the qualitative nature of visual experience. We must also explain the nature of the spatial character of visual experience. Just as there is a qualitative difference between seeing something red and seeing something green, there is a qualitative difference between seeing a red patch off to one's right and seeing a red patch off to one's left. What it is like to see a red patch off to one's right is different from what it is like to see a red patch off to one's left.

But what are these qualitative spatial properties and relations? Are they actually spatial? When one has a visual experience of a red patch to the left of another red patch are there two phenomenal red entities located next to one another? And if they are located in any sense, where are they located? Are they located in some mental space—a visual field?

I argue that we do need to posit a mental space or visual field to explain the spatial character of visual experience. And I argue that the homomorphism view of sensory qualities, pioneered by Wilfrid Sellars (1956, 1959, 1960, 1967)[1] offers the best solution. In so doing I examine and reject Austen Clark's (1996, 2000) recent repudiation of mental space.

1. From Sensations to Sensory Fields

At the most basic level, we become conscious of our surroundings by having sensations that represent those surroundings. Sensations have perceptual roles. We see a red firetruck because we have a sensation of a certain type. We see a yellow Volkswagen because we have a sensation of another type. We see a red firetruck to the left of a yellow Volkswagen because we have a sensation of yet another type. Visual sensations enable us to perceive the firetruck next to the Volkswagen.

If we detect differences in visual stimuli by having different sensations, those sensations must vary in ways corresponding to perceptible differences in visual stimuli. Since we see entities by seeing differences in color, visual sensations must have properties corresponding to physical color properties. I will call these properties mental colors. I adopt Sellars's notational device of suffixing a '*' to color predicates to indicate reference to mental colors—e.g., red* is the sensory quality that enables us to perceive surfaces we call red.

We also perceive visual stimuli as having spatial properties. That we perceive the red firetruck as being to the left of the yellow Volkswagen seems to entail that our visual sensations have properties corresponding to the locations of the firetruck and Volkswagen. If sensations enable us to perceive stimuli as being located, sensations must have properties corresponding to locations. They must have mental locations, or locations*. Seeing an entity off to the right requires that one has a visual sensation with a property corresponding to being off to the right. Thus, we can infer that there are mental locations from the fact that

[1] The homomorphism view has also been argued for more recently by David Rosenthal (1998, 1999, 2000) and Sydney Shoemaker (1975). The version I argue for is closest to Rosenthal's.

we can perceive distal stimuli as occupying physical locations.

We can also introspect our sensations. When we do, we are conscious of them as having certain qualities. For instance, when introspecting the sensation that enables us to perceive the red firetruck to the left of the yellow Volkswagen, we are conscious of the sensation as being of a certain type—a sensation of a big red patch to the left of a little yellow patch. Introspection reveals the ways that sensations differ from one another, so it reveals something about the mental properties of those sensations. Inasmuch as sensations can differ with respect to apparent color and apparent location, they must have colors* and locations*.

In fact, we have sensations even in the absence of the appropriate stimuli. For instance, I can have a sensation of red at the center of my visual field without there being anything red directly in front of my eyes. We might claim that I am in the kind of sensation normally had when there is a red thing in the center of my distal visual field. Inasmuch as this state differs from the kind of sensation normally had when there is a red thing in the periphery of my distal visual field, we need to explain how it differs. This suggests some property of the sensations corresponding to the locations of their normal distal causes.

A strong example of sensations in the absence of stimuli is the phenomenon of nonillusory afterimages. A nonillusory afterimage is a sensation of a bright pattern one has after a flashbulb goes off in one's eyes. The afterimage seems to occlude objects in the distal visual field. When one moves one's eyes, the afterimage appears to occlude different objects.

But these afterimages are nonillusory. One does not think that there is some bright patterned object moving along with one's eyes. One thinks that it just appears that way. As Paul Boghossian and David Velleman put it, "The after-image must … be described as appearing in a location without appearing to be in that location ..." (1989, p. 91). An explanation of this fact, according to Boghossian and Velleman, is that the afterimage is located in a visual field. This visual field overlays the distal visual field, so the afterimage occludes whatever its region of the visual field happens to overlay. Since an afterimage appears in a location without appearing to be in a location, there must be mental space in addition to physical space.

But how do we explain mental space? Is it actually spatial? Is the afterimage located on some two dimensional transparency? This hardly seems feasible. If the mental visual field is an overlay through which we look at the world, we still need to explain how it is that we look through the overlay. Such an explanation must posit further states to mediate our seeing through the overlay. This will require another overlay, and so on ad infinitum.

Further, sensations are mental states, or events, not objects. Although a state is a state of some entity located somewhere, it is not clear how that location helps explain differences in the apparent locations of sensations.

If we must posit mental space, we must explain it as nonspatial. And if mental space is nonspatial, we must explain how mental locations correspond to spatial locations. The homomorphism view of sensory experience meets these challenges.

2. The Homomorphism View

The homomorphism view explains the relationship between a physical stimulus property and its mental counterpart property in terms of a common structure between their respective quality families. I will motivate the view with respect to color vision, and I will then explain how it extends to spatial experience.

According to the homomorphism view, physical red and red* are not the same property, nor do they resemble each other. They are counterparts in virtue of a similarity between the property families of which they are members—the color and color* families.

A property family is comprised of properties that resemble and differ from one another in varying degrees. For instance, the color family is comprised of perceptible colors.[2] Red is more similar to orange than it is to green. Green is more similar to blue than it is to pink. It is a similarity between the relationships among their respective members that make two property families counterpart families. Two properties of different property families are counterparts in virtue of occupying the same positions in their respective quality families. And a property's position is determined by the similarities and differences it bears to all of the other members of the quality family.

For instance, just as red is more similar to orange than it is to green, red* is more similar to orange* than it is to green*. Red* resembles and differs from the other colors* in ways that are homomorphic to the ways that red resembles and differs from the other colors. In virtue of this, red* and red occupy the same place in their respective quality families.

The homomorphism view also explains the correlations between the spatial properties of distal stimuli and the mental spatial properties of sensations.[3]

---

[2] I take physical colors to be sets of reflectance properties. Two surfaces that appear in normal lighting conditions to be the same shade of red are the same color. But such surfaces can have very different physical makeups. These surfaces, called metamers, pose a problem for the view that colors are physical light-reflectance properties of surfaces (see C.L. Hardin, 1993). But the problem can be countered by taking colors to be sets of reflectance properties, all of which yield the same ratio of light wavelength.

[3] This paper concerns the issue of location. But the homomorphism view accounts for other spatial properties, such as shapes and sizes. Squares are more similar to trapezoids than they are to circles. Likewise a square* sensation is more similar to a trapezoidal* sensation than

Sensations have apparent locations that normally correspond to the locations of distal stimuli. A red* sensation at the center of the visual field is normally caused by a red stimulus at the center of the distal visual field. The homomorphism view posits two distinct properties: Center-of-the-visual-field* and being at the center of the visual field. Stimuli in the center of the distal visual field normally cause sensations at-the-center-of-the-visual-field (CVF*, hereafter). A red* sensation to-the-left-of* a green* sensation is normally caused by a red stimulus to the left of a green stimulus, both of which are located in the distal visual field.[4]

The sum total of location* properties of visual sensations at a given time constitute the mental visual field at that time. So the CVF* is that location* equidistant* from all opposing points on the boundary* of the visual field, where the boundary* is defined by the limits of locations*. For instance, the left* boundary is set by the sensation to which no other sensation is to-the-left* of it.

Locations* within the mental visual field correspond to locations of entities in the distal visual field in virtue of resembling and differing from other locations* in ways homomorphic to the ways locations in the distal visual field resemble and differ from one another.

Two stimuli can resemble each other more than either resembles a third with respect to location in a distal visual field. Two objects to my left are more similar to each other than either is to an object to my right, with respect to at least one dimension of location. Both have the property of being to the left of me, while the third has the property of being to the right of me. The left objects will be more similar with respect to location to a fourth object directly in front of me than they will be to the object on the right. This is because being to the left of me is more similar to being directly in front of me than it is to being to the right of me (with respect to the left/right axis of location properties).

And sensations can resemble and differ with respect to mental location. Take a red* sensation off-to-the-left*, a yellow* sensation in the CVF*, and a blue* sensation off-to-the-right*. The red* sensation resembles the yellow* sensation more than it resembles the blue* sensation, with respect to location*. This is because to-the-left* is more similar to CVF* than it is to to-the-right*.

The structures of the quality families of the distal visual field locations and of the location* properties are homomorphic to one another. So CVF* and being in the center of the distal visual field are counterpart properties in virtue of their occupying the same place in their respective quality families, as fixed by the ways they resemble and differ from other properties of those families.

The result of this view is an explanation of how we see objects as being located where they are. We have visual sensations with location* properties. These sensations are not really located in any two-dimensional overlay visual field. Rather, the sensations are located* in the mental visual field. An afterimage appears where it appears because it has a certain location*. It appears to occlude the photographer's face because its being in that location* means that no sensations of his face can have that location* at that time.

Location* properties help explain how it is that having a CVF* sensation enables us to locate a distal stimulus directly in front of us. CVF* sensations carry information to the effect that there is something directly in front of one's eyes in virtue of CVF* being the counterpart property of being in the center of the distal visual field. It is in virtue of this counterpart relation that having a CVF* sensation helps us locate an object in the center of the visual field, as opposed to one off to the left of the visual field. And it is important to note that the homorphism view explains the counterpart relation in terms of similarity matrices that are readily accessible to us in ordinary visual experience and introspection.

When we introspect our sensations we pick them out, not by their perceptual role, but by their sensory qualities—that is, by their *-properties. When I introspect my sensation of a red patch to the left of another red patch, I pick out two sensations in virtue of their different locations*. That is, I pick them out in virtue of the ways they resemble and differ from one another and other sensations.

3. Clark's Rejection of Mental Space

Austen Clark (1996, 2000) rejects the existence of mental sensory fields. He claims that we need not mention locations of sensations to explain spatial experience. And he offers his feature-placing theory to this end.

Feature-placing aims to explain spatial experience in terms of the spatial properties of distal stimuli, the spatial properties of sensory receptors, and neural activation patterns. The only space needed is physical space.

According to Clark, "Sensing proceeds by picking out place-times and characterizing qualities that appear at those place-times." (2000, p. 74) A sensation identifies a location and qualifies it as being a certain way.[5] It does this in virtue of two variables. The

---

it is to a circular* sensation. The structure of the shape quality family and that of the shape* quality family are homomorphic to one another. Square* occupies the same position in its quality family as square occupies in its quality family.

[4] Stimulus location properties are determined relative to a perceiver. Which stimulus is to the left of another depends on the location from which one sees them.

[5] Stimulus location properties are determined relative to a perceiver. Which stimulus is to the left of another depends on the location from which one sees them.

sensation characterizes the place-time as being some way in virtue of its sensory qualities. A sensation qualifies a place-time as being red in virtue of the sensation's being red*. Clark's theory is in keeping with the homomorphism view with respect to so called secondary qualities.

But which place-time is qualified as being red is determined, not by some location* property, but by the firing of what Clark calls a sensory name—a stand-in for the mechanisms of spatial discrimination. These mechanisms identify place-times by what Clark calls place-coding, which he describes with respect to somesthetic experience.

A group of sensory receptors on the surface of the skin fire when stimulated, sending a neural impulse to the somatosensory cortex, where a certain neural activation pattern occurs. That neural activation pattern is the neural correlate of some bodily sensation—e.g., that of an itch (pp. 169-170). Where it is that the physical itch is felt to be depends on which groups of receptors fire (p. 173). These receptor groups are picked out by n-tuples of coordinates corresponding to the different dimensions in which the receptor groups vary in location. Similarly, the qualities of sensations can be coordinatized according to the dimensions in which those sensations vary (p. 176).

Accordingly, in a visual experience a surface is represented as being red in virtue of receptor groups on the retina firing in a certain way, leading to an activation in the visual cortex corresponding to red*. The red surface is represented as being off to the left in virtue of receptor groups on the left side of the retina firing. The red* state realized in the cortex is indexed to a particular place-coding n-tuple picking out that receptor group.

Having a sensation of red in the left of the visual field is a function of which receptor groups fire, and how they fire. The difference between a sensation of red in the left of the visual field and a sensation of red in the center of the visual field is just a difference in which retinal receptor groups fire. Cases of sensations without distal causes, and anomalies like afterimages are just misfirings of receptor pools. Feature-placing appears to have solved the problem of the spatial character of sensations without reference to mental space.

4. Why We Need Mental Space and Why Clark Does Too

But feature-placing cannot account for differences in the apparent locations of sensory qualities for two reasons. First, we cannot pick out our sensations without reference to some kind of spatial properties of those states. And second, we cannot identify the neurophysiological processes responsible for such variations without first individuating sensations by their mental spatial properties. Clark avoids positing mental space by resorting to spatial properties of stimuli and neurophysiological mechanisms. But his theory can only get off the ground if it accepts some sort of locations for sensations.

A visual sensation of a red patch to the left of a green patch is different from an experience of a red patch above a green patch. All of us who have visual experiences know this. We are conscious of these states as differing in some locational way. Without properties of sensations corresponding to spatial properties, we cannot discriminate between these two states. They would both be states of just a green patch and a red patch. So, unless the color* patches are located in physical space[6], and thus have spatial properties, they must either (a) be located in some sensory field, or (b) not exist. Clark must reject the existence of sensory states, or accept the existence of sensory fields and the sensory locations that comprise them.

But Clark does not reject sensations. He claims that sensations have sensory qualities such as red*, itchy* and high-C*. These are properties sensations must have if they fill the perceptual roles they fill. And they are properties in virtue of which we become conscious of those sensations when introspecting them. When I introspect the sensation I have when looking at a red firetruck, I am conscious of it as a red* sensation.

But I am conscious of such sensations as varying in apparent location as well. And two sensations can only help in discriminating between two differently located, but otherwise identical objects if those sensations differ in ways relating to the differences in object locations. The best explanation is that sensations have mental locations.

Further, we need to pick out our sensory experiences by their mental properties in order to identify their neurophysiological correlates. In order to identify the neurophysiological processes responsible for the appearance of a red patch in the center of my visual field, we need to pick out the appearance of a red patch in the center of my visual field. We do not do this by identifying properties of sensory receptors, nor of neural activation patterns. We pick out the appearance by its properties. Since such appearances can differ with respect to apparent location, there must be mental location properties.

Clark claims that variation in the spatial character of appearances is explained in terms of the spatial locations of distal stimuli and sensory receptors. Clark thus appeals to the properties of neurophysiological processes to explain spatial variations in experience.

But we determine that firings of receptor groups are responsible for certain locational features of sensory experience by discovering that those firings occur when

[6] Frank Jackson (1977) has argued that colors are mental entities that exist in physical space. An important distinction between his account of colors and Clark's account is that Jackson takes colors to be sense-data, whereas Clark takes mental colors to be properties of mental states.

and only when subjects have sensory experiences with those locational features. To determine which receptor groups are firing we monitor neurophysiological activity in the subjects. To determine the kind of sensory experience the subject is having we monitor the subject's overt and verbal behavior.[7] If the subject reports having a sensation of red in the center of the visual field, we infer that he has a sensation of red in the center of the visual field. These inferences rely on the presumed ability of the subject to pick out sensory experiences by their mental properties—in these cases, in part by their mental spatial properties. So Clark's explanation of the spatial character of experience relies on the existence of spatial qualities of sensations by which we pick out these sensations.

But the homomorphism avoids these problems. We pick out our sensations by their sensory qualities. These qualities include mental locations. And since we can pick out our sensations by these location* properties, we can come to identify the neurophysiological correlates of these states. Further, the homomorphism view explains the spatial character of visual experience without the implausible claim that such character depends on actual spatial locations of sensations and sensory qualities.

[7] I am sympathetic to David Lewis's (1972) account of psychophysical identifications. Lewis claims that identifying the neural correlates of mental states requires an understanding of the platitudes about mental states. This seems the right way to go about identifying the neural correlates of mental states inasmuch as mental states are the sensations, thoughts, desires, emotions, etc. that we report having. This should not preclude the importance of scientific psychology in making the identifications. Scientific psychology will have to draw distinctions that the folk do not always make themselves with respect to their mental states. These distinctions are drawn by running controlled experiments designed to isolate certain phenomena. But the psychologist can only design the experiments to draw these distinctions if he accepts that what he is trying to determine is somehow determined first by folk psychology.

HOW PRIMITIVE IS SELF-CONSCIOUSNESS?: AUTONOMOUS NONCONCEPTUAL CONTENT AND IMMUNITY TO ERROR THROUGH MISIDENTIFICATION

Roblin R. Meeks (rmeeks@gc.cuny.edu)

New York, NY 10016-4309 USA

Abstract

Traditionally, investigations into the nature of self-consciousness have focused on the peculiarities of the first-person pronoun. But can we extend the notion to non-language-using creatures as well, including pre-linguistic infants? José Luis Bermúdez has recently argued that creatures possessing no conceptual abilities whatsoever nevertheless possess states that can be considered primitive forms of self-consciousness. I discuss one such form Bermúdez gives—that of somatic proprioception—and show that it fails to satisfy the conditions he adopts for states funded by that type of perception to be representational as well as to be immune to error through misidentification. This conclusion forces a choice between abandoning either immunity to error through misidentification or a sharp conceptual/nonconceptual distinction with regard to representational states.

Introduction

Most traditional accounts of self-consciousness have focused exclusively on the peculiarities of the first-person pronoun. To be self-conscious from this perspective is to possess the ability to make judgments employing a first-person concept, judgments canonically expressed with 'I'. But do creatures lacking linguistic abilities thereby lack self-consciousness? After all, when hungry, even lobsters are self-possessed enough to avoid eating themselves. And what of pre-linguistic infants? If they are eventually to come to entertain thoughts involving a first-person concept, how does self-consciousness for them arise out of their wordless beginnings?

Venturing away from such traditional accounts requires that we should be clear concerning what we mean when we speak of a creature as self-conscious. In general, to be self-conscious, a creature must possess states with first-person content. We need to restrict our search further, however, for first-person content comes in (at least) two flavors. Consider the following examples:

(1) I am the winner of the New York Lottery.

(2) RM is the winner of the New York Lottery.

Intuitively it seems that (2) does not entail (1), for I can rationally believe that (2) is true while denying the truth of (1)—I could lack a further belief that I am identical with RM. In (1), I am thinking of myself nonaccidentally, perfectly aware to whom I am ascribing the property of lottery-winner, even if I have misread the numbers on my ticket and am actually no wealthier than before. In contrast, (2) leaves open the possibility that I am thinking of myself only accidentally, ascribing a property to someone unbeknownst to me who in fact turns out to be myself. Naturally, for me the above cases will further differ radically in the amount of joy expressed at their tokening. But the crucial distinction between the two illustrates the cardinal feature of self-consciousness: For a creature to be self-conscious it must be capable of possessing states that, like (1), have nonaccidental first-person content.

Can creatures lacking any conceptual resources whatsoever possess states that capture the distinction between (1) and (2), or at least approximate the nonaccidental nature of (1)? José Luis Bermúdez has offered an affirmative answer to this question, arguing at length in The Paradox of Self-Consciousness that certain forms of autonomous nonconceptual content—states with which a creature represents the world as being such-and-such a way despite possessing no conceptual resources whatsoever—can be considered forms of genuine self-consciousness.[1] We have good initial reason to agree with Bermúdez: Extending the range of types or forms of content that can correctly be characterized as genuinely first-personal gives us a hope of dispelling the mystery of how the richer,

[1] Bermúdez is motivated to look for nonconceptual content that is genuinely first-personal to escape what he calls the paradox of self-consciousness. This paradox is roughly that analyzing self-conscious thought solely in terms of a subject's mastering the first-person pronoun will rely upon the notion of him thinking of he himself as the author of the thought. Spelling out the "he himself" condition requires reference to the first-person pronoun, and we thus fall prey to circularity. Whether one finds Bermúdez's paradox compelling, it is an interesting question in its own right as to whether creatures lacking conceptual resources should be thought of as self-conscious and if so on what grounds.

conceptual forms of self-consciousness actually arise in the normal course of human psychological development.

In what follows we will consider one source of perceptual contents—namely somatic proprioception—that Bermúdez believes gives rise to genuine, albeit primitive, forms of self-consciousness. We will find, however, that a widely accepted condition that must be met for a state to be considered nonaccidentally first-personal stands at odds with certain nonconceptual states' being representational. In light of the incongruity, we face a choice between rejecting that condition, that nonaccidental first-person states be immune to error through misidentification, or accepting that a clear distinction between conceptual and nonconceptual states cannot be maintained.

Autonomous Nonconceptual Content

Elucidating exactly what nonconceptual content in general amounts to is a difficult task. Bermúdez himself is interested in establishing the existence of states with autonomous nonconceptual content to fend off circularity in a certain explanation of nonaccidental first-person thought. Though one can dispute his charge of circularity, his overall approach to primitive self-consciousness is instructive. He motivates the theoretical necessity of nonconceptual representational states via inference to the best explanation. Arguing on a broadly functionalist line, Bermúdez contends that no account of the behavior of an intentional system can be given without reference to representational states. However, certain intentional systems—including non-linguistic animals and pre-linguistic infants—lack concepts, yet still succeed, for example, in navigating their environment. We know that such creatures are representing their surroundings (and the states of their bodies) because no law-like relation holds between sensory input and behavioral output. Differences in behavior when faced with the same sensory input indicate that a creature is possibly misrepresenting a current state of the world or perhaps that its behavior is a function of a complex group of states, some of which differ from a previous occasion (a past predator can become prey, e.g.). Once general room has been made for states with autonomous nonconceptual content, Bermúdez goes to great lengths to provide specific examples of nonconceptual contents that qualify as primitive forms of self-consciousness.

One such example Bermúdez gives is that of somatic proprioception.[2] One's proprioceptive system provides a stream of information regarding the state of one's body, the position of limbs, skin and joint tension, bodily feedback during motion, etc. These states are representational states because they, like any other representational state, "serve as intermediaries between sensory input and behavioral output" (Bermúdez, 1998). Granting for the moment that such states are both representational and autonomously nonconceptual, how are we to determine if they qualify as forms of primitive self-consciousness? Bermúdez offers that such states must meet the two core requirements for any self-conscious thought: They must have immediate implications for action,[3] and they must be nonaccidentally about oneself. Skipping the former for the moment, thoughts are nonaccidentally about oneself, Bermúdez and many others argue, because they are immune to error through misidentification relative to the first-person pronoun. To assess the claim such states have to self-consciousness with any accuracy, we must briefly review what this condition amounts to more generally.

Immunity to Error Through Misidentification

In The Blue Book Wittgenstein (1958) distinguishes between what he calls 'I' used as subject and 'I' used as object. The latter, he claims, permits the possibility of misidentifying the referent of the first-person pronoun, whereas the former does not.[4] When uttering 'I am in pain'—the canonical instance of 'I' used as subject—Wittgenstein offers that the identification of the speaker is not in question: I cannot ascribe a felt pain to someone who, unbeknownst to me, is actually myself. In a genuinely self-conscious ascription of a property, it is no accident that I recognize that I am the subject of the ascription, for it could not be otherwise. In Wittgenstein's memorable phrase: "The man who cries out with pain, or says that he has pain, doesn't choose the mouth which says it" (Wittgenstein, 1958, emphasis his).

Sydney Shoemaker has done much work to elucidate and to extend this condition, labeling it with the now standard terminology "immunity to error through misidentification relative to the first-person pronoun" (Shoemaker, 1968).[5] For Shoemaker, roughly as for

[2] For a fairly extensive summary of the informational systems that constitute somatic proprioception, see the general introduction to Bermúdez, Marcel, & Eilan (1995).

[3] For a characterization of this requirement see Perry (1979).

[4] Indeed, Wittgenstein claims that 'I' in cases of its use as subject is not a referring expression at all. This position is endorsed and quite forcefully defended by Anscombe (1975).

[5] Shoemaker (1968) basically accepts Wittgenstein's distinction tout court, though he does hold that instances of 'I' in judgments immune to error through misidentification do genuinely refer. In recent work, Shoemaker (1994) has adopted Gareth Evans's (1982) coinage for this immunity, calling such judgments "identification free". The argument that follows does not depend on favoring a particular terminology, and therefore I will use the original phrase to avoid possible confusion. For a recent exploration of the kinds

Wittgenstein, a certain class of judgments permit error in the predicate position but do not leave the identity of the subject of the predication in question, for knowing in a particular way that a property is instantiated simply obviates the need for identifying its source. Bermúdez rightly points out, as Gareth Evans did before him, that these contents are immune to error through misidentification in virtue of the "evidence base from which they are derived, or the information on which they are based" (Bermúdez, 1998), not in virtue of any particular predicate or predicates. Ascriptions of pain to myself as well as to others employ the same predicate; the claim is that immunity issues from the way in which I know a pain to be present.[6] Fundamentally, Bermúdez– like nearly all other participants in this dialectic— accepts that contents cannot be considered genuinely self-conscious unless they possess this type of immunity.[7]

Somatic proprioception provides just such an evidence base, argues Bermúdez, for "somatic proprioception cannot give rise to thoughts that are accidentally about oneself" (Bermúdez, 1998). He writes:

> One of the distinctive features of somatic proprioception is that it is subserved by information channels that do not yield information about anybody's bodily properties except my own (just as introspection does not yield information about anybody's psychological properties except my own). It follows from the simple fact that I somatically proprioceive particular bodily properties and introspect particular psychological properties that those bodily and psychological properties are my own. (Bermúdez, 1998)

Focusing just on the particular bodily properties reported on by proprioception, how are we to assess the claim that I cannot be mistaken about within whose body those properties are instantiated when perceived in that way? For somatic proprioception to be a source of genuine self-consciousness, it must serve as an evidence base for contents where the subject cannot be in doubt, even for creatures lacking any conceptual resources whatsoever. Yet to qualify as representational– that is, to be considered contentful at all– thoughts funded by proprioception must allow for the possibility of misrepresentation. Misidentification is but a special case of misrepresentation, and hence endorsing immunity to error through misidentification at this primitive level precludes misrepresentation, which apparently serves to disqualify proprioceptive states from being representational.

To put the point another way, how can states funded by proprioception misrepresent? States in general can only "who" or "what" misrepresent– viz., they can misrepresent the subject of the state ("who") or the presence of a property ("what"), or presumably both. Misrepresentation of the "who" variety amounts to misidentification. To have "what" without "who" misrepresentation requires some representation of the subject with which a mistaken ascription can be made. Since nonconceptual states lack subject-predicate structure, no such representation of the subject is available in that case. Hence, to "what" misrepresent is to misidentify.

Unlike those who discuss immunity to misidentification as it relates to judgments, it is not at all clear that proponents of nonaccidental nonconceptual content have the philosophical machinery to relieve this tension. Evans, for example, does not fall into a similar predicament, for his 'I'-thoughts possess a conceptual structure that localizes— as Shoemaker's condition in its long form indicates— the immunity to error through misidentification relative to the first person pronoun. Misrepresentation can still occur with regard to the predicate position and the ascription of bodily properties, and hence immunity to misidentification and misrepresentation can co-exist in the same thought or judgment. Non-language-using creatures, of course, do not have the first-person pronoun at their disposal. Without conceptually structured thoughts, it seems that these types of subjects cannot possess contents that are both representational and immune to error through misidentification, for they have nothing that that immunity could be relative to.

Or do they? Bermúdez argues that inference to the best explanation warrants ascribing "protobeliefs", or nonconceptual belief analogs, to non-language-using creatures requiring intentional explanations to account for their behavior. As he presents them, perceptual protobeliefs[8] are nearly as rich as their conceptual correlates: they can embody "nonextensional modes of presentation" in terms of Gibsonian affordances, and they are somewhat compositional, though they do not allow for "global recombinability", failing to meet

---

of immunity, including fundamental ways in which Evans and Shoemaker disagree, see Pryor (1999).

[6] Cf. Evans (1982). Bermúdez also argues, persuasively I think, that Shoemaker's elucidation of immunity to error through misidentification should be stated in terms of justification as opposed to knowledge. For if one can still be mistaken about the instantiation of a predicate— even if one cannot be mistaken about the first-person identification in that case— that belief cannot be considered knowledge. It remains a question whether for Shoemaker this is possible.

[7] John Campbell (1999), for example, has recently remarked that "immunity to error through misidentification is a datum" that can be used to test the viability of various theoretical approaches to the first person.

[8] Bermúdez (1998) also briefly discusses instrumental protobeliefs, but our discussion can safely ignore them. Bermúdez draws this bit of his theoretical apparatus from Peacocke (1992).

Evans's Generality Constraint (Bermúdez, 1998; Evans, 1982). So structured, perceptual protobeliefs support primitive inference and the limited generation of further new nonconceptual contents from a set of others. Accordingly, perceptual protobeliefs so construed—including contents based on somatic proprioception—seem capable of supporting something like a discrete subject component, analogous to an 'I'-idea, that could serve as the locus of immunity to error through misidentification, as well as a predicative component that could misrepresent a property of the world or body.

One certainly becomes puzzled at this point, however. If nonconceptual contents based upon somatic proprioception can support both a component immune to misidentification and a component preserving the possibility of misrepresentation, then what are we to make of the original motivation for maintaining a clear conceptual/nonconceptual distinction with regard to contents? Indeed, it seems that inference to the best explanation warrants thinking of the constituents of protobeliefs as "protoconcepts". Much like concepts, protoconcepts could be defined in terms of their inferential role, where a protoconcept's inferential role can be cashed out in terms of the protopropositions or protobeliefs in which it features. As the analogy deepens between concepts and protoconcepts, we seem to have less reason to conclude that creatures lacking language likewise lack conceptual abilities of any sort, however limited or nascent. After all, the set of protopropositions may be quite limited for non-language using creatures, but they nevertheless succeed in satisfying two subtle and sophisticated philosophical criteria. Perhaps that success itself provides compelling evidence of some degree of concept possession.

Bermúdez himself would no doubt resist this approach since it seems to run afoul of what he calls the Priority Principle:

> The Priority Principle: Conceptual abilities are constitutively linked with linguistic abilities in such a way that conceptual abilities cannot be possessed by nonlinguistic creatures. (Bermúdez, 1998)

Priority was initially important because it "allows us to make a very clear distinction between conceptual and nonconceptual modes of content-bearing representation" (Bermúdez, 1998), and hence provides us with a means of explaining, for example, how conceptual forms of self-consciousness can arise over the course of normal human psychological development. Yet, given that protobeliefs are in some measure compositional and fund limited inference—indeed are constituted by protoconcepts—it is no longer clear how we can maintain a very clear distinction between conceptual and nonconceptual contents.

Still, perhaps the protoconcept/concept analogy runs fairly shallow, for even if non-language-using creatures possessed a range of protoconcepts defined in terms of protoconceptual roles, they do not have an explicit grasp of these roles. Such creatures are merely sensitive to the truth of inferential transitions. Bermúdez (1998) writes:

> Certainly, it is possible to be justified (or warranted) in making a certain inferential transition without being able to provide a justification (or warrant) for that inferential transition. It is a familiar epistemological point, after all, that there is a difference between being justified in holding a belief and justifying that belief. What does not seem to be true is that one can be justified in making an inferential transition even if one is not capable of providing any justifications at all for any inferential transitions. But providing justifications is a paradigmatically linguistic activity. Providing justifications is a matter of identifying and articulating the reasons for a given classification, inference, or judgment. It is because prelinguistic creatures are in principle incapable of providing such justifications that the priority thesis is true. Mere sensitivity to the truth of inferential transitions involving a given concept is not enough for possession of that concept. Rational sensitivity is required, and rational sensitivity comes only with language mastery.

For Bermúdez, then, possessing and deploying concepts demands a fairly advanced capacity to identify and to provide reasons for beliefs, and limited inferential ability—even an ability to make inferences that one is justified in making—does not indicate concept possession.

This seems a bit too stringent, however. Being able to give reasons as reasons is a function of possessing the concepts of justification, belief, and reason, among others. Imposing the further requirement on inferential ability that one recognize that one is in fact giving reasons may disqualify attributing conceptual abilities where we normally would be comfortable doing so. To take an example Bermúdez himself gives, the children in Susan Carey's experiments who concluded that a worm was more likely to have a spleen than a toy mechanical monkey are probably not in position to identify their reasons for this conclusion as reasons and to answer a call to justify their inferences. Still, he wants to credit these four-year olds with possessing the concepts HUMAN BEING, LIVING ANIMAL, INTERNAL ORGANS, and the inferential relations between them.

Conclusion

It seems that maintaining that nonconceptual contents be immune to error through misidentification entails that a sharp distinction between conceptual and nonconceptual contents must be abandoned. Perhaps we can spare a fairly strong distinction by instead abandoning the requirement that these contents be immune to error through misidentification. That is, we accept that protobeliefs are only minimally structured,

ultimately lacking the propositional precision required to support the weight of an immunity claim. It's not clear to me that we sacrifice much explanatory power in making this move, since we can still hold firmly to the second core condition for genuine self-conscious thought– namely, that nonconceptual proprioceptive contents must have immediate implications for action, which in fact they do (Bermúdez, 1998). Moreover, in preserving this second condition we still have a means of determining the class of nonconceptual contents that qualify as a form of genuine primitive self-consciousness. Alternatively, we can retain immunity to error as a necessary condition of self-consciousness, relinquishing instead the Priority Principle and the sharp conceptual/nonconceptual division that it was intended to capture. Choosing this route has interesting implications, for in doing so we greatly expand the range of creatures that can be said to possess conceptual capacities of one sort or another– including, evidently, those possessing some form of self concept.

Whatever route we choose, something, it seems, must be surrendered. For despite what doubts we might harbor concerning the lowly lobster, higher animals and our own infants should give us pause. Self-consciousness is certainly not ours alone; we just have yet to understand it in its more primitive forms.

Abstract

Automated theorem proving based on proof planning is a new and promising paradigm in the field of automated deduction. The idea is to use methods and heuristics as they are used by human mathematicians and encode this knowledge into so-called `methods`. Naturally, the question arises whether these `methods` can be beneficially used in *learning* mathematics too. This paper investigates and compares the effect of different instruction materials (textbook-based, example-based, and method-based) on problem solving performance. The results indicate that the performance for the method-based instruction derived from automated proof planning in the ΩMEGA system is superior to that of the other instructions that were derived from a textbook and an example-based classroom lesson. These results provide a first support for introducing proof planning based on methodological knowledge into the school curriculum for mathematics.

Introduction

Recent developments in automated deduction, one of the areas of Artificial Intelligence (AI), have shown the advantage of employing methods and heuristics used by human mathematicians. Naturally, the question is whether they can be beneficially used in teaching mathematics, for instance in interactive e-courses such as ACTIVEMATH (Melis et al., 2001).

The goal of the research reported in this paper has been to gather empirical evidence for the hypothesis that the knowledge we made explicit in proof planning `methods` for a restricted area of mathematics, namely limit problems, is indeed useful for learning to prove theorems in this area. A positive answer in this and other areas of mathematics can serve as a basis for the long-term goal to acquire `methods` to solve mathematical problems and then to use them to gradually change the teaching of mathematics.

To understand the interdisciplinary context, we will have a quick look at automated theorem proving.

Automated and Human Theorem Proving Traditional automated theorem proving systems such as OTTER have attained a remarkable strength in deductive search. They are, however, weak when it comes to nontrivial mathematical theorems where long range planning or other global search control is needed. Moreover, long proofs generated by these systems are almost incomprehensible. Therefore, techniques like proof planning that more closely follow the reasoning patterns observed in humans became more prominent.

The goal of automated proof planning (Bundy, 1988; Melis & Siekmann, 1999) is to identify and to employ human-like strategies and methods for theorem proving in order to avoid the almost exhaustive search in super-exponential search spaces that makes traditional automated theorem proving infeasible for most nontrivial mathematical conjectures. We investigated reports and mathematical textbooks (Melis, 1994) to make such strategies and methods explicit and then available for the ΩMEGA proof planner. Essentially, these methods are (generalized) macro-steps. This is in accordance with Koedinger and Anderson (1990) who investigated human theorem proving in geometry and found that humans employ macro-steps when proving theorems.

The identification and design of `methods` and control knowledge is very laborious as this kind of knowledge is not explicit in mathematical texts. However, some progress has now been made in the identification of mathematical methods and control knowledge (Melis, 1998). Based on these achievements we focus on questions such as

Is the knowledge that was made explicit for automated proof planning useful for supporting human learning of mathematical problem solving?

We are inclined to say *yes*. One reason is the explicit availability of this knowledge that can be used for proof presentation. An automated proof planner produces proof plans which in turn can be *presented in a more comprehensible way*. We investigated how proof presentation for teaching and learning can be generated from proof plans, see Melis and Leron (1999). Moreover, we investigated how such a presentation of proof plans can meet pedagogically and cognitively motivated requirements for presenting mathematical problem solutions and proofs, in particular the requirement for a hierarchically structured presentation originating from empirical results in Leron (1983) and Catrambone (1994).

A second reason is that this knowledge is needed for problem solving but not always present in textbooks (VanLehn, Jones, & Chi, 1992). Indeed, interviews with teachers of mathematics indicate a need for teaching methodological knowledge as captured in `methods`. Some even claim this is the essence of good teaching and

a source of improved learning and thus de-mystifying mathematics to some extent. As opposed to merely checking the correctness of single proof steps as in learning with traditional mathematical instruction, learning of *methods* should help in understanding the discovery of a proof. This leads to an improved performance based on understanding. The methodological knowledge includes the systematic construction of mathematical objects which is needed in many proofs.

The idea of making an expert's tacit problem solving knowledge explicit to learners is in accordance with some well known approaches in instructional psychology such as cognitive apprenticeship (Collins, Brown, & Newman, 1989) or the provision of instructional explanations (Chi, 1996).

Certainly, the success largely depends on the actual proof planning *methods* made explicit and encoded and therefore another direction of research, see Melis and Pollet (2000), aims at describing `methods` for interactive proof planning most appropriately. In addition to the evaluation of the concrete `methods` there is the more general question on whether the explicit teaching of relatively abstract methods helps in learning mathematics.

Although there are reasons to believe in instructional benefits, empirical evidence is required to substantiate the *yes*, and this is the focus of this report.

In this paper we present first empirical results. To begin with, proof planning is briefly reviewed, in particular proof planning of limit theorems which is the object of the described experiment.

Proof Planning Basics

Proof planning is based on classic AI-planning (Fikes & Nilsson, 1971) which reduces a goal to subgoals by introducing operators until all open subgoals match one of the initial state descriptions. When the sequence of operators is applied (in forward direction), the initial state is transformed into a state in which the goals hold. In proof planning, the goal is the theorem to be proved and the initial state consists of the proof assumptions.

For instance, for proving the theorem LIM+ which states that the limit of the sum of two real-valued functions f and g for a real number a is the sum of their limits L_1 and L_2, the conjecture to be proven is

$$\lim_{x \to a}(f(x) \quad g(x)) = L_1 \quad L_2$$

and the proof assumptions are

$$\lim_{x \to a} f(x) = L_1 \text{ and } \lim_{x \to a} g(x) = L_2.$$

A proof plan is a sequence of operators whose application realizes an inference from the proof assumptions to the theorem. In proof planning, the operators are called `methods`. They are frequently designed in a way corresponding to typical mathematical techniques such as `proof by induction`, `proof by refutation`, and `proof by diagonalization`, to quote some of the best-known `methods`. There are, however, less well-known `methods` which do not have a distinct name in mathematics. For instance, certain `estimation methods` for inequalities are typically not explicitly mentioned although they encode a frequently used trick. One of these `estimation methods` (`ComplexEstimate`) and another `method` (`TellCS`). These have been used in our experiments and are explained below.

Those non-name `methods` are often used only implicitly in course materials. This implicit treatment of proof `methods` is one reason why textbooks do not provide enough explanation of *how to find* a proof.

Proof Planning in the Limit Domain

In this section we describe a class of theorems, the way their proofs can be discovered mathematically, and the way proof planning in the ΩMEGA system implements this with `methods`.

The Theorems Limit theorems are taught at German high schools. Limit theorems claim something about the limit $\lim_{x \to a} f(x)$ for a function f or about the continuity of a function f.[1]

The definition of $\lim_{x \to a} f(x) = l$ describes formally that if x converges to a, then $f(x)$ converges to the limit l. The convergence $x \quad a$ means that the distance $x - a$ of x and a becomes arbitrary small. The definition of the limit describes that if $x - a$ becomes arbitrary small, then $f(x) - l$ becomes arbitrary small too. Put formally, for every arbitrary small real number ε exists a real number δ such that if $x - a < \delta$,[2] then $f(x) - l < \varepsilon$.[3]

Example Take the linear function $f(x) = 2 \quad x \quad 3$. When x converges to 0, then $f(x)$ converges to 3, i.e., for any arbitrary small ε, there is always a δ-environment $U_\delta(0)$ of $a = 0$ such that for any x in that environment $f(x)$ is in the ε-environment.

Counter Example Take as a counter example the function

$$f(x) = \begin{array}{rcl} 2 & : & x > 0 \\ -2 & : & x < 0 \end{array}$$

in Figure 1 which does not converge at point $x = 0$.

If ε is smaller than 2, there is always an x close to 0 for which $f(x)$ is not in the ε-environment of $l = \quad 2$ or of $l = -2$.

The Proofs The proofs of limit theorems have to suggest a δ, in relation to the given ε, such that the limit inequalities, e.g. $f(x) - l < \varepsilon$, hold. That is, a relation between ε and δ has to be determined such that for each x from the δ-environment of a the value $f(x)$ is in the ε-environment of l. Therefore, the standard proofs of these theorems are often called ε–δ–proofs.

Typically, textbooks postulate an appropriate relation between ε and δ out of the blue. Then they show

[1] or about the limit of a sequence which is a special case of a function.

[2] i.e., x is in the δ-environment $U_\delta(a)$ of a

[3] i.e., $f(x)$ is in the ε-environment $U_\varepsilon(l)$ of l

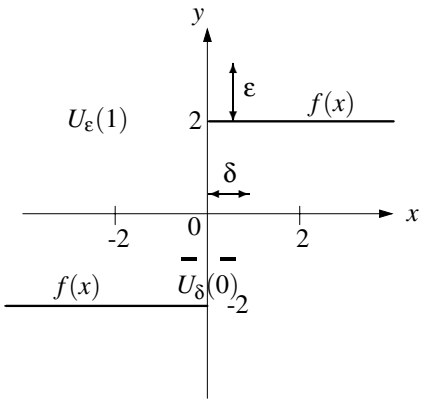

Figure 1: A function that does not converge at point $x = 0$

that the stipulated δ which is dependent on ε make the (inequality)-conjectures true. In contrast, proof *discovery* reveals the relation either by intuition or by systematically detecting conditions/constraints under which $f(x) - l$ becomes arbitrary small given that $x - a$ becomes arbitrary small. Those constraints result from analyzing the inequalities to be proven. This analysis often includes an abduction of new simpler inequalities/constraints sufficient to not invalidate the original ones.

These constraints may restrict the relation between ε and δ. For instance, if the constraints are $0 < \delta$ and $\delta < \varepsilon$, then $\delta = 2\ \varepsilon$ would be an invalid relation but $\delta = \frac{\varepsilon}{2}$ would be a valid one. When all possible constraints have been collected, then it is more transparent how to choose the relation between ε and δ. For instance, if the collected constraints are $0 < \delta$ and $\delta < \varepsilon$, then it is easy to see that the relation $\delta = \frac{\varepsilon}{2}$ satisfies the constraints. In particular, for complicated problems the systematicity is indispensable because ad hoc guesses and trial and error do not help much.

Proof Planning Proof planning for ε–δ–proofs (in a backward fashion) introduces a sequence of `methods` transforming $x - a\ < \delta$ to $f(x) - a\ < \varepsilon$:

$$\begin{array}{rrcl} & f(x) - l & < & \varepsilon \\ = & \ldots & < & \varepsilon \\ = & x - a & < & \delta. \end{array}$$

Each of the methods may yield restrictions on the relation of ε and δ. Therefore, proof planning systematically restricts the relation of ε and δ by uncovering constraints sufficient for making the inequalities true which are required in the theorem.

If a subgoal is a primitive inequality such as $0 < 1$ or $\delta < \varepsilon$, then `TellCS`[4] just collects it as a new constraint. If the constraints are not as immediate/primitive, then they can only be shown via a reduction to less complicated, primitive inequalities. For instance, to show $x^2 - a^2 < \varepsilon$ one might reduce the goal to the subgoals $x\ \ a < r$ and $x - a < \frac{\varepsilon}{r}$ for a number r to be determined and then conclude $x^2 - a^2 = (x\ \ a)\ \ (x - a) < r\ \ \frac{\varepsilon}{r} = \varepsilon$ and therefore $x^2 - a^2 < \varepsilon$. In proof planning such reductions are realized by estimation methods. One of those methods is `ComplexEstimate` whose simplified version is used in one of the instruction materials and described below.

Simplified ComplexEstimate The simplified `ComplexEstimate method` delivers the first reduction step in the following plan.

$$\begin{array}{rrcl} & f(x) - l & < & \varepsilon \\ = & k\ \ x - a & < & \varepsilon \\ = & x - a & < & \frac{\varepsilon}{k} \\ = & x - a & < & \delta \end{array}$$

It rewrites $f(x) - l$ to $k\ \ x - a$, determines the k which can be a number but also, in more complicated cases, a term like $x\ \ 1$ (see the Binomial computation above), and conjectures the subgoal that k has an upper bound (a real number r). The latter subgoal $k < r$ is a constraint and gives rise to establishing the relation $\delta = \frac{\varepsilon}{r}$ in order to guarantee $\delta < \frac{\varepsilon}{k}$ which implies the last proof step.

`ComplexEstimate`'s general procedure to determine k is polynomial division but manual computation may use simpler procedures in simpler cases, e.g. a Binomial formula.

This general `ComplexEstimate` (not used in the instruction materials) reduces an inequality goal to three subgoals (rather than two in the simplified version) by means of decomposing a term t into a linear combination $t = k\ \ a\ \ \ m$ for which an estimation of a is already known. It justifies the original goal by the three subgoals and the Triangle Inequality.[5] For difficult decompositions the `method` can call a polynomial division function without any problems.

The general `ComplexEstimate` as used in the automatic proof planner ΩMEGA covers the simpler cases for $k = 1$ and $m = 0$. Its generality allows for proving pretty complicated theorems that are beyond the range of our experiments. All test problems in the experiment require the special case $m = 0$ only. In the first, second, third, fourth, and fifth test problem, k is a real number, whereas in the sixth test problem k is the term $(x - 1)$.

Hypotheses

The overall goal of the study presented in this paper is an empirical validation of the assumption that the instructional presentation based on `methods` leads to an improved problem solving performance in mathematics. This differs from typical textbooks or classroom lessons where the methodological knowledge is currently not explicitly used.

The first hypothesis states that instructional material that includes information about proof-generation methods improves the overall problem solving performance.

[4] for "Tell the Constraint Solver".

[5] $A\ \ B < A\ \ \ B$

The second hypothesis postulates that the method-based instruction is especially helpful in solving far-transfer test problems that presuppose the generation of new solution paths.

To test the first hypothesis instructional material based on ΩMEGA's proof plan `methods` was designed. The method-based instructions were contrasted with conventional instruction materials: textbook-based instruction and example-based instruction.

To test the second hypothesis test problems of different transfer distance were used[6] .

Experiment

Method

Participants The subjects were 38 students of Saarland University, Germany who either participated for course credit or payment. Average age was 24.1 years.

Materials and procedure Each student was provided with the following material in a booklet: (1) An introduction that described the nature and purpose of limits. Additionally, the introduction presented a definition of the notion of an *environment* as a prerequisite for the formal definition of *limit*. (2) A formal definition of the notion *limit* together with an illustrating graph. (3) One worked-out example that illustrated how the limit $\lim_{x \to a} f(x)$ for a given function f and a given value a can be proven. Depending on the experimental conditions different solution approaches were selected in the worked-out examples.

Subjects were advised to study the instructional material carefully. After reading the booklet subjects had to solve six test problems that differed in their transfer distance with respect to the instructional example. The six text problems were of increasing difficulty and decreasing structural similarity to the example explained in the instruction.

Design and dependent measures Four different instructional materials were designed as independent variables: Textbook-based instruction, example-based instruction, and two types of method-based instruction (only differing in the sequence of the parts of instructional materials). The instructional conditions differed only with respect to the solution approach for the worked-out example and with respect to the sequence of the instructional materials.

In the textbook-based instruction the introductory page was immediately followed by a short formal definition of the notion *limit* and an illustrating graph. Subsequently, one example of a worked-out ε-δ-proof for a linear function ($f(x) = x \quad 2$, with x being undefined at $x = 1$) was presented. The example solution was taken from an university-level textbook. The textbook-based instruction merely postulated the pivotal relation between ε and δ without derivation from more general principles. The mere stipulation of pivotal assumptions is a frequent feature of example proofs in textbooks.

The example-based instruction differed from the textbook-instruction in that the example problem was presented immediately after the introductory page. To establish a general relation between ε and δ, suitable values for δ are introduced for several concrete ε values of decreasing size. This approach allowed for an inductive derivation of a general relation between these two parameters. Additionally, the example-based instruction differed from the textbook-instruction in the sequence of the instructional materials: The example proof was presented before the formal definition of the notion *limit* and the respective illustrating graph were introduced.

The method-based instruction took the `methods` simplified `ComplexEstimate` and `TellCS` from ΩMEGA's proof planner and described an example solution explicitly using `ComplexEstimate` and `TellCS` (the collection of constraints). It shows how `ComplexEstimate` reduces a complicated estimation to several simpler ones. As a general approach it also employs the collected constraints for defining a relation between ε and δ. The `methods` are applied to prove the example problem and an abstract description of the `method` is provided.

Two versions of this method-based instruction were designed that differ with respect to the sequence of instructional materials. In version A the definition of the notion *limit* was followed by an abstract description of `ComplexEstimate` and an illustrating example applying this `method`. In version B the worked-out example was presented before the notion *limit* was defined and the `ComplexEstimate` method was described in a more abstract way.

As dependent variables problem-solving time and problem solving performance for the six test problems were registered. The test problems differed in transfer distance. The first two test problems were isomorphic to the example used in the instructional material (proving a limit for a linear function of the form $f(x) = x \quad b$). The next three test problems were near-transfer problems (proving a limit for a linear function of the form $f(x) = ax \quad b$). Finally, a far-transfer test problem had to be solved (proving a limit for a quadratic function of the form $f(x) = ax^2 \quad bx \quad c$). After the experiment, data were collected by means of a questionnaire, in particular, the subjects' last maths grade in school, the subjects' interest in mathematics, sociodemographic data, and whether they were taught anything about limit theorems in (past) school lessons.

Results

The six test-problem solutions were scored as follows. For a totally correct answer a score of 1 for isomorphic problems, a score of 2 for near-transfer problems, and a score of 4 for far-transfer problems was assigned. Hence, the maximum total score is 12. 50% of the full score were assigned to a solution, if the answer was correct except for minor, nonconceptual mistakes (e.g. numerical calculation errors, mixing up δ and ε in the solution

[6] Transfer distance is a measure for structural similarity.

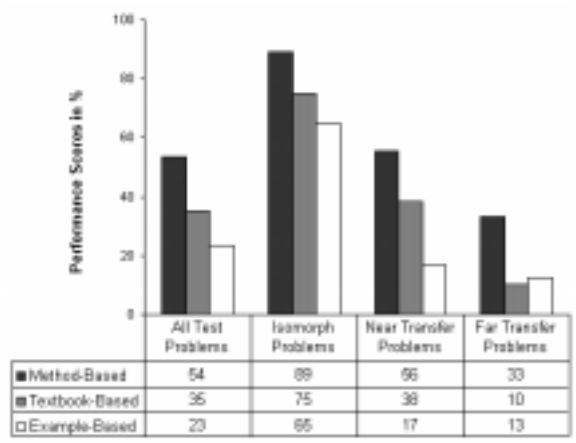

Figure 2: Mean performance scores (in percentage of possible maximum score) as a function of instructional condition and transfer distance between test problems and example problems

equation). 75% of the full score were assigned in case of incorrect solution of the polynomial in the last test problem.

Nonparametric tests were used in all performance analysis because of distorted distributions. In a first step, we compared the two method-based instructions with respect to performance differences. Mann-Whitney U-tests revealed that there were no differences in the total problem-solving score (U(9, 9) = 36; p(two-tailed) = .69) or in problem-solving time (U(9, 9) = 39; p(two-tailed) = .89). Thus, both method-based instructions were collapsed for further analysis. An overall comparison of the method-based, the example-based and the textbook-based instruction with Kruskal-Wallis H-test revealed that there were significant differences in the total problem-solving score ($\chi^2(2, N = 38) = 5.87$; $p = .05$) but not in problem-solving time ($\chi^2(2, N = 38) = 2.45$; $p = .29$). The instructional conditions did not differ with respect to the last math grade in school, domain-specific knowledge they were taught in school, interest in mathematics, sex, and age. Figure 2 provides the mean performance scores (in percentage of possible maximum score) for all three instructional conditions and all levels of transfer distance.

Paired one-tailed comparisons with Mann-Whitney U-tests (see Table 1) yielded that the method-based instruction outperformed the textbook-based instruction (marginally) as well as the example-based instruction with respect to the total problem-solving score. The textbook-based instruction and the example-based instruction did not differ in total problem-solving score.

A more detailed analysis revealed that the method-based instruction and the textbook-based instruction differed marginally with respect to isomorphic problems and to far-transfer problems but not with respect to near-transfer problems. The method-based instruction and the example-based instruction differed with respect to all performance measures, at least marginally. The textbook-based instruction and the example-based instruction did not differ with respect to isomorphic problems and far-transfer problems. However, there was a marginal significant difference with respect to near-transfer problems.

Table 1: Comparison between all instructional conditions with respect to all levels of transfer distance (one-tailed Mann-Whitney U-tests)

	All Test Problems	Isomorph Problems	Near Transfer Problems	Far Transfer Problems
Method (n_1=18) vs. Textbook (n_2=10)	**p = 0,08** U = 60,5	**p = 0,10** U = 69,5	p = 0,17 U = 71,5	**p = 0,07** U = 66
Method (n_1=18) vs. Example (n_3=10)	**p = 0,01** U = 43,5	**p = 0,07** U = 66,5	**p = 0,01** U = 48	**p = 0,10** U = 68
Textbook (n_2=10) vs. Example (n_3=10)	p = 0,15 U = 36,5	p = 0,37 U = 46	**p = 0,10** U = 35,5	p = 0,31 U = 46

Discussion

As postulated in our first hypothesis the method-based instructional material based on ΩMEGA's proof plan presentation has a significant beneficial effect on learners' subsequent problem-solving performance. Compared to more conventional instructional formats usually found in textbooks and highschool lessons the method-based instruction improves learners' problem-solving performance without requiring more time to be invested.

Contrary to the expectation expressed in our second hypothesis, the performance improvements due to the method-based instructional format are not larger for far-transfer test problems than for isomorphic and near-transfer test problems. An explanation for this unexpected result might be that the far-transfer test problem has been chosen as a too-far one that requires an additional computation (polynomial division) the subjects might have been not capable to carry out or did not even try.

To conclude, the results indicate that the method-based instruction that originated from proof planning *methods* implemented in ΩMEGA is superior to the two other instructions in terms of subsequent problem solving performance. These results provide first evidence that proof planning based on mathematical knowledge may also be used and introduced into highschool curricula for mathematics.

Conclusion

Is the methodological knowledge used in proof planning useful for human learning of maths problem solving?
The results of our experiments indicate that the method-based instruction that originated from automated proof planning is, indeed, superior to the two other instructions in terms of subsequent performance. These results provide first support for introducing proof planning based on

methodological knowledge into the highschool curricula for mathematics.

It is not necessary to restrict this methodological knowledge to `methods` which have been acquired for and used in automated proof planning. We can, however, re-use these results. Then the advantage is that those `methods` are formalized and implemented and, therefore, can be employed by a system supporting *interactive* problem solving.

The presented empirical results are limited, however, to only one area of highschool mathematics. Future work will try to provide similar evidence in other areas as well.

Interestingly, we met many committed mathematics teachers in Germany who have been engaged in activities targeting a similar idea without knowing, of course, about automated theorem proving and proof planning. Their concern is a reshaping of mathematics lessons that aims at learning problem solving methods, heuristics, and structuring problems and solutions rather than at memorizing facts and procedures.

Future Work

In the future we will replicate the experiment reported here with several augmentations. First, we will obtain think-aloud protocols to get more detailed insights into the learning and problem-solving processes elicited by different instructional materials. Second, we will try to shed more light on the results with respect to second hypothesis by adjusting the difficulty of the far transfer test problems. Third, we will additionally consider certain features of instructional situations like domain-specific prior knowledge or degree of time pressure that have been shown to influence the profitability of different instructional materials (Gerjets, Scheiter, & Tack, 2000).

Another line of research will pertain to the fact that the provision of profitable instructional materials does not ensure that learners indeed use these materials appropriately. This is especially true for computer-based learning environments that allow learners to control for many aspects of the learning process, e.g. the selection of instructional materials (Gerjets, Scheiter, & Tack, 2001). Therefore, we will examine whether learners select method-based instructional materials when they are allowed to choose between different types of information in electronic learning environments. Finally, we will design experiments investigating the influence of explicitely teaching control knowledge (i.e. knowledge on when to choose which method) in addition to the teaching of method knowldege.

Abstract

A computational model of a user navigating Web pages was used to identify factors that affect Web site usability. The model approximates a typical user searching for specified target information in architectures of varying menu depth. Search strategies, link ambiguity, and memory capacity were varied and model predictions compared to human user data. A good fit to observed data was obtained for a model that assumed users 1) used little memory capacity; 2) selected a link whenever its perceived likelihood of success exceeded a threshold; and, 3) opportunistically searched below threshold links on selected pages prior to returning to the parent page.

Introduction

The World Wide Web continues to revolutionize how people obtain information, buy products, and conduct business transactions. Yet many companies and organizations struggle to design Web sites that customers can easily navigate to find products or information. The identification of factors that affect the usability of the World Wide Web has become increasingly important. While many of these factors concern the graphical layout of each page in a Web site, the way in which the pages link to each other, often called the site's information architecture, plays a decisive role in the site's usability, especially for sites allowing access to large databases (Rosenfeld & Morville, 1998) Our effort focuses on understanding how a site's information architecture impacts a user's ability to effectively find content in a linked information structure such as a Web site.

We develop our understanding through the construction and testing of a working computational model. The model simulates a user navigating through a site making choices about whether to select a given link or evaluate an alternate link on the same page. Constructing and testing a working model not only complements empirical studies, but also offers advantages over empirical usability testing. Empirical studies are generally too expensive and time consuming to address the wide range of content, configurations, and user strategies that characterize the Web. In contrast, an implemented model can run thousands of simulated sessions in minutes. Also, empirical studies do not inherently provide explanations for their results and thus make it more difficult to determine how a given result generalizes to other circumstances, whereas a cognitive model can describe the underlying processes that produce behavior. For example, computational models have been used to highlight patterns of interactions with a browser (Peck & John, 1992) and report on the accessibility of the site's content (Lynch, Palmiter & Tilt, 1999).

In this paper, we build upon methods that we presented in an earlier paper (Miller & Remington, 2000a). For the sake of presentation, we describe the methods and our model in its entirety. We introduce a new navigation strategy and show how the model's aggregate behavior tightly fits results from an empirical comparison of different site architectures (Larson & Czerwinksi, 1998). Finally, we experiment with the model's assumptions by exploring alternate designs and parameters in order to help identify critical elements in the model's design.

Modeling Information Navigation

We simulate common patterns of user interaction with a Web site with the goal of providing useful usability comparisons between different site architectures. A model that precisely replicates a user's navigation is not possible, nor is it necessary. Useful information can be obtained from a simple model that captures functionally significant properties of the user and site architecture. Here we show how a simple model can predict and explain benefits of one design over another, such as when it is advantageous to use a two-tiered site instead of a three-tiered site.

In constructing our model, we use the following principles:

- The model should only perform operations that are within the physical and cognitive limitations of a human user. In Web navigation, for example, limits on visual attention dictate that a user can only focus upon (and evaluate) one link at a time. Likewise, limits on short-term memory dictate

navigation strategies that minimize memory requirements, an assumption consistent with evidence that people often adopt memory minimization strategies (Ballard, Heyhoe, Pook, & Rao, 1997).

- The model should make simplifying assumptions whenever they are not likely to have much impact on aggregate behavior. For example the model takes a fixed amount of time to evaluate a link even though human users' times are certainly variable. Since the model simulates the average user, this simplification will provide a good fit given a reasonable estimate of fixed time from human performance data (Card, Moran & Newell, 1983).
- The model should employ the most effective strategy for a given environment unless compelling evidence from human usage suggests otherwise. Given the large set of navigation strategies that can operate within reasonable physical and cognitive limitations, we examine a strategy that is most effective within known cognitive constraints. This design constraint is the rationality principle (see Card, Moran & Newell, 1983), which assumes that human cognition is generally rational.

Representing a Web Site

Our model interacts with a simplified, abstract representation of a Web browser and a Web site. Each site has one root node (i.e. the top page) consisting of a list of labeled links, each leading to a separate child page. For a shallow, one-level site, child pages are terminal pages, one of which contains the target information that the user is seeking. For deeper, multi-level sites, a child page consists of a list of links, each leading to child pages at the next level. The bottom level of all our sites consists exclusively of terminal pages, one of which is the target page. Our examples are balanced trees (i.e. pages at the same level have the same number of links) since we generally compare our results to studies that use balanced tree structures (e.g. Miller, 1981 and Larson & Czerwinski, 1998). However, our representation does not prevent us from running simulations on unbalanced trees, or even on structures involving multiple links to the same page and links back to parent pages.

When navigating through a site, a user must perceive link labels and gauge their relevance to the targeted information. Rather than model the complex and interesting process of link evaluation, we fix a number for each link, which represents the user's immediately perceived likelihood that the target will be found by pursuing this link. This simplification allows us to easily investigate a range of numerical relationships between the link label and the target information.

In an ideal situation, after evaluating a link, the user would know with certainty whether to select and pursue that link. Figure 1 represents a site with such links. Each link (underlined number) on each Web page is understood without ambiguity. The user need only follow the links labeled with a 1.0 to find the targeted page with no backtracking. We describe the architecture of this site as having a two-tiered, 4x2 structure.

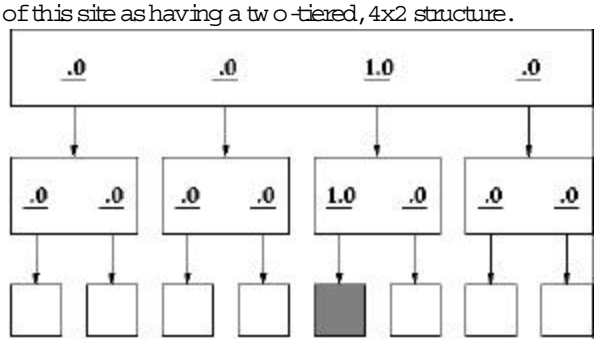

Figure 1 Site with sure path

More often, the user is less certain of which link to select. The links in the site shown in Figure 2 are more ambiguous. For the top page, the most likely link has a perceived likelihood of only .7, thus indicating that the user is less certain that this link will lead to the targeted item. In some cases, a user strategy that merely follows the most likely links would directly lead to the target. However, this figure shows a site where the user would find the target under what he or she perceives as a less plausible sequence of link selections (the target is under a likelihood value of 0.2 instead of the 0.5 value). In this way it is possible to represent sites that differ widely in strength of association between link label and target information.

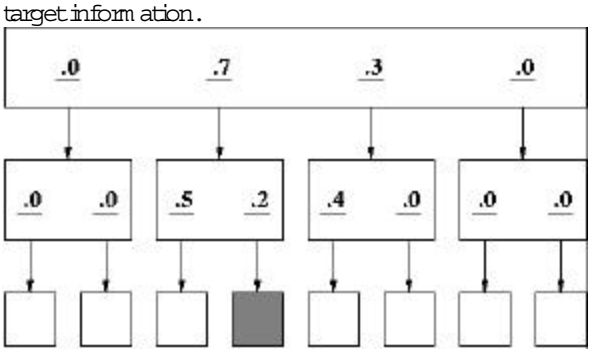

Figure 2 Site with ambiguous labels

Modeling the Browser and User Actions

Byrne et al. (1999) found that selecting a link and pressing the Back button accounted for over 80% of the actions used for going to a new page. Consequently, we focused our modeling on the component actions underlying these behaviors. These include:

- Selecting a link
- Pressing the Back Button

- Attending to and identifying a new page
- Checking a link and evaluating its likelihood

To further simplify our model, attending to and identifying a new page can be folded into the actions of Selecting a Link and Pressing the Back Button since this action only occurs when either of these actions occur. Our revised model has three primitive actions:

- Selecting a link (and attending to and identifying a new page)
- Pressing the Back Button (and attending to and identifying a new page)
- Checking a link and evaluating its likelihood

Because of physical and cognitive limitations, only one of these actions can be performed at any one time. Fixed times are assigned to each action to account for its duration during a simulation. The model also simulates changing the color of a link when it is selected so that the modeled user can "perceive" whether the page under this link was previously visited.

Modeling Navigation Strategies

The model navigates a Web site by serially executing these three primitive actions, meaning that links are sequentially evaluated. Serial evaluation is motivated by evidence that the human user has a single unique focus of attention that must be directed at the link for this decision.

A user could employ any of a large set of possible strategies for link selection that vary in sophistication. Two examples include:

- The threshold strategy: The user immediately selects and pursues any link whose probability of success exceeds threshold.
- The comparison strategy: The user first evaluates a set of links and then selects the most likely of the set.

The threshold strategy is most effective if the first likely link actually leads to the targeted object. The comparison strategy is more effective only if a likely link is followed by an even more likely link that actually leads to the targeted item. Both represent simple yet effective strategies. We chose to begin by examining the threshold strategy on the principle that it requires the fewest computational (cognitive) resources.

The model is neutral as to the actual order in which the links are evaluated. The design and layout of a page principally determine which links a user would evaluate first. Any understanding of how page layout and design affect the user's focus could eventually be incorporated into the model. For our purpose of investigating site structure, the model simply establishes a fixed order in which links are evaluated for each run. To avoid systematic order biases, our simulations randomly place the targeted item at a different terminal page for each run.

With the appearance of a new page, the model's threshold strategy first attends to the page, which, if it is a terminal page, includes checking if it contains the target information. If it does not, the model sequentially scans the links on a page selecting any link whose likelihood is equal to or above a fixed threshold (0.5 in the simulations reported below). When a page appears by selecting a link, the process of checking and scanning the page is repeated.

Once the model detects no unselected links above the threshold value, it returns to the parent page by pressing the Back button and continues scanning links on the parent page starting at the last selected link. It does not scan links it has already evaluated. Determining the last link selected places no demands on memory since the last selected link is easily detected by its color, and many browsers return the user to the location of the last selected link.

Selecting the most probable link will often lead to the targeted item. However, sometimes the targeted item lies behind ostensibly improbable links and, after some initial failures, human users must start selecting links even if the link labels indicate that they will probably not lead to the targeted item. An earlier version of our model (Miller & Remington, 2000a) started selecting improbable links only after completing a full traversal of the site. We will call this the traverse-first strategy. However, a more effective strategy may opportunistically select improbable links at a lower tier immediately after trying the more probable links and before returning to a higher tier in the site. We call this the opportunistic strategy.

Figure 2 illustrates how the opportunistic strategy may be more effective. The model scans across the top page and selects the second link (0.7). On the second level it selects the first link it encounters (0.5). After discovering that this is not the targeted item, it returns to the page on the second level. However, before returning to the top level, it temporarily reduces its threshold to 0.1, selects the second link (0.2) and finds the target on the new page. Had the targeted item been elsewhere in the site, the strategy backs up twice, returning to the top-level and resetting the threshold to the previous value (0.5).

The opportunistic strategy is more efficient than the traverse-first strategy. First, it explores less probable links when the cost of doing so is minimal, that is, when the less probable links are immediately available. Secondly, it implicitly takes into account the positive evaluation of the parent link, which had indicated a high likelihood that the targeted item is under a link on the current page.

The opportunistic strategy is not efficient if employed in cases where all the links on a page have very low likelihood values (defined as less than 0.1). In such cases our model assumes that the user has sufficient memory to know that rescanning the page would be futile, and returns to the parent page. This memory of knowing that the page has nothing worthwhile only lasts as long as the model remains on the current page. Thus, if the model leaves the page and then returns to this same page, the model must assume that the page may be worth rescanning and the opportunistic strategy is employed. This qualification is also consistent with our design principles in that it contributes to an effective strategy while minimizing memory resources.

While generally consistent with our design principle of preferring strategies that place minimal demands on memory, the opportunistic strategy does require state values to be held in memory. If opportunistic search fails to find the targeted item, the model must reset the link selection threshold to the previous value upon returning to the upper level. Resetting a value requires storing the old value before reducing it. Storing and recalling one or two values reasonably fall within the limits of human cognition, but storing and recalling an arbitrary number of values does not. For this reason, our model allows us to fix a limit on the number of previous threshold values it can recall. We initially set this number to one, but later in this paper we will explore the impact of being able to store and recall additional values.

Part of our reason for adopting the opportunistic strategy in place of the traverse-first strategy was our examination of usage logs for a site search task. We conducted a pilot study using a Web site whose structure mirrored a popular department store's organization. Preliminary results suggest that users frequently select ostensibly less probable links before backtracking to other possibilities (see Miller & Remington, 2000b, for more details and an example). We plan future studies that could further identify usages of this strategy.

Simulation Parameters

Our previous work established plausible time constants for link evaluation and link selection (Miller & Remington, 2000a). We compared the model and results from hierarchical menu selection studies and obtained good fits with link evaluation costs set to 250 ms and link selection costs set to 500 ms. The use of time constants is well established (e.g., Card, Moran, & Newell, 1983) and these values are consistent those previous estimates.

To assign likelihood factors to the links, the ideal link values (1, 0) are perturbed with noise according to the formula below:

$$g * n + v$$

where g is a number chosen randomly from a standard normal gaussian distribution (mean=0, stdev=1); n is the noise factor multiplier (equivalent to increasing the variance of the normal distribution); and v is the original likelihood value (0 or 1). Since this formula occasionally produces a number outside the range from zero to one, our algorithm may repeatedly invoke the formula for a link until it generates a number in this range. The noise factor n thus models the level of label ambiguity in the site. Higher levels of ambiguity lead to more frequent backtracking, which may be more prominent in Web search than menu search.

Simulations

To further evaluate the model's design decisions, we compare its performance to the Web navigation results of Larson and Czerwinski (1998). They studied users navigating two-tiered (16x32 and 32x16) and three-tiered (8x8x8) site architectures that were otherwise comparable. Participants took significantly longer to find items in the three-tiered site (58 seconds on average) than the two-tiered sites (36 seconds for the 16x32 site and 46 seconds for the 32x16 site).

Simulations of the Opportunistic Strategy

For our simulations using the opportunistic strategy, sites were constructed as described above, except that the noise was not applied to the bottom level, which leads to the terminal pages. This reflects the fact the participants in Larson & Czerwinski could clearly tell whether the link's label matched the text of the targeted item.

For each site architecture (8x8x8, 16x32, and 32x16) 10,000 simulations were run using the following time costs: 250ms for evaluating a link, 500ms for selecting a link, and 500ms for return to the previous page (pressing the back button). Following Larson and Czerwinski (1998), any run lasting more than 300 seconds was coded as lasting 300 seconds.

Figure 3 shows the calculated mean times of the simulation runs. Not surprisingly, the time needed to find a target increased with link ambiguity. What is more interesting is how link ambiguity interacts with site structure. The 8x8x8 architecture produced slightly faster times at low levels of noise but substantially slower times at noise levels above 0.2. At these higher noise levels the results are consistent with the human users. At noise levels of 0.4 and higher, simulated times were faster with the 16x32 architecture than the 32x16 architecture. This difference was also noted in the study with human users, albeit not reported as statistically significant.

At a noise level of 0.4, the simulation results closely match the human results in absolute terms: 62s

(compare to 58s for humans) for 8x8x8, 43s (compare to 46s) for 32x16, and 35s (compare to 36s). It appears that the 0.4 serves a good parameter estimate describing the amount of label ambiguity in the sites used by Larson and Czerwinski.

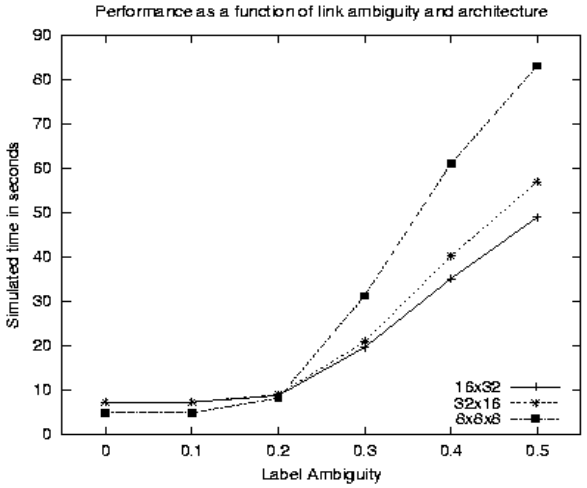

Figure 3 Simulating threshold and opportunistic strategies

Impact of Time Costs

While changing the time costs (250ms for link evaluations and 500ms for link selection and returning to the previous page) will affect absolute simulation times, it is less clear if different time costs will change which architecture produces the fastest times. For example, one may wonder if the 8x8x8 architectures would still produce the slowest times if the link selection cost were double, which may occur for a slower internet connection.

To explore the impact of time costs, we look at the number of link evaluations, link selections and page returns. If independent counts of these actions correlate with the aggregate simulation time, we conclude that varying the time costs have minimal impact on the relative performance of the different architectures. For example, if the 8x8x8 requires more evaluations, more selections and more returns than the other architectures, we know that 8x8x8 will produce slower search times regardless of the time costs.

Looking at the number of evaluations, selections and returns, we see that the 8x8x8 architecture required more of each action (173, 17, and 19 respectively) at the 0.4 noise level than the 16x32 (125, 3, and 5) and the 32x16 (134, 6, and 8). Further experimentation reveals that this relationship holds across all but the lowest noise levels (0.2 and less). We conclude that changing the time costs have no effect on the relative comparisons provided that the noise level is at least 0.3.

Impact of Memory Capacity

Recall that the opportunistic strategy requires the model to store and retrieve threshold values so that the previous threshold can be reinstated upon returning to a parent page. So far, our simulations have assumed that only one threshold value can be restored. Thus, if the model returned to the top level of a three-tier architecture, it would no longer be able to recall the previous threshold and would simply leave the threshold at its current state.

Because this limited memory capacity only hinders performance in a three-tiered site (e.g. 8x8x8), we ran simulations where the memory capacity could hold the additional threshold value so that the previous value could be reinstated when navigating through a three-tiered site. Figure 4 shows the results using the same scale as Figure 3. While we see that the extra memory capacity improves the performance of the 8x8x8 architecture, its navigation is still slower than the two-tiered architectures.

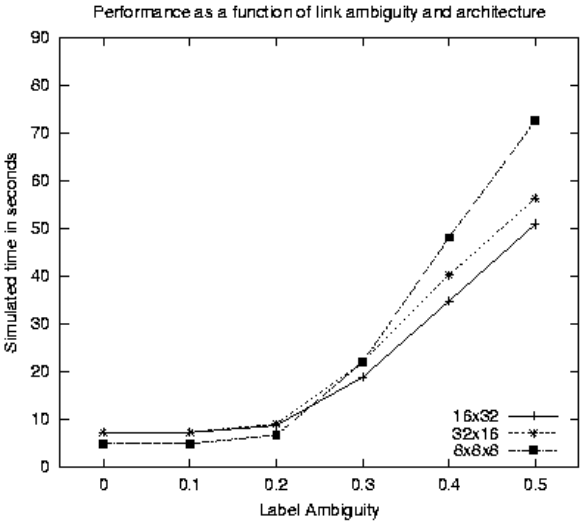

Figure 4 Results using a larger memory capacity

Discussion

We have shown that a simple model of a Web user can provide an excellent account of user behavior and reveal important factors underlying Web usage. The model suggests that link ambiguity interacts with the depth of information architecture to determine site navigation time. As link ambiguity decreases, better performance is found from architectures with deep structures that minimize the number of links searched. As link ambiguity increases, the model shows performance degradations for architectures with deeper structures. The same pattern is characteristic of human users. However, the preference for shallow hierarchies is observed only with sufficient ambiguity in the link

labels and with no ambiguity at the bottom level. Thus, the results of Larson and Czerwinski (1998) may not generalize to large numbers of real Web pages with ambiguity at all levels.

As for Web search strategies, combining threshold-based selection with opportunistic search strategies produced simulated times that are very close to observed times for 0.4 noise level. This also corresponds to the behavior of several users searching a department store site in the pilot study mentioned above. We recognize the need for converging methods to independently determine link ambiguity and are exploring theoretical and empirical methods of estimating actual values.

To make time predictions, our model assumes plausible time costs for link evaluation, link selection and returning to the previous page. By noting the actual counts for these operations, our simulations help us understand what happens when the link selection time is significantly longer, as would be the case for a slow internet connection. We found, however, that the time costs have no effect on the relative comparisons provided that the noise factor is at least 0.3. This suggests that a slower internet connection does not impact the relative advantage of shallow architectures when significant link ambiguity is present, at least for the case where no noise is present at the bottom level.

Our simulations also aid our understanding of how human memory impacts effective navigation. Increasing the model's memory capacity improved performance for the deep (8x8x8) structure but left the other two architectures largely unaffected. This suggests that memory is more useful in keeping track of site architecture than in searching within a page. Since searching a page is facilitated by visual cues (e.g., changes in the color of previously selected links) users can avoid reliance on memory. Visual cues are typically not present to remind users of the names and locations of previous links. The interaction of structure with memory capacity indicates further that simple heuristics for representing capacity are insufficient to capture memory phenomena of importance. Instead, it is necessary to examine how the structure of information sites provides aids to memory. Our analysis contrasts with previous advice suggesting that the number of links per page should be limited to 10 (Rosenfeld & Morville, 1998) (see Larson & Czerwinski, 1998, for a discussion based on experimental results).

We have shown that a simple model of a user interacting with a simplified Web site can reveal important factors that affect usability and can support the investigation of the interactions between those factors across a wide range of conditions. What we have presented is not a comprehensive model of Web navigation. No attempt is made to account for how people scan a page, or evaluate link labels or images. By abstracting these processes, and representing only their functionality, the model focuses on understanding how information architecture affects the navigation process. As an approximation of user navigation, the model can account for a range of human behaviors by varying likelihood factors in its site representations. We have shown that the model provides a good approximation of the behavior of the common (modal) user. By varying parameters it should be possible to extend the model to account for alternate strategies.

Emergence of Effects of Collaboration in a Simple Discovery Task

Kazuhisa Miwa (miwa@cog.human.nagoya-u.ac.jp)
Graduate School of Human Informatics, Nagoya University
Nagoya, 464-8601 JAPAN

Abstract

We discuss the effects of collaboratively finding a target in a simple discovery task, using the Wason's 2-4-6 task. We control the following two factors: hypothesis testing strategies that participants use, and the nature of targets that they find. First, we propose, through computer simulations, a hypothesis on a situation in which the effects emerge. Then we verify the hypothesis by psychological experiments. Last, we generalize, through theoretical analysis, the findings obtained by the two empirical approaches above. As the result, it has been concluded that the effects of collaboration emerge in the following situations: (1) two participants repeatedly conduct a positive test for finding a general target, and (2) each of them maintains a different hypothesis.

Introduction

In psychological studies on scientific discovery, relatively simple tasks, such as the Wason's 2-4-6 task and New Elusis, have been so far used (Gorman, 1992; Newstead & Evans, 1995). In recent days, using those tasks, the effects of collaboration have been empirically discussed when several participants collaboratively find a target.

We usually think that working together provides positive effects. However, those empirical results obtained in the psychological studies above do not necessarily support the intuitive prediction.

In these studies, the performances (the proportions of correct findings) in the single condition in which a single subject performs the task and those in the collaborative condition in which a group of n subjects collaboratively performs the task are compared. In this comparison, even when the latter performance exceeds the former, the advantage may be introduced not by the interaction among the subjects, but simply by the quantity of the subjects. That is, in the latter case n solutions (final hypotheses) by the n subjects are considered, and the probability of that at least one of them is accidentally identical to the target is much higher than that in the former case. So we should consider the independent condition in which n participants independently perform the task without interaction. The performance in the independent condition can be theoretically calculated from the performance in the single condition. That is, the probability of that at least one of n subjects reaches the solution is $1 - (1 - p)^n$ where the probability of each subject's finding the correct target is p ($0 < p < 1$). We utilize this score as the performance in the independent condition.

Table 1 reviews the comparison of the performances in the single, independent, and collaborative conditions in the preceding studies (Freedman, 1992; Laughlin & Futoran, 1985; Laughlin & McGlynn, 1986; Laughlin, VanderStoep, & Hollingshead, 1991; Laughlin, Bonner, & Altermatt, 1998; Okada & Simon, 1997). Table 1 shows that the performance in the collaborative condition cannot exceed that in the independent condition in almost all cases.

In this study, we will discuss states in which the effects of collaboration emerge based on the results above. As an approach, first we will propose a hypothesis on when the effects of collaboration appear by computer simulations using a computational model that solves the Wason's 2-4-6 task (Wason, 1960). Then we will verify the hypothesis by psychological experiments. Last we will generalize the empirical findings by theoretical task analysis, and discuss why the effect emerges only in the specific situation.

Fundamental issues

Klayman & Ha, in their paper in 1987, gave some decisive answers to several historical questions that had been discussed in the psychological studies using traditional discovery tasks such as the Wason's task (Klayman & Ha, 1987). One of their major conclusions was that there was substantial interaction between the nature of found targets and the effectiveness of hypothesis testing strategies used by subjects. So in this study we will control these two factors in the following experiments.

First, we briefly explain some important concepts about the two factors: the nature of targets that subjects should find and the hypothesis testing strategies that subjects use.

The nature of targets: we categorize targets used in our experiments from the viewpoint of their generality. General targets are defined as the targets, the proportion of whose member (positive instances) to whole instances in the searched space is large. On the other hand, specific targets are defined as the targets, the proportion of whose member is small. For example, the proportion of the instances fitted to "the product is even" and "three evens" to all possible

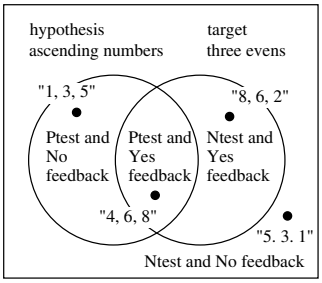
Table 1 Comparisons of the performances in the single, independent, and collaborative conditions in the preceding studies.

	Laughlin (1985)	Laughlin (1986)	Laughlin (1991)					Laughlin (1998)	Freedman (1992)		Okada (1997)
# of group members	4	4	4					4	4		2
task	New Elusis	New Elusis	New Elusis					New Elusis	2-4-6 task		simulated molecular genetics laboratory
single	0.15	0.19	0.06	0.13	0.15	0.14	0.16	0.16	0.33	0.08	1.7
independent	0.47	0.57	0.2	0.3	0.38	0.3	0.41	0.38	0.80	0.28	2.1
collaborative	0.35	0.34	0	0.1	0.2	0.1	0.41	0.34	0.83	0.67	2.9

instances are 7/8 and 1/8 respectively. So the former is an example of a general target and the latter is an example of a specific target.

Hypothesis testing strategies: There are two types of hypothesis testing: a positive test and a negative test. The positive test (Ptest) is conducted by an instance subjects expect to be a target. That is, Ptest is hypothesis testing using a positive instance for the hypothesis; the negative test (Ntest) is hypothesis testing using a negative instance. For example, when a hypothesis is "ascending numbers", hypothesis testing, using an instance, "1, 3, 9", is Ptest; hypothesis testing, using "1, 5, 2", is Ntest.

In the following description, for avoiding the confusion of the basic concepts, we define *Yes* and *No* instances as members and non-members (positive and negative instances) for targets that subjects do not know. On the other hand, we also define *Positive* and *Negative* instances as members and non-members for hypotheses that subjects form. When a subject conducts an experiment using a *Positive* instance for his/her hypothesis, and knows, through the feedback from an experimenter, that the instance is a *Yes* instance for a target, we call that the subject receives *Yes* feedback as a result of his/her *Ptest.*



hypothesis	target: Yes	target: No
Ptest	confirmation	disconfirmation
Ntest	disconfirmation	confirmation

Figure 1 Patterns of confirmation and disconfirmation.

Klayman et. al. summarized the states when a subject's hypothesis was disconfirmed. Figure 1 illustrates those states in the example situation of that the target is "three evens" and the subject's hypothesis is "ascending numbers". When the subject conducts Ptest, using an instance, "1, 3, 5", and receives No feedback, his/her hypothesis is disconfirmed. Another state of disconfirmation is introduced by the combination of Ntest and Yes feedback, using an instance, "8, 6, 2". On the other hand, the states of confirmation are introduced by the combination of Ptest and Yes feedback, using "4, 6, 8", and the combination of Ntest and No feedback, using "5, 3, 1".

Computer simulations

First, we will propose a hypothesis on when advantages of collaboration appear by computer simulations.

Specifications of the model

In the following, we will explain only the summary of our model. Detailed specifications of the model can be seen in our other papers (Miwa, 1999).

The model was constructed on the interactive production system architecture that we had developed for simulating collaborative problem solving processes. The architecture primarily consists of five parts; production sets of System A, production sets of System B, the working memory of System A, the working memory of System B, and a common shared blackboard. Two systems interact through the common blackboard. That is, each system writes elements of its working memory on the blackboard and the other system can read them from the blackboard.

The model has knowledge on the regularities of three numerals. The knowledge is organized as the dimension-value lists. For example, "continuous

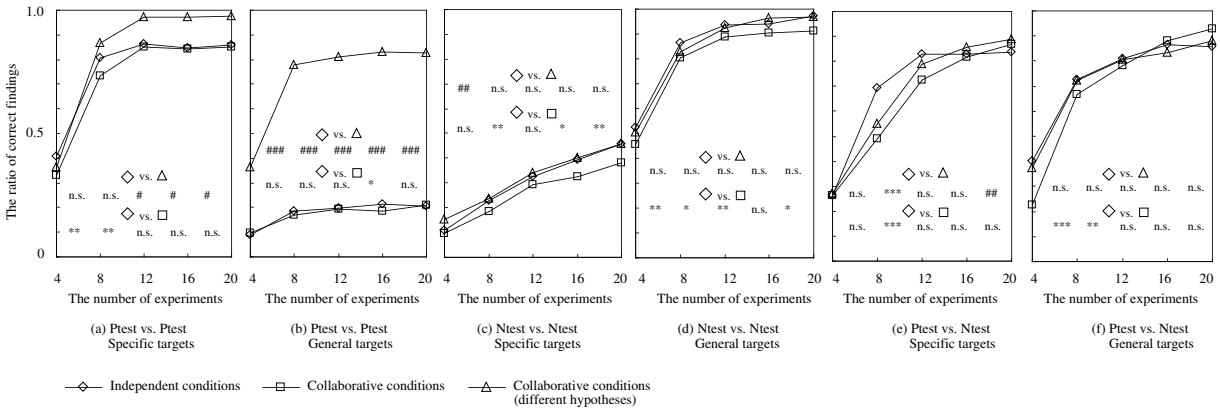


Figure 2 Results of the computer simulations.

evens", "three evens", and "the first numeral is even" are example values of a dimension, "Even-Odd". The dimensions the model uses are: Even-Odd, Order, Interval, Range of digits, Certain digit, Mathematical relationship, Multiples, Divisors, Sum, Product, and Different.

Basically the model searches the hypothesis space randomly in order to generate hypotheses. However, three hypotheses, "three continuous evens", "the interval is 2", and "three evens" are particular. Human subjects tend to generate these hypotheses at first when the initial instance, "2, 4, 6", is presented. So our model also generates these hypotheses first prior to other possible hypotheses.

As for a way of hypothesis verification, the principle on when a model's hypothesis is disconfirmed and a next hypothesis is reconstructed is based on the Klayman & Ha's schema shown in the previous section.

The design of simulations

In our computer simulations, we let the two systems find 35 kinds of targets. Examples of the targets are: three continuous evens, ascending numbers, the interval is 2, single digits, the second numeral is 4, first numeral times second numeral minus 2 equals third numeral, multiples of 2, divisors of 24, the sum is a multiple of 12, the product is 48, and three different numbers. The initial instance was "2, 4, 6". For each target, we executed 30 simulations to calculate the percentage of correct solutions.

The computer simulations were conducted based on the following 2 * 3 experimental design.

The nature of targets: We divided the 35 targets into two categories: (a) 17 specific targets and (b) 18 general targets.

Hypothesis testing strategies: Three combinations of hypothesis testing strategies were investigated. They were (a) Ptest and Ptest, (b) Ntest and Ntest, and (c) Ptest and Ntest.

Results of the simulations

Figure 2 shows the results of the computer simulations. The horizontal axis of the figure indicates the number of experiments, that is, the number of generated instances whereas the vertical axis indicates the proportion of correctly finding the 17 specific targets and the 18 general targets.

In Figure 2, the performances in the independent condition and those in the collaborative condition are compared. In the independent condition, we regard that the targets are correctly found when at least one of the two systems, each of which independently tries to find the targets without interaction, reaches the correct solution.

In the collaborative condition, experiments are alternately conducted. Through each simulation, one system generates the half of whole instances; and the other half is generated by the other system. Each experimental result is shared by both two systems, that is, each system knows whole generated instances with Yes or No feedback that is given to each instance.

In addition, the collaborative condition is subdivided into the following two sub-conditions. In one sub-condition, each system simply alternately conducts experiments, not referring to another hypothesis that the other system forms. In this sub-condition, two systems share only the experimental space. In the other sub-condition, one system tries to form a different hypothesis, referring to another hypothesis of the other system. In the latter sub-condition, two systems share the hypothesis space in addition to the experimental space (Klahr &Dunber, 1988).

In the figure, the results of statistical analysis are also indicated. The upper row indicates the difference

between the performances in the independent condition and those in the collaborative condition where two systems try to form different hypotheses, whereas the lower row indicates the difference between the performances in the independent condition and those in the collaborative condition where each system does not refer another hypothesis of the other system. The asterisks show the advantage of the independent condition whereas the sharps show the advantage of the collaborative condition. Three levels of significance are used: ### (or ***) for $p < .01$, ## (or **) for $p < .05$, and # (or *) for $< .1$. No significance is indicated with n.s.

Figure 2 indicates that the performance in the collaborative condition exceeds that in the independent condition only when (1) both systems use the Ptest strategy for finding general targets, and (2) both systems try to form different hypotheses, sharing their hypothesis space. In the other cases, the effect of collaboration is not remarkable.

Psychological experiments

To verify the results of the computer simulations in the previous section, we conducted psychological experiments.

Design and procedure

A total of 136 subjects participated in the experiments. Each of them was assigned to each of the following five experimental conditions: (1) the single Ptest condition where a single participant solved a task using Ptest, (2) the single Ntest condition, (3) the collaborative Ptest and Ptest condition where two participants, both of whom were required to use Ptest, collaboratively solved a task, (4) the collaborative Ntest and Ntest condition, and (5) the collaborative Ptest and Ntest condition. Each subject solved two problems. In one problem, "three evens", as a specific target, was discovered. In the other problem, "three different numbers", as a general target, was discovered. The order of the problems was counter-balanced. Twenty-four trials (experiments) were permitted for finding each target. The experimental design is summarized in Table 2.

Table 2 The number of subjects and pairs in each experimental condition.

	single		pair		
	Ptest	Ntest	Ptest v.s. Ptest	Ntest v.s. Ntest	Ptest v.s. Ntest
specific	17(15)	18(14)	16(15)	15(11)	17(11)
general	17(10)	17(12)	17(12)	16(9)	17(9)

In the following discussion, we exclude the results of the subjects who did not follow the experimental instruction requiring to use each hypothesis testing strategy. Table 2 shows the number of subjects (or pairs) assigned to each experimental condition, and, in parenthesis, the number of them who correctly follow the Ptest and Ntest instruction.

Results of the experiments

Figure 3 indicates the experimental results, using the same format of Figure 2. In Figure 3, experimental results that were actually obtained in the experiments are the performances in the collaborative condition (collaborative conditions in (a) through (f)), and those in the single condition where both participants used the same hypothesis testing strategy (single conditions in (a) through (d)). On the other hand, the performances in the single condition, where each subject used a different strategy, are the average scores of the performances in the single Ntest condition and those in the single Ptest condition (single conditions in (e) and

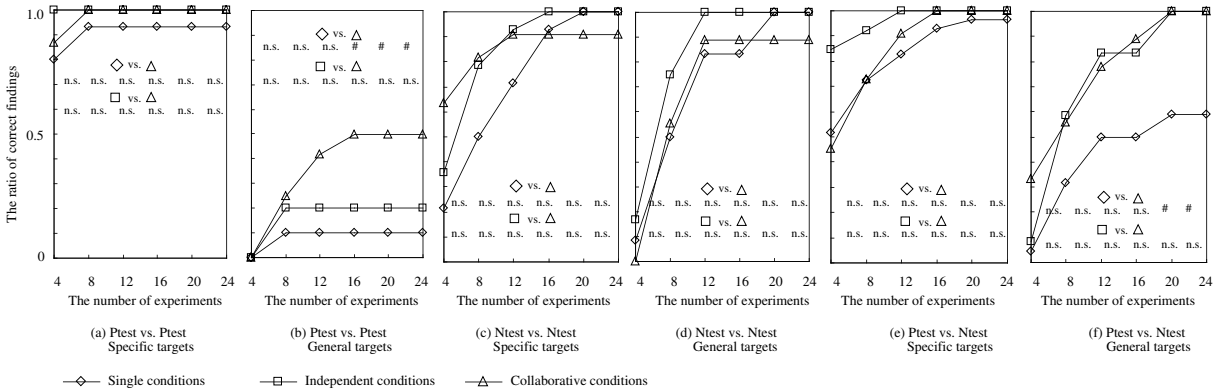

Figure 3 Results of the psychological experiments.

(f)). Additionally the performances in the independent condition are calculated from the performances in the single condition by using the similar procedure indicated in the introduction (independent conditions in (a) and (f)).

As for statistical analysis, the upper row indicates the difference between the performances in the single condition and those in the collaborative condition, whereas the lower row indicates the difference between the performances in the independent condition and those in the collaborative condition.

The statistical analysis shows, in every combination of the hypothesis testing strategies, that the performances in the collaborative condition cannot exceed those in the independent condition. However, only in the combination of Ptest and Ptest for finding the general target, the performance in the collaborative condition exceeds that in the single condition, and a tendency of the advantage of the collaborative condition over the independent condition is observed even though the statistical analysis does not indicate the significant difference.

Next, to confirm the effect of two subjects' forming different hypotheses, we will conduct the following additional analysis. First, we divide the subjects in each collaborative condition into two groups: the subjects who found the correct target earlier and those who did later. The latter group includes those who did not find correct target. Then we measure the average of the proportion of that the subjects in each group maintained different hypotheses through the trials till reaching the solution. Figure 4 shows the result. What we note is that the effect of forming different hypotheses appears in the combination of Ptest and Ptest, especially when finding the general target, whereas this effect does not appear in the combination of Ntest and Ntest. These results are consistent with the findings of the computer simulations.

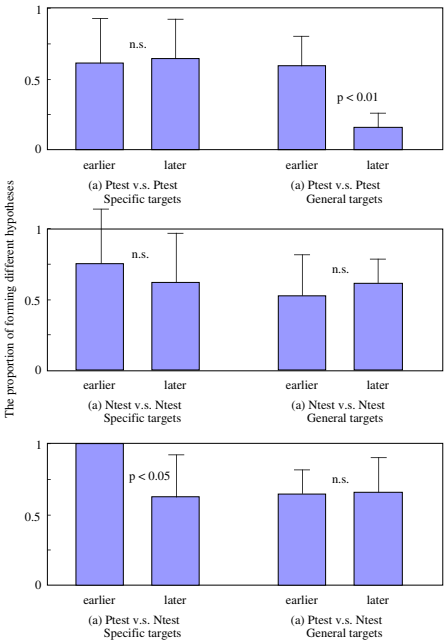

Figure 4 Proportion of forming different hypotheses in the earlier finding group and the later finding group.

Theoretical analysis

Why does the advantage of collaboration emerge only when both participants, for finding the general targets, repeatedly conduct Ptest? We will discuss the reason based on the Klayman & Ha's framework of analysis.

Klayman et. al. indicated, by their mathematical analysis, that Ptest was an effective heuristic for finding specific targets; on the other hand, Ntest was effective for finding general targets.

When a target is general, the possibility of receiving Yes feedback is high in the experiments. In the situation, it is difficult that Ptest introduces disconfirmation because the combination of Ptest and Yes feedback introduces confirmation. So Ptest often prevents subjects from finding general targets. In addition, Ntest is an ineffective strategy for finding specific targets because subjects very often receive No feedback as a result of their Ntest. The collaboration of two systems can compensate for these week points of hypothesis testing strategies.

Let us consider the collaborative condition in which both two systems (or two subjects), System A and System B, alternately conduct Ptest, and the systems have different hypotheses. In this situation, it happens that a positive instance for a hypothesis of System A, HA, corresponds to a negative instance for another hypothesis of System B, HB. For example, when a hypothesis HA is "the interval is 2" and a hypothesis HB is "ascending numbers", an instance, "2,

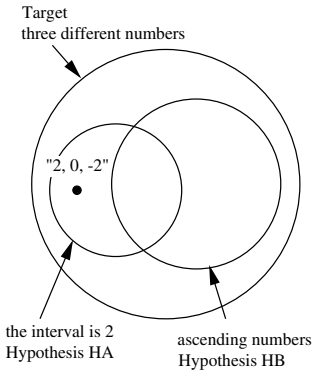

Figure 5 A situation of that Ptest of one system, System A, introduces Ntest of the other system, System B.

0, -2", is this kind of instance (see Figure 5).

When System A conducts Ptest, using this instance, it happens that for System B Ntest is introduced by the instance generated by System A. As a result, Yes feedback introduces disconfirmation of the hypothesis HB because the combination of Ntest for HB and Yes feedback is carried. This brings the effect of collaboration when two systems, both of which use Ptest, find general targets.

An important point is that this function emerges in the interaction between two systems. This advantage is not introduced as the effect of the quantity of the systems. That is, the advantage is not the effect of that the number of systems in the collaborative condition is twice as many as that in the single condition. As you can confirm in Figure 5, when each system independently conducts Ptest, a hypothesis of each system is never disconfirmed. Chances of hypothesis disconfirmation can be introduced only through the collaboration of two systems.

A next question is why this kind of effect does not appear in the combination of Ntest and Ntest when finding specific targets where the probability of subjects' receiving No feedback is very high.

If the above-mentioned type of interaction between two systems emerges in the combination of Ntest and Ntest, the situation in which Ntest of System A introduces Ptest for System B should happen. However, generally speaking, members (positive instances) of a hypothesis is much fewer than the non-members (negative instances). So the possibility of constructing the situation in which Ntest of one system accidentally introduces Ptest for the other system, where the effect of the Ntest and Ntest collaboration appears, is much lower than the possibility of constructing the situation in which Ptest of one system introduces Ntest for the other system, where the effect of the Ptest and Ptest collaboration appears. This is the reason why only the combination of Ptest and Ptest introduces the effect of collaboration.

Conclusions

In the introduction of this paper, we indicated that the effects of collaboration rarely appeared in the psychological experiments, using orthodox simple discovery tasks. We empirically demonstrated a situation in which those effects of collaboration emerged, and theoretically discussed why the effects were introduced. Concretely, we indicated that the effects appeared when both subjects (systems) verified their hypotheses by using Ptest for finding general targets. This result is more interesting, as a finding on collaborative discovery, when we note that humans have a cognitive bias of tending to use Ptest more frequently.

Our empirical findings and theoretical discussions conclude that (1) generally speaking, simply solving a problem together rarely introduces the effects of collaboration, (2) to introduce the effects of collaboration, it is needed that the interaction between collaborative systems brings new abilities, such as a function for introducing disconfirmation of their hypotheses, which are not involved in each individual system, and (3) the possibility of bringing those abilities depends on natures of objects that systems investigate, strategies and heuristics that systems use, and the relation between these factors.

Abstract

This study examined the effects of a competing signal on sentence-word priming using an auditory lexical decision paradigm. Previous studies have suggested that the facilitatory component of the sentential priming effect is particularly sensitive to acoustic distortions that reduce the perceptibility of the sentence context, whereas the inhibitory component is more sensitive to increased attentional demand. Three competing signal conditions were compared: forward speech presented to a different ear, backward speech presented to a different ear, and forward speech presented to the same ear. The results demonstrate that the competing signal has different effects on priming depending upon the semantic content of the signal and its perceptual isolability from the sentence context.

Introduction

The influence of sentence meaning on lexical processing has been studied extenstively in sentence-word priming studies, which have demonstrated that sentence context has both facilitatory and inhibitory effects on responses to single words (e.g., Stanovich & West, 1983; Meyer & Schvaneveldt, 1976; Simpson, Peterson, Casteel, & Burgess, 1989; Duffy, Morris, & Henderson, 1989). In other words, reaction times for words preceded by a highly congruent sentence context are faster than those preceded by a neutral context, whereas responses to words presented in an incongruent are slowed relative to a neutral context. Further, facilitatory and inhibitory effects tend to emerge under different experimental conditions in both sentence-word and word-word priming studies. Specifically, facilitation effects emerge at brief stimulus onset asynchronies (SOAs), and are generally insensitive to expectancy and processing strategies (Neely, 1991; Utman & Bates, 1998a,b), to the extent that facilitation is observed even when a prime stimulus is presented briefly and then masked, such that subjects are not consciously aware of the identity of the prime (Neely, 1991). In contrast, inhibitory effects are more pronounced at longer SOAs, and are sensitive to factors that affect expectancy, such as the proportion of related/unrelated test trials in the stimulus set (Neely, 1991), and tend to be reduced in populations with limited attentional capacity (e.g., Faust, Balota, Duchek, Gernsbacher, & Smith, 1997). Based on this evidence, researchers have argued that facilitation occurs rapidly and requires little in the way of attentional and/or processing resources, whereas inhibition occurs later in the time course of lexical access, and may reflect more controlled or strategic processing (Faust & Gernsbacher, 1996; Gernsbacher, 1997; Neely, 1991; Utman & Bates, 1998a,b).

Recent studies have revealed that the facilitatory and inhibitory components of the sentence-word priming effect respond differently to acoustic distortion of the semantic context. Specifically, facilitatory effects are particularly sensitive to distortions that reduce the intelligibility of the acoustic signal, whereas inhibitory effects are more sensitive to distortions that reduce processing time and/or increase attentional demand (Utman & Bates, 1998 a,b; Utman, Dick, Prat, & Mills, 1999). For example, low-pass filtering of the sentence context significantly reduces facilitation of congruent targets (Utman & Bates, 1998a,b). In contrast, temporal compression of the context significantly reduces inhibition of incongruent targets, but has no effect on facilitation (Utman & Bates, 1998a,b). These findings suggest that facilitation effects are more dependent on bottom-up information from the acoustic signal, whereas inhibition effects are more dependent on attentional resources.

In the present study, we sought to investigate how competing speech influences the facilitatory and inhibitory components of the sentence-word priming

effect. The separate influences of perceptual and attentional factors on facilitation and inhibition have particular implications for competing speech. It is generally recognised that competing speech places an increased demand on processing resources, as the listener must selectively attend to one signal while suppressing another. For example, Downs & Crum (1978) found that competing speech significantly increased effort required for auditory learning, although actual performance was not affected. They concluded that competing speech increased attentional load, thereby decreasing resources for speech processing. More recently, Connolly, Phillips, Stewart, & Brake, (1992) found that hearing competing speakers resulted in a decreased ability to process semantic features of the target speech, indicating that the increased attentional demand of competing speech directly affects semantic processing.

Competing speech may also be relatively more demanding than a competing signal with no semantic content, because the speech signal will activate linguistic representations that are in conflict with the attended signal. Unattended speech has been found to be processed at a semantic level by Moray (1959) as well as Bentin, Kutas, & Hillyard (1995). Further, Garstecki & Mulac (1974) found that subjects had more difficulty on an auditory discrimination task when competing speech was played forwards than when it was played backwards, although subjects described the backwards speech as sounding like language. The interference effect was attributed to the semantic content of the forward speech. In addition, Harris, Benedict, & Leek (1990) observed that performance on a language-based task was more severely disrupted by more intelligible competing speech, and that performance was worst with only one competing speaker, as it is easier to extract semantic information from the competing signal of a single voice than several.

In addition to placing increased demands on attentional resources, competing speech may also affect the perceptibility of the attended signal by masking the spectral frequencies of the signal, thereby interfering with the bottom-up encoding of phonetic contrasts. This effect may be particularly pronounced when the two competing signals come from a similar spatial location, making the target signal more difficult to isolate.

These possibilities were explored in a sentence-word priming study, in which the sentence context was presented in isolation or in the presence of a competing signal. Lexical decision responses to target words were compared when the targets were presented in congruent, neutral, and incongruent sentence contexts. Given the framework described above, it was possible to predict the effect of different forms of auditory competition on lexical decision following biasing sentence contexts.

When the context was easily isolable from the competing signal, we expected that the primary effect of competing speech would be to increase attentional demand, leaving the perceptibility of the context relatively unaffected. As a result, we predicted that strategic or attentional inhibitory processes would be severely compromised, while facilitation would remain intact. This hypothesis was tested by presenting the semantic context and the competing speech signal to different ears. In this case, we predicted no significant change in reaction times to contextually congruent targets, but a significant decrease in inhibition for contextually incongruent words.

We expected this release from inhibition to be more pronounced for a competing signal with semantic content, as a meaningful signal should place relatively greater demands on available resources for semantic processing. To confirm this prediction, we compared the effect of competing speech with that of a similar competing signal with no semantic content, i.e. backward speech. Since backward speech does not appear to greatly tax attentional resources despite its speech-like properties, we predicted no significant difference in reaction times between targets preceded by sentence contexts presented in isolation and targets preceded by sentence contexts accompanied by competing backward speech in a different ear.

We also considered the effect of competing speech when presented in the *same* auditory channel as the sentence contexts, by presenting forward speech in the same ear as the semantic context. In this case, we expected that the competing signal would have a masking effect, disrupting the peripheral encoding of the speech input, as well as making it more difficult to attend only to the appropriate sentence. Consequently, we predicted that both facilitatory and inhibitory effects of sentence context would be affected.

Method

Participants

Thirty-six undergraduates (15 male and 21 female) at Oxford University participated in the experiment. All participants were right-handed, native British English speakers. None reported any hearing impairments.

Stimuli

The stimuli consisted of 30 target words, 30 nonwords, a neutral sentence, and 60 highly constraining sentence contexts (30 to be paired with targets and 30 with nonwords).

The targets were one-syllable words containing 3-5 phonemes (mean = 3.27, SD = 0.64) with a mean Kucera-Francis print frequency of 139 (SD = 99) (Kucera and Francis, 1967), a mean London-Lund spoken frequency of 14 (SD = 81) (Brown, 1984), and a mean concreteness rating of 546 (SD = 81) as specified in the MRC Psycholinguistic Database (Coltheart, 1981). To avoid possible morphological and morpho-phonological constraints of determiners (*a/an*, *the*), mass nouns (e.g., *blood*, *dust*) were excluded, and all targets were consonant-initial. The nonword distracter targets consisted of phonologically permissible one-syllable nonsense items, which did not differ significantly from the targets in terms of number of phonemes (mean = 3.33, SD = 0.61).

The sentence contexts matched with the word targets were approximately ten syllables in duration (mean = 9.47, SD = 2.66), containing a maximum of six content words (mean = 3.37, SD = 1.07), and a maximum of three words related to the congruent target (mean = 1.13, SD = 0.51). There was no significant difference in length or number of content words between sentences paired with word targets and sentences paired with nonword distractors.

In the congruent condition, word targets were matched with the appropriate sentence context (e.g., *He wanted to come in, but she refused to open the...* - DOOR). In the incongruent condition, word targets were matched with a sentence context appropriate to another target in the stimulus set (e.g., *He wanted to come in, but she refused to open the...* - HORSE). Pilot analyses revealed that word targets had a mean cloze probability of 100% (SD = 0%) when presented in the correct context. Therefore, if a target was presented in an incongruent context its cloze probability was 0%. A neutral sentence context, providing no semantic cues with regard to the target (*The next item is...*), was created to serve as a neutral baseline.

Each participant received one of six randomised lists, each containing 60 trials. Across lists, each target appeared in each condition (congruent alone, congruent + competing signal, neutral alone, neutral + competing signal, incongruent alone, and incongruent + competing signal), with no target or biasing context appearing more than once per list. In each of the three semantic context conditions, half of the sentences were presented without a competing signal (presented alone in only one ear), or with a competing signal (presented in one ear with the competing signal presented in the same ear or the other ear). Thus, semantic bias (congruent, neutral, or incongruent) and competing signal (present or absent) served as within-subjects variables (each participant received all six conditions). This pattern also applied to the thirty nonwords and their sentence contexts in each list.

The stimuli were produced by native speakers of British English. To distinguish each target clearly from the preceding context, the words and nonwords were produced by a male speaker, and the sentences were produced by a female speaker. The stimuli were recorded onto digital audio tape in an Industrial Acoustics 403-A audiometric chamber with a Tascam DA-P1 Digital Audio Tape recorder and a Sennheiser ME65/K6 supercardioid microphone and pre-amp at gain levels between -6 and -12 db. The recorded stimuli were then digitised via digital-to-digital sampling onto a Macintosh G4 computer via a Digidesign audio card using ProTools LE software at a sampling rate of 44.1 kHz with a 16-bit quantization. The waveform of each sentence, target, and nonword was then edited and saved in its own mono-audio file. All the stimulus files were converted into 16-bit 22.05 kHz stereo files in SoundEdit16 and saved in System 7 format.

Competing Speech Conditions

A passage from the book *Profit Patterns* (Slywotzky, 1999) was also recorded and edited on the same equipment and under the same conditions (including gain levels) but using a different female speaker. This recording was then used for both the forward and backward competing speech conditions.

In the forward competing speech condition (different ear), copies of all the stereo sentence files were made and segments of competing speech of the same duration as the sentence context were excised at random and inserted on the blank track in the stereo sound file.

In the backward competing speech condition (different ear), the same competing speech was used as in the forward speech condition, played backward. This was achieved using the backwards function in SoundEdit16. This condition was intended to produce auditory interference with the same frequency spectrum as speech but without semantic content.

In the forward competing speech condition (same ear), the sentence contexts were mixed with the forward speech and presented through a single channel. All the original stereo files containing forward competing speech were converted into new stereo files in which the two tracks had been mixed together using the mix function in SoundEdit16.

Type of competing signal (forward/different ear, backward/different ear, and forward/same ear) served as a between-subjects variable (each participant was assigned to one of the three conditions).

Procedure

The test trials were presented auditorily with an inter-stimulus interval of 1500 ms on a Macintosh G4 computer using SuperLab software. The stimuli were

presented through Sennheiser HD 25-1 headphones via a Sirocco VideoLogics amplifier in a sound-protected testing room. Reaction times (RTs) and accuracy were recorded in SuperLab from a Cedrus RB-610 response box. Subjects were instructed to respond as quickly and accurately as possible after hearing the target word, and to press a green button if they heard a real English word or a red button if they heard a nonword. Whether the participant heard the context sentence in the left or right ear was counterbalanced across both lists and male and female subjects.

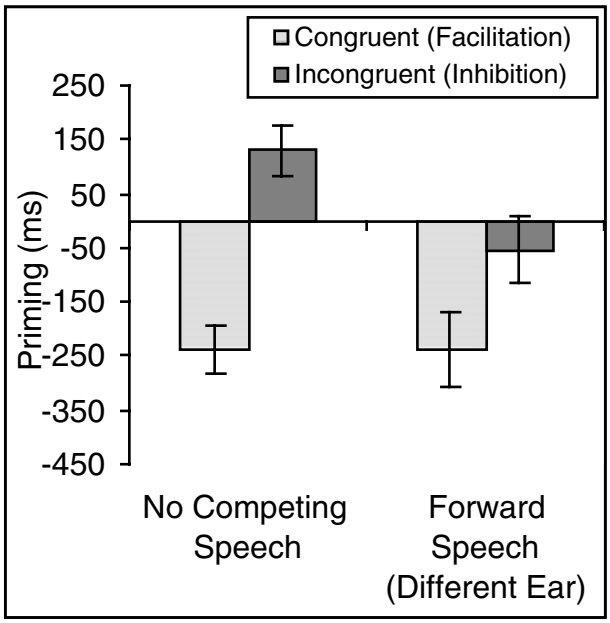

Figure 1. Effect of forward competing speech (different ear). Error bars indicate standard error.

Results

To minimise the effect of outliers in the RT data, the median RT for correct responses was calculated for each subject in each condition for use in the statistical analyses (Wilcox, 1992; Ulrich & Miller, 1994). The magnitude of the priming effect was obtained for both RTs and accuracy by subtracting average median values in the biasing conditions from average median values in the neutral baseline condition for each subject. Four-way subject and item analyses of variance (ANOVAs) comparing the magnitude of the priming effect across conditions were conducted for accuracy (percent correct) and RTs (milliseconds), with competing signal (present vs. absent) and semantic bias (congruent vs. incongruent) as within-subjects variables and type of signal (forward/different ear vs. backward/different ear vs. backward/same ear) and context ear (left vs. right) as between-subjects variables. There was no main effect of context ear in either the accuracy or RT analyses. Further, there was no significant interaction of context ear with competing signal, type of signal, or semantic bias, and no four-way interaction, in either the accuracy or RT analyses. Thus, there was no significant right ear advantage for semantic context, and no significant difference between the pattern of performance obtained across conditions when the semantic context was presented to the right ear and the pattern when the semantic context was presented to the left ear.

A significant interaction of competing signal x semantic bias x type of signal emerged (Subject $F(2,30) = 4.69$, $p < .05$) emerged, although this effect failed to generalise across items. The accuracy analyses revealed no significant three-way interaction, nor was the pattern of results indicative of speed-accuracy trade-offs when compared with the RT data.

To provide a clearer picture of the patterns of performance produced by the three types of competing signal, separate ANOVAs were conducted on the RT data for each competing signal condition.

Forward Speech (Different Ear)

Figure 1 shows the average priming effect produced by biasing contexts presented in the presence or absence of a competing signal in the forward speech condition (different ear). The magnitude of the priming effect was analysed in two-way subject and item ANOVAs with semantic bias and competing signal as within-subjects variables. There was a significant main effect of semantic bias (Subject $F(1,11) = 45.17$, $p < .001$; Item $F(1,29) = 11.28$, $p < .01$), but no significant main effect of competing signal. A significant semantic bias x competing signal interaction emerged for RTs (Subject $F(1,11) = 10.31$, $p < .01$; Item $F(1,29) = 4.54$, $p < .05$). Planned contrasts conducted within a general linear model revealed that inhibition was significantly reduced when the context was presented along with competing forward speech in a different ear, relative to when the context was presented in isolation (Subject $F(1,11) = 20.35$, $p < .001$; Item $F(1,29) = 5.41$, $p < .05$). However, this manipulation did not significantly affect facilitation.

Backward Speech (Different Ear)

Figure 2 shows the average priming effect produced by biasing contexts presented in the presence or absence of a competing signal in the backward speech condition (different ear). The magnitude of the priming effect was analysed in two-way subject and item ANOVAs for RT and accuracy with semantic bias and competing signal as within-subjects variables. There was a significant main effect of semantic bias (Subject $F(1,11) = 48.77$, $p < .001$; Item $F(1,29) = 63.62$, $p < .001$), but no significant main effect of competing signal. The interaction of semantic bias and competing signal did

not approach significance in either the subject or item analysis. Further, planned contrasts revealed no significant effect of this competing signal on facilitation or inhibition.

Forward Speech (Same Ear)

Figure 3 shows the average priming effect produced by biasing contexts presented in the presence or absence of a competing signal in the forward speech condition (same ear). The magnitude of the priming effect was analysed in two-way subject and item ANOVAs with semantic bias and competing signal as within-subjects variables. There was a significant main effect of semantic bias (Subject $F(1,11) = 21.92$, $p < .001$; Item $F(1,29) = 16.02$, $p < .001$), but no significant main effect of competing signal. A significant semantic bias x competing signal interaction emerged (Subject $F(1,11) = 14.24$, $p < .01$; Item $F(1,29) = 4.76$, $p < .05$). Planned contrasts revealed that facilitation was significantly reduced when the context was presented along with competing forward speech in the same ear (Subject $F(1,11) = 22.40$, $p < .001$; Item $F(1,29) = 13.58$, $p<.001$). However, this manipulation did not significantly affect inhibition.

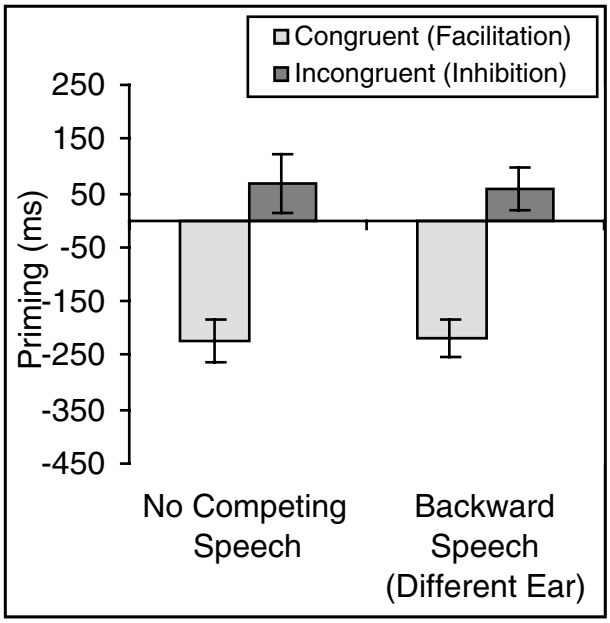

Figure 2. Effect of backward competing speech (different ear). Error bars indicate standard error.

Discussion

These results demonstrate that competing speech modulates the effect of sentence context on the processing of spoken words. Further, the pattern of these effects depends crucially upon the semantic content of the competing signal and the perceptual separability of the competing and target signals. Specifically, competing speech presented in a different ear from the target signal significantly reduced the inhibitory effect of context on incongruent targets, without affecting the facilitatory effect of context on congruent targets. Thus, as predicted, increased attentional demand disrupted only the inhibitory component of the priming effect. However, when backward speech was presented to a different ear, there was no significant effect on facilitatory or inhibitory priming. This finding suggests that it is the semantic content of the competing signal, rather than the signal itself, that increases attentional demand. When forward speech was presented to the same ear, however, the facilitatory effect of context was significantly reduced, whereas the inhibitory effect was unaffected. Thus, when the target signal cannot be isolated from the competing speech, the masking effect of the competing signal disrupts the perceptibility of the target signal, resulting in reduced facilitation.

These results are compatible with previous claims that the facilitatory component of the priming effect reflects the early and automatic processing of lexical-semantic information, whereas the inhibitory component reflects later, more controlled or strategic processes (Faust & Gernsbacher, 1996; Gernsbacher, 1997; Neely, 1991; Utman & Bates, 1998a,b). Future research will examine the implications of these results for language comprehension populations with limited perceptual and attentional capacity, including hearing-impaired and elderly individuals.

The consistency of children's responses to logical statements: Coordinating components of formal reasoning

Bradley J. Morris (bmorris@andrew.cmu.edu)
David Klahr (klahr@cmu.edu)
Carnegie Mellon University, Dept of Psychology
5000 Forbes Ave. Pittsburgh, PA 15213

Abstract

Processing of formal statements has three distinct phases: assessing truth-values a priori, requesting evidence, and if requested, evaluating this evidence. Previous investigations of children's ability to process formal assertions have studied each of these phases in isolation, but have not asked whether responses to each processing phase are coordinated into consistent response patterns. This study examined the consistency of 28 third (M= 8.9) and 33 sixth graders (M= 12.0) responses to four types of logical statements: tautologies, contradictions, conjunctions, and disjunctions. The results indicated that third graders' between-item responses are significantly less consistent than sixth graders, that sixth graders are more likely to give correct response on each question phase than third graders, and that development on each question phase may occur independently.

An important milestone in the development of scientific reasoning is the point at which children recognize that some statements are true or false simply because of the their formal structure while others require the gathering and evaluation of empirical evidence. We propose that there are three phases in processing theoretical assertions: 1) evaluating a priori truth values, 2) requesting evidence only if a statement's truth-value is unable to be determined a priori, and 3) correctly mapping evidence to formal states, for statements requiring evidence, so that correct conclusions can be drawn. Thus, a complete account of how children process formal properties requires an examination not only of the development of all three phases in isolation but also of their coordination.

Most previous research in young children's logical reasoning has focused only on one component at a time. That is, research has focused separately on a priori truth-values of statements (Braine & O' Brien, 1998), evidence requests (Osherson & Markman, 1975), or evidence evaluation (Suppes & Feldman, 1971).

This piecemeal focus has led to seemingly contradictory results. For example, preschool children correctly evaluate the a priori truth-values of contradictions as false but incorrectly request evidence for these statements (Osherson & Markman, 1975; Braine & Rumain, 1981). The goal of the present study is to examine children's coordination of all three components involved in processing formal properties.

Logical Statements and Formal Properties

Formal properties describe the relationship between form, evidence and truth-values. A logical statement's formal properties are defined by values on three phases: 1) truth-values before evidence (true, not true, can't tell), 2) whether evidence is necessary (yes, no), and 3) if evidence is necessary, correctly evaluating evidence (true, not true, can't tell). We will focus on the following statement forms: conjunctions, disjunctions, tautologies and contradictions. Each statement type represents different formal properties. The values on each phase distributes the statements into two classes: *logically indeterminate* statements that require evidence to determine their truth-values (hereafter called indeterminate) and *logically determinate* statements that do not require evidence to determine their truth-values (hereafter called determinate) (Suppes, 1957). The statements and components are described in Table1.

Research into young children's processing of formal properties shows mixed evidence for children's competence. While preschool and elementary children show some sensitivity to statements such as contradictions (often evaluating them as false) (Braine & Rumain, 1981) children of the same age tend to request evidence for most problems even when unnecessary and rarely coordinate evaluation and evidence requests correctly (Osherson & Markman, 1975; Morris & Sloutsky, 1999; Ruffman, 1999).

To address this limitation, we examined children's response patterns to determine the degree of between-phase dependence as an index of processing competence. That is, if children correctly process formal properties, then we would expect correct responses in each of the necessary phases. For example, correctly responding to a contradiction requires processing two phases: an a priori evaluation of "not true" and denying a request for evidence. However, a child who lacks such an understanding may not only err on individual question phases (e.g., "true" a priori evaluation) but may fail to link response phases (e.g.,

Table 1- Comparison of Logical Statements by Dimension

	Statement	Example	A Priori?	Evidence Necessary	Evidence/Form Mapping
Determinate	Tautology	The shape is a circle or the shape is not a circle	True	No	All True states
	Contradiction	The shape is a triangle and the shape is not a triangle	False	No	No True States
Indeterminate	Conjunction	The shape is a square and the shape is not red	Can't Tell	Yes	1 True State (square, not red)
	Disjunction	The shape is a square or the shape is not blue	Can't Tell	Yes	2 True States (square) (not blue)

denying request for evidence). In examining this question, we implicitly examined a related question: Are children's responses from a single dimension of formal properties (e.g., a priori evaluations) diagnostic of their overall processing competence?

To examine these research questions, we presented a 'game' to a group of third and sixth grade children in which they were asked to evaluate 16 logical statements. For each statement, each child was asked up to three questions ("phases") per statement: a priori evaluation, a request for evidence, and, if evidence was requested, evidence evaluation. Each child's response to each question phase was coded as correct or incorrect then these question phases were compiled into a response pattern for each of the 16 statements. Response patterns were aggregated and compared to levels predicted by 'chance' decisions at each question phase.

Method

Participants

A total of 28 third graders (8.5-9.5 years, *M*= 8.9) and 33 sixth graders (11.3-13.6 years, *M*= 12.0) participated. The children were recruited from three public schools in Pittsburgh, PA.

Materials

There were four examples of each of four statement types: tautology, contradiction, disjunction, and conjunction. 'Evidence' was provided in the form of a picture (approximately 5"x7") that displayed information related to each statement card. For example, given the statement "The circle is red AND the circle is not red" the picture displays a red circle. Four additional cards and pictures were used for the warm-up tasks. The statements and evidence were designed to allow us to differentiate among response patterns.

Procedure

The experiment was conducted in a single 15-20 minute session that included two segments: a warm-up and an experimental segment. Each participant was tested individually. In the warm-up segment, the interviewer read a set of instructions explaining the game's purpose. The warm-up period lasted approximately five minutes and consisted of four trials. All instructions and statements for the experimental segment were read to each participant and repeated if requested. Two cards were placed in front of each child: a statement card (face up) and a picture card (face down). The order of presentation was counterbalanced across participants. Each child was given 16 trials, with 1 statement per trial.

For each trial, the following procedure was used. The statement card and picture were placed in front of the child. The child was read the statement card. (Q1) The child was then asked the first question phase: An evaluation of truth status of the statement before evidence (*a priori* evaluation): "Is this statement True, Not True, or Can't Tell. (Q2) After the child responded to the statement, they were asked a second question: Do you need to see the picture to help figure out the sentence? Yes or No. (Q3) If the child requested to see the picture, then they were shown the picture and asked the following: "Now that you have seen the picture, is the statement True, Not True, or Can't Tell."

Coding

Compiled Phase Analysis (CPA) Traditionally, children's responses to each phase of questioning have been analyzed independent of their responses to the other phases. We suggest an analysis of children's response patterns, that is, the frequency of the different types of sequential responses that children generated as they moved through each of the three processing phases for each statement. Because each pattern represents the compilation of

responses across the three phases, we call this the Compiled Phase Analysis (CPA).

The set of all possible response patterns – both correct and incorrect – is listed in Table 2. For example, as shown in the top row of Table 2, if a child's responses to a Contradiction were A priori- "False" and Evidence Request- "No", we would code that pattern as C-C because each phase was answered correctly. But many other patterns could – and did - occur. For example, one erroneous response pattern for a contradiction is: A priori- "False", Evidence Request- "Yes" and, Evidence Evaluation- "True," which would be coded as C-I-I, (Table 2 last row of upper section) because the answer to the first phase is correct, but the other two are incorrect. This pattern demonstrates correct a priori evaluation, but incorrect evidence request and evaluation. Another erroneous response pattern for a contradiction is A priori- "Can't Tell", Evidence Request- "Yes", Evidence Evaluation- "False". (Coded as I-I-C). This pattern reveals a different type of misunderstanding: one in which, because the contradiction is not recognized as such, evidence is (incorrectly) requested, but then correctly evaluated. The other patterns listed in Table 2 imply other types of errors. For the remainder of this section, we will look more closely at the distribution of these patterns, without further discussing their underlying implications.

These distributions are informative because a child responding at random to each phase could have generated any particular response pattern. By analyzing the relative frequency of different response patterns – in particular the extent to which they deviate from what would be expected from a random responder - we can begin to understand whether children are responding consistently, albeit erroneously, to these statements or whether their responses to each phase are random, and based only on guessing.

Examining Response Patterns In this section we investigate the extent to which children's response patterns deviate from a randomly generated set. Chance values are based on the assumption that, for each phase, each alternative response is equally likely and is independent of all other phases. Response patterns consisted of either three questions (if evidence was requested) or two questions (if evidence was not requested). The first, a priori evaluation, has three possible responses: "true," "not true" or "can't tell," only one of which is correct, with probability 1/3. The second phase, request for evidence, had two possible responses: "yes or no". Thus the probability of correctly answering this question was 1/2. The third phase, evidence evaluation, occurred only if evidence had been requested (and obtained). Like the first question, this question had three possible responses, with the probability of the one correct response being 1/3.

These probabilities were used to generate the expected chance distribution of the different response patterns for determinate and indeterminate statements. The expected and observed results for each type of pattern are displayed in Table 2 as counts. Also displayed in Table 2 are the observed proportions of each type of pattern for each grade level.

For determinate and indeterminate statements, there were 6 possible response patterns, one correct and five incorrect. Chance values were calculated by computing the probability of choosing a correct or incorrect response on each question phase. For example, for the determinate pattern (I-I-I), the probability of an incorrect a priori response is 2/3, an incorrect evidence request is 1/2, and an incorrect evidence evaluation is 2/3. The conditional probability of selecting this pattern of responses is 2/3*1/2*2/3=2/9. Once the conditional probability was calculated for each possible response pattern, we calculated the total number of patterns we would expect by chance given the number of responses in the data set (229, 3rd graders). So the numbers in Table 2 reflect the number of times we would expect to see each response pattern if a child simply 'flipped a coin' at each decision point.

Finally, the response pattern analysis also indicates the degree to which children correctly process individual response phases. That is, if children err in processing one question phase (e.g., a priori evaluations only) then errors should focus on those patterns that indicate correct response on two phases and errors on one phase. Further, the overall distribution of responses should deviate from chance on patterns that reflect errors on this particular response phase. Such evidence would support the notion of independent developmental trajectories for each question phase.

Results

Configurational Frequency Analysis

We conducted a configurational frequency analysis to compare the observed and expected values from the CPA analysis (von Eye, 1990). This analysis uses assumptions similar to a chi-square analysis to compare the distribution of expected and observed response frequencies. This analysis controls the overall significance level by using the Bonferroni adjustment. The results provide a

significance level for the difference between the observed and expected values. When these differences are significant the CFA indicates two classifications: types (in which the observed value is significantly higher then the predicted value) and antitypes (in which the observed value is significantly lower then the predicted value). The analysis was conducted using the 'CFA program for 32 bit operation systems' (von Eye, 1998). The results of the analysis determinate the significance levels indicated in Table 2. Recall that for each of the possible CPA patterns, there is one correct and five incorrect patterns for both determinate and indeterminate statements.

For indeterminate statements, sixth grader's correct CPA responses deviate significantly from chance, while third graders CPA responses do not differ significantly from chance. Sixth graders are below chance on one incorrect pattern. Conversely, third grader's response patterns were above chance on one pattern- I-C-C- and below chance on two patterns- C-I and I-I. This suggests that children requested evidence for most problems failing to distinguish when evidence was unnecessary and often failed to assign correct truth-values before evidence. For determinate statements, neither third nor sixth graders' correct patterns were above chance. Of note however, is that both sixth and third grader's response patterns were significantly above chance for one incorrect pattern- I-C- suggesting that they were not processing a priori and evidence request responses dependently. Third graders were above chance for one incorrect pattern- I-I-I indicating that they erred on all question phases.

Finally, an examination of the types (observed levels are significantly above those predicted by chance) and anti-types (observed levels are significantly below those predicted by chance) supports the notion of independent developmental trajectories for each question phase. Third graders response patterns demonstrated a lack of understanding of the necessity of evidence often erroneously requesting evidence for determinate statements. Few third (or sixth) graders failed to request evidence for indeterminate statements (I-I and C-I patterns) suggesting that in general, children erred on the side of evidence requests.

For determinate statements, third and sixth graders also made fewer I-C patterns than expected by chance. Thus, children rarely made an error on a priori evaluations and were correct on evidence requests suggesting that the former is better established in third graders than the latter. Overall, children's patterns suggested that errors on evidence evaluation were the least frequent while errors on evidence requests were the most frequent.

Correct Response Patterns

In order to compare the number of correct responses by age and type a 2 (grade) X 2 (statement type: determinate v. indeterminate) ANOVA was performed with grade as a between-subjects factor and statement type as a within-subjects factor. Each correct pattern was scored as 1 while each incorrect pattern was scored as 0. Results indicated that sixth graders gave significantly more correct responses on both determinate F (1, 114) = 39, $p < .001$ and determinate statements F (1, 114) = 42, $p < .001$ than third graders.

CPA: Summary

The Compiled Phase Analysis examined the degree to which children are correctly processing each question phase. The formal properties of each statement type require a particular response pattern in which each question phase is dependent on the previous response. The CPA compared the number of responses due to chance responding on each phase to the number of observed responses. The results suggest 1) a high amount of variability in all children's between phase processing, 2) sixth graders were more likely than third graders to correctly process all phases, and 3) each processing phase develops independently. However, while the CPA indicated phase to phase dependencies, it does not reveal the specific strategies that could produce these patterns (see Morris & Klahr, in review for such as analysis).

Table 2- Predicted and Observed Compiled Response Patterns

Type of response patterns[a]					*Number of responses of each type*[b]			
Statement Type	*A Priori*	*Evidence Request*	*Evidence Evaluation*	*Pattern Code*	*Third Grade*		*Sixth Grade*	
Determinate	**Correct**	**Correct**	**N/A**	**C-C**	15	(38)	85	(44)
	Incorrect	Correct	N/A	I-C	12	(74)+	21	(87)+
	Incorrect	Incorrect	Incorrect	I-I-I	96	(50)*	86	(58)
	Incorrect	Incorrect	Correct	I-I-C	51	(25)	40	(29)
	Correct	Incorrect	Correct	C-I-C	27	(14)	17	(16)
	Correct	Incorrect	Incorrect	C-I-I	23	(25)	14	(29)
					224		263	
Indeterminate	**Correct**	**Correct**	**Correct**	**C-C-C**	35	(13)	110	(16)*
	Correct	Correct	Incorrect	C-C-I	25	(25)	40	(29)
	Correct	Incorrect	N/A	C-I	1	(38)+	3	(44)+
	Incorrect	Correct	Incorrect	I-C-I	57	(48)	22	(58)
	Incorrect	Correct	Correct	I-C-C	78	(25)*	40	(29)
	Incorrect	Incorrect	N/A	I-I	27	(74)+	47	(86)
					223		262	

a. Responses are coded as being 'correct' or 'incorrect' compared to optimal response patterns. Correct response patterns are in bold.

b. Entries indicate the total number of individual response patterns summed over all children's responses in each grade. A total of 28 3rd graders and 33 6th graders were given 8 determinate and 8 indeterminate statements. Numbers in parentheses indicate the number of responses expected from a random response pattern.

* Indicates a type (significantly above chance at the $p < .05$ level) while + indicates and anti-type (significantly below chance at the $p < .05$ level).

Discussion

We have argued that one previously overlooked component of logical reasoning is the coordination of individual responses into consistent response patterns that reflect an understanding of formal properties. The present study attempted to examine simultaneously children's responses to each component of formal properties (operationalized as component question phases) and to compare the distribution of children's responses to what would be expected if children answered each question phase as if they were independent of each other.

The results indicated that sixth graders' compiled response patterns demonstrated a greater degree of question phase dependence than the response patterns of third graders. When the aggregated patterns were compared to chance, sixth graders' responses were significantly above chance for 'correct' patterns on indeterminate statements while third graders patterns were above chance only for a specific error pattern for indeterminate problems (I-C-C). Overall, third graders response patterns deviated from levels predicted by 'chance' responding only on incorrect response patterns.

The results suggest that each of the component properties of formal properties has an individual developmental course and that once each component property is established, the individual components must then be coordinated. The distributions of response patterns suggest the following: 1) children are likely to err when requesting evidence demonstrated by high levels of incorrect evidence

requests for determinate statements and low levels of evidence refusal for indeterminate statements, 2) sixth graders often evaluated evidence correctly, even when such evidence is unnecessary. Taken together, the evidence suggests that correct processing on all phases is not present early in development and that correct processing may occur at different times for each phase.

While sixth grader's performance was significantly better than third graders, they still erred on a large number of statements suggesting that they do not correctly process formal properties.

Finally, the large amount of variance in children's response patterns suggests that a focus on one component of formal properties is not diagnostic of children's overall understanding of formal properties. That is, children's responses on one component may erroneously suggest competence (or lack of competence) when only partial competence exists.

Abstract

We present several experiments using dual-task (DT) methodology to explore use of working memory (WM) during analogical reasoning. Participants solved verbal and figural analogy problems alone or while performing articulatory suppression (AS), spatial tapping (ST) or verbal random generation (VRG). As in other studies of relational reasoning we found that VRG disrupted both verbal and figural analogy performance. In addition, we found disruption of analogy performance by WM slave system distractors (i.e., AS and ST) consistent with the dominant modality of the analogy task. These findings are discussed with respect to Baddeley's model of WM and other studies of WM involvement in relational reasoning.

Introduction

Central to the ability to reason by analogy is the ability to form and manipulate mental representations of relations between objects and events. For instance, in a verbal analogy such as:

BLACK:WHITE::NOISY:QUIET

the reasoner needs to form mental representations of the relation between BLACK and WHITE (black is the opposite of white) and map it to the second pair in order to verify that the analogy is appropriate. Thus, BLACK:WHITE is mapped to NOISY:QUIET and the analogy is successfully solved. It has long been assumed that this type of process requires the use of WM (cf., Baddeley & Hitch, 1974); however, until recently relatively little attention has been given to how WM limits affect analogical reasoning (Halford et al., 1994; Hummel & Holyoak, 1992; Hummel & Holyoak, 1997; Keane, Ledgeway, & Duff, 1994). In the present paper we report experiments using dual-task (DT) methodology (employed extensively by Baddeley, 1986) to study the involvement of the various modules of WM in analogical reasoning.

Baddeley's (Baddeley, 1986; Baddeley & Hitch, 1974; Baddeley & Logie, 1999) model of WM has dominated cognitive accounts of short-term memory for nearly three decades. The model consists of three components: the Phonological Loop (PL), the Visuo-Spatial Sketchpad (VSSP), and the Central Executive (CE). In Baddeley's model the PL and VSSP are modality-specific slave systems that are responsible for maintaining information over short periods of time. Baddeley (Baddeley & Hitch, 1974) originally conceived of the CE to account for functions of WM not performed by the PL and VSSP; however, Baddeley (1986) later embraced Norman and Shallice's (Norman & Shallice, 1986) Supervisory Attentional System as a possible model of the CE. Most recently, Baddeley (1996) has segmented the CE in an attempt to study its component processes. From this perspective the CE is responsible for (1) the capacity to coordinate performance on 2 separate tasks, (2) the capacity to switch retrieval strategies as reflected in random generation, (3) the capacity to attend selectively to 1 stimulus and inhibit the disrupting effect of others, and (4) the capacity to hold and manipulate information in long-term memory, as reflected in measures of WM span (Baddeley, 1996 p. 5). Baddeley suggests that the CE manages the work of WM while the slave systems actually maintain the information.

Also central to Baddeley's model is the concept of limited capacity. The slave systems and the CE share this limited capacity, such that increasing CE functioning would reduce the capacity of either the PL or VSSP to maintain information; however, there is evidence that each system may have its own limits as well (e.g., the PL capacity is limited by the amount of information that can be subvocally cycled in approximately two seconds).

Evidence for a multi-module WM system is copious, coming from both the cognitive and neuropsychology literatures. However, relatively little attention has been paid to the implications of WM for relational reasoning particularly analogical reasoning. Review of the functions of the CE as outlined above suggests that the CE should be critical for relational reasoning. Experimental evidence has confirmed this hypothesis for deductive reasoning, with random generation (e.g., Baddeley & Hitch, 1974; Gilhooly, Logie, Wetherick, & Wynn, 1993; Klauer, Stegmaier, & Meiser, 1997) and memory load (e.g., Baddeley & Hitch, 1974; Gilhooly et al., 1993; Toms, Morris, & Ward, 1993) both interfering

with performance. Klauer et al. (1997) found that random generation interfered with spatial reasoning (transitive inference), and Waltz, Lau, Grewal, and Holyoak (2000) found that performing VRG or maintaining a concurrent memory load discouraged participants from using relational mappings in a task that can be solved via either featural or relational similarity (see Markman & Gentner, 1993, for a task description). What is not clear from these studies is what aspects of the DTs actually cause the interference in relational reasoning. At the very least, random generation involves task switching, memory insertion and storage, and relational binding of numbers with temporal location; whereas maintaining a concurrent memory load involves memory insertion and storage. Both tasks are very demanding on WM resources.

It is also not clear to what extent the WM slave systems are important for reasoning, particularly in situations where all the information is available visually to the reasoner. Gilhooly et al. (1993) and Toms et al. (1993) found no effect of PL- or VSSP-based DTs on propositional reasoning, while Klauer et al. (1997) found a small effect of articulatory suppression (AS; a PL secondary task) on reasoning latencies. It is important to note that in each of these propositional reasoning tasks all information necessary to complete the task was perceptually available in the task. For example, a propositional reasoning problem such as:

There is either a circle or a triangle.
Therefore, there is no triangle.

requires only the information presented to answer the problem. In contrast, a transitive inference problem such as:

The circle is to the right of the triangle.
The square is to the left of the triangle.
Therefore, the square is to the left of the circle.

requires the reasoner to generate a new proposition based on the information presented (i.e., left-of (square, circle)).

Similarly, Waltz et al. (2000) found that performing AS while performing the Markman and Gentner similarity task discouraged participants from using relational correspondences just as VRG did. A recent replication of this result in our lab showed that ST had an effect similar in magnitude to AS. Like the transitive inference task described previously, in order to make a relational choice propositions not immediately obvious from the stimuli must be generated. This characteristic is a hallmark of analogical reasoning. Thus, it is not clear at present to what extent the slave systems of WM are necessary for relational reasoning. It is likely that the modality and quantity of information that must be retrieved and relationally bound in order to perform a reasoning problem will determine which WM slave systems will be necessary.

Methods

To explore to what extent the various modules of WM are recruited in analogical reasoning, participants performed several relational reasoning tasks while performing one of several DTs. Participants in the AS condition were instructed to say the English non-word zorn once each second. Another group in the ST condition was instructed to tap four red dots in a clock-wise pattern one dot each second. Participants in the VRG condition were instructed to say a random digit from 0 to 9 once each second. A fourth group of participants served as controls, performing only the primary reasoning tasks. 96 undergraduate students from the University of California, Los Angeles participated in the study in exchange for course credit.

Verbal Analogy

In the verbal analogy (VA) task participants verified A:B::C:D analogies such as: BLACK:WHITE:: NOISY:QUIET (i.e., participants answered TRUE or FALSE). Analogy problems were based on those developed by Sternberg and Nigro (1980). A:B pairs were related by one of five common relations (antonyms, synonyms, category members, functions, or linear ordering). In TRUE problems, C:D pairs shared the same relation as the A:B pairs but were from a different domain than the A:B pair (e.g., color vs. sound). We created FALSE problems by substituting a D term that was related to C in a different way (e.g., linear-ordered (noisy, noisier) instead of opposite-of (noisy, quiet)).

Figural Analogy

In the figural analogy task (FA) participants verified A:B::C:D analogies based on Sternberg's (1977) People Piece Analogy (PPA) task. In PPA each item was a cartoon character that possessed one each of four binary traits (male/female, black/white, tall/short and fat/thin). TRUE analogies showed the same changes in traits between the A:B pair and the C:D pair as well as between the A:C pair and the B:D pair. Problems of varying degrees of relational complexity (RC, cf. (Halford, Wilson, & Phillips, 1998) were constructed based on the number of traits that were manipulated. RC=1 problems had only one trait manipulated across either the A:B or A:C pair. Thus, RC=1 problems were semi-degenerate, with only two repeated characters making up the entire analogy (see Figure 1a). RC=2 and RC=4 problems had either 1 or 2 traits manipulated across both the A:B and A:C pairs (for a total of either 2 or 4 total relations). Thus, RC=2 and RC=4 problems were non-degenerate, consisting of four unique characters in each problem (see Figure 1b). We created FALSE items by changing the Identity of one trait in the

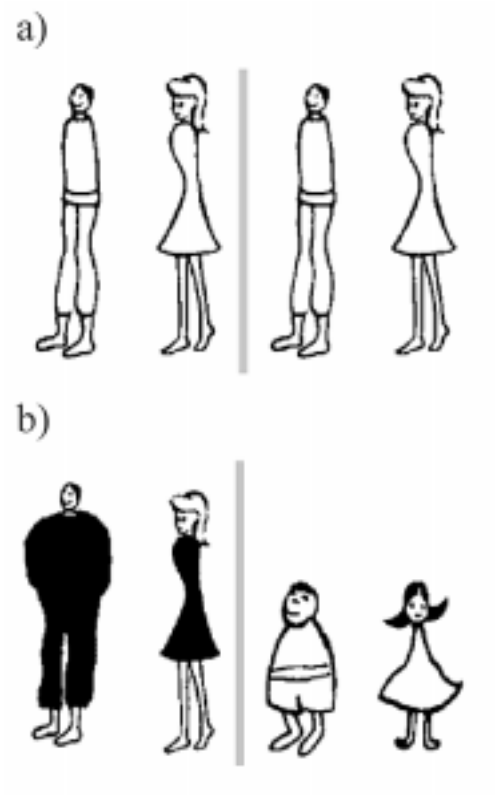

Figure 1: PPA figural analogy problems. a) semi-degenerate, RC=1, b) non-degenerate, RC=4.

fourth character so that it was not analogous.

Procedure

Reasoning problems were presented on a computer screen and participants indicated their response by pressing either a left or right foot pedal. Prior to beginning an experimental block, participants practiced their DT alone, the reasoning problems alone, and then practiced the two tasks together. Participants in the control group practiced the same total number of reasoning problems as participants in the DT groups. Reasoning problems were presented in three one-minute blocks. PPA problems were presented in blocks of increasing RC. The computer recorded analogy RT and accuracy as well as the frequency at which participants performed their DT.

Each block began with the participant pressing the right foot pedal. The participant was instructed to begin their DT. After 5s the first analogy problem appeared on the monitor. When the first problem appeared the experimenter began to hit a key each time the participant performed their DT. In this way the actual frequency and spacing of DT performance was recorded. After 60s a prerecorded voice told the participant to stop both tasks. The next block began after a 30s delay. After the final block the participant received instructions on the next task in the testing battery. The order of tasks was counterbalanced across participants.

Results

We predicted, as in past studies of both deductive (Gilhooly et al., 1993; Klauer et al., 1997) and analogical (Waltz et al., 2000) reasoning, that VRG would interfere with reasoning in both analogy tasks. We also predicted, as in a past study of transitive inference (Klauer et al., 1997) and analogy (Waltz et al., 2000), that DTs that interfered with WM slave systems corresponding to the modality of the task would interfere with performance. Thus, we expected that AS would interfere with VA performance and that ST and possibly AS (because of a verbal strategy frequently employed during PPA solving) would interfere with FA performance.

We analyzed both reasoning and DT performance from both the VA and FA tasks with between-subjects analysis of variance (ANOVA). In addition, we examined reasoning task performance by comparing control group performance to each of the DT groups using single DF planned comparisons.

Verbal Analogy

VA task performance is summarized in Figure 2. A between-subjects ANOVA revealed a reliable effect of DT type on accuracy (d-prime); F (3,92) = 4.5, MSE = .44, p = .005. Planned comparisons showed that AS and VRG had reliable effects on VA accuracy; t (46) = 3.7, p = .003 and t (46) = 2.8, p = .008, respectively. ST did not have a reliable effect on VA performance, t (46) = 1.1, ns. We conducted a similar analysis on RTs for the VA results. An ANOVA revealed a nearly reliable effect of DT type on VA RT; F (3,92) = 2.3, MSE = 979432, p = .085. Planned comparisons showed that VRG had a reliable effect on VA RT; t (46) = 2.3, p = .025. AS and ST did not have a reliable effect on VA RT; t (46) = .35, and t (46) = .96, respectively, both ns. DT data were analyzed using two metrics. First, a measure of DT frequency (mDT) was calculated for each subject (mean time between repetitions in ms). Second, a standardized measure of DT variance (vDT) was calculated for each subject (SD of time between repetitions divided by mDT). Participants performed AS (M =789 ms) and VS (M = 612 ms) faster than VRG (M = 1165 ms); t (69) = 4.4, $p < .001$. A second planned comparison showed that participants performing VRG were more variable in their performance than those performing AS or ST, even when the variance was corrected for the difference in mDT (vDT); t (69) = 3.2, p = .01. Thus, results for the VA task suggest that both the phonological loop (AS DT) and central executive (VRG DT) are important for performance of verbal analogies, with VRG producing a greater effect.

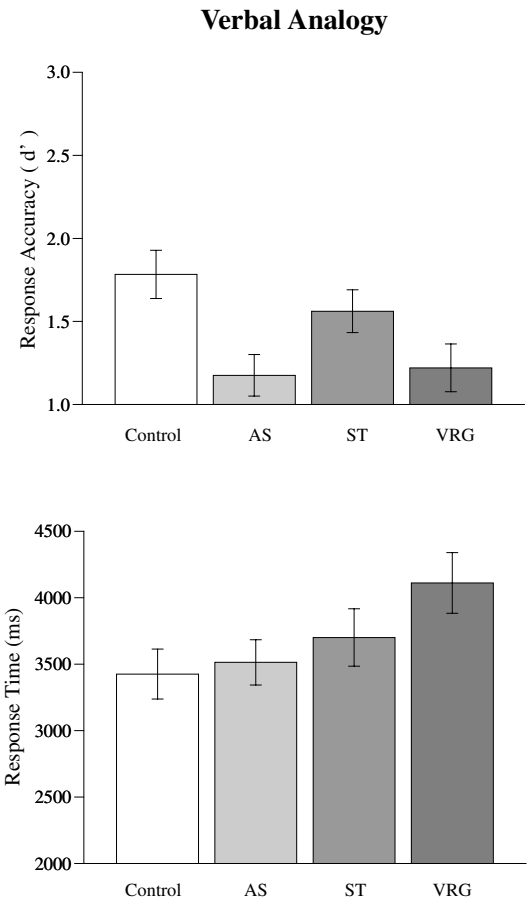

Figure 2: Accuracy and RT performance for verbal analogy under different dual-task conditions. Error bars reflect SEM.

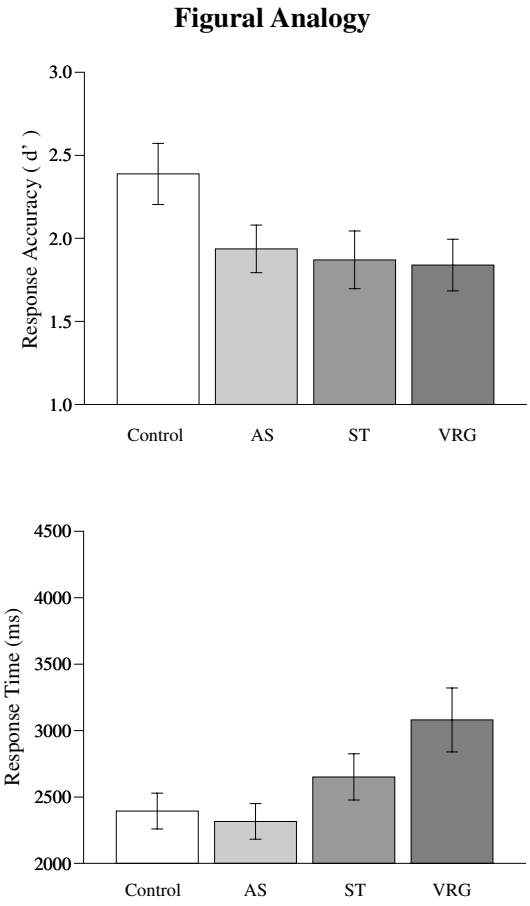

Figure 3: Accuracy and RT performance for People Pieces analogy under different dual-task conditions. Error bars reflect SEM.

Figural Analogy

FA task performance is summarized in Figure 3. A between-subjects ANOVA revealed a reliable effect of DT type on accuracy (d-prime); F (3,92) = 3.1, MSE = .65, p = .032. Planned comparisons showed that ST and VRG had reliable effects on FA accuracy; t (46) = 2.2, p = .036 and t (46) = 2.7, p = .01, respectively. AS had a marginal affect on FA accuracy; t (46) = 1.9, p = .059. We conducted a similar analysis on RTs for the FA results. An ANOVA revealed a reliable effect of DT type; F (3,92) = 3.8, MSE = 748368, p = .013. Planned comparisons showed that VRG had a reliable effect on RT for the FA task; t (46) = 2.5, p = .017. AS and ST did not have reliable effects; t (46) = 1.2 and t (46) = .41, respectively, both ns. Participants performed AS (M =1030 ms) and VS (M = 849 ms) faster than VRG (M = 1626 ms); t (69) = 2.6, p = .01. A second planned comparison showed that participants performing VRG were more variable in their performance than those performing AS or ST, even when the variance was corrected for the difference in mDT (vDT); t (69) = 2.5, p = .02. Thus, results for the FA task suggest that both the visuospatial sketchpad and central executive are important for performance of figural analogies, with the phonological loop perhaps playing a more minor role.

Discussion

In this study we have shown that WM slave systems can be recruited in the service of analogical reasoning and that the specific WM slave systems involved depend of the dominant modality of the task. This result agrees with a previous study of the affect of DTs on analogical reasoning (Waltz et al., 2000) and also of a similar study involving transitive inference (Klauer et al., 1997). All of these tasks have in common the need to generate propositional structures based on the information present in the problem.

In addition to the involvement of the WM slave systems we found robust effects of VRG on both verbal and figural analogies. This result is consistent with a growing body of findings for both deductive and inductive reasoning.

Multimodal vs. Unimodal Working Memory

Discussion of WM has traditionally been divided into two camps camps that are frequently divided by the Atlantic Ocean. The multi-modal camp (centered to the east of the Atlantic) has typically relied on DT methodologies, and results from neuropsychology and more recently neuroimaging. The uni-modal camp (centered to the west of the Atlantic) favors WM-span measures used as probes to investigate individual differences in language and reasoning. The current results, while not inconsistent with the capacity limits that are central to the uni-modal models, require a multi-modal model for a complete interpretation.

On first consideration, DTs such as AS or ST could simply require less WM resources than tasks such as VRG. Inductive reasoning tasks that require retrieval of semantic information and/or generation of additional propositions in WM may simply be more load intensive than propositional reasoning tasks in which all of the information necessary to solve the problem is perceptually available. Thus, AS and ST interfere with inductive reasoning and not propositional reasoning (at least the simple propositional reasoning problems typically used in DT studies). This account predicts that slave system tasks should interfere with reasoning less than VRG and also predicts no dissociation of PL or VSSP DTs if AS and ST interference is simply load dependent then the modality of the resource drain should not matter. The results of Waltz et al. (2000) argue against the weak form of this interpretation, in that AS and VRG produced equal interference in the analogy task. However, it is possible that the analogy measure used in their task (which shows a robust individual difference most likely not related to WM capacity) may not have been sensitive enough to pick up the differences in resource demand caused by AS and VRG. Also, performance on the secondary tasks was not assessed in that prior study.

The results reported here--showing a dissociation in slave system DT interference across analogy tasks of different modality--rule out this interpretation and argue for a multi-modal WM system that requires separate phonological and visuospatial systems. Specifically, the finding of strong interference by AS in the VA task with no corresponding ST interference argues that the PL is necessary for verbal analogy, while the VSSP is not. In contrast, the stronger interference of ST in the predominantly visual FA task compared to PL shows the opposite pattern of interference.

It is not clear from these results, however, what role the slave systems play in analogy. One possibility is that they are used to maintain relational information while it is organized into the propositional structures necessary for further relational processing. In this view, AS and ST DTs interfere with activation of the semantic or visual information necessary to solve the analogy task. This interpretation is consistent with Baddeley's view of the slave systems if one considers the role of the PL and VSSP to be maintenance of representations via continual firing of their mental representations in long-term memory (LTM), a conception proposed by Fuster (1997).

The Role of the Central Executive in Reasoning

One criticism of the multi-modal WM model has been the amorphous nature of the CE. However, a general consensus among researchers is beginning to emerge: the CE is viewed as important for task switching, inhibition of internal representations or prepotent responses, and the activation of information in LTM during an activity that requires the active manipulation of material. All of these functions appear to be critical for higher-level cognition--particularly relational reasoning. What this consensus fails to provide is a detailed account of how the CE actually performs relational reasoning.

Hummel and Holyoak (1997) proposed a model of how the CE may perform relational reasoning. This model, LISA (Learning and Inference with Schemas and Analogies), is an artificial neural-network model of relational reasoning. LISA uses synchrony of firing to bind distributed representations of relational roles (e.g., the roles of *opposite-of* (X, Y)) to distributed representations of their fillers (e.g., *black* and *white*). The process of "thinking about" a proposition, such as *opposite-of* (black, white), entails keeping separate role-filler bindings (e.g., those for black and those for white) firing *out* of synchrony with one another. According to LISA, WM is therefore necessarily capacity-limited: It is only possible to keep a finite number of role-filler bindings simultaneously active and out of synchrony with one another. The synchronized (and de-synchronized) patterns of activation representing propositions in LISA serve as the basis for memory retrieval, analogical mapping, analogical inference and schema induction. That is, all the operations of WM depend critically on the role-filler bindings in WM. As such, an important component of the "job" of the CE is to control which patterns enjoy the "privilege" of remaining active and mutually desynchronized. This process requires no homunculus to operate; rather, it is governed simply by the way that relational information is structured in LTM and the extent to which different mental representations are relationally similar.

According to LISA, a second function of the CE is to keep track of the correspondences between elements of the source and elements of the target (see Hummel & Holyoak, 1997). Algorithmically, LISA accomplishes this function by monitoring which units in the source fire in synchrony with which in the target. Hummel and Holyoak assume that this "keeping track" is performed by neurons in prefrontal cortex with rapidly-modifiable

synapses (e.g.,Asaad, Rainer, & Miller, 1998; Fuster, 1997), and thus needs no greater executive control.

If these are the roles of the CE in relational reasoning, then why does VRG so potently interfere with reasoning? We argue that VRG requires exactly the same operations as relational reasoning. To produce a random stream of numbers it is important not only to know what numbers one has recently said (e.g., 3,8,2), but also the order in which one said them (e.g., 3,8,2,8,2,3 seems more "random" than 3,8,2,3,8,2; Baddeley, 1966, noted that as VRG performance breaks down di- and tri-grams start to emerge in the number stream). That is, it is necessary to bind the numbers to their serial position. According to LISA, VRG consumes exactly the kind of binding resources as the binding and mapping of relational information in WM. As a result, VRG disrupts analogical reasoning and other forms of relational reasoning.

Abstract

Psychotic delusions, defined as false immutable culturally discordant beliefs, constitute an endemic symptom among patients with schizophrenia. We examined whether the deficits in reasoning responsible for the formation and maintenance of delusions are a product of inappropriate discrimination between relevant and irrelevant data or rather the product of inappropriate processing from data that is appropriately relevant. We used a Logical Reasoning Task that presents items that test inferences and the choice of relevant information within two separate sections, one of which uses language designed to be affect-neutral, the other of which uses language with violent imagery that is designed to be affect-laden. Our preliminary results indicate that all patient groups show significant deficits on the types of reasoning that we measured, relative to healthy controls. While non-delusional patients also showed deficits in reasoning, delusional patients were unique in that their performance on reasoning tasks was most similar to that of healthy individuals *as long as the context was affect-neutral*. In the affect-laden contexts, however, delusional patients' reasoning significantly declined, while healthy individuals' performance was only mildly affected. We suggest that delusional patients may suffer from a vulnerability to arousal which causes them to commit types of reasoning errors similar in kind to those made by healthy controls under much more severe forms of stress.

Logic Deficits and Psychotic Delusions

A 36-yr-old man is arrested upon trying to enter the United Nations, arguing that he is Ambassador to Alpha Centauri; a 48-yr-old homeless woman believes that she is the wife of Thomas Aquinas; a 22-yr-old college student gradually becomes convinced that the CIA, FBI, and New York City Police Department have been following him since birth. All three of these individuals suffer from "psychotic delusions," the adoption of false, often bizarre, beliefs that are held in spite of ample evidence that contradicts the belief or greatly diminishes its likelihood. Psychotic delusions are characteristic of a number of mental and neurological illnesses, but are most common in schizophrenia and the manic phase of bipolar disorder. Delusional ideation produces much of the social alienation, lack of treatment compliance, and poor functioning associated with these diseases. Even so, the neurobiological and cognitive mechanisms responsible for the formation and maintenance of psychotic delusions are one of the least understood aspects of these illnesses.

In the absence of sensory distortion, it seems reasonable to assume that delusional patients have access to the same information about the world as everyone else. Yet if this is the case, we are left with two large puzzles. The first is why patients, who presumably start from the same premises as healthy individuals, manage to reach such radically different conclusions. The second is why patients' false conclusions revolve so consistently around certain themes, such as paranoia and grandiosity. Our study was designed to begin to address both questions.

Since logic was first developed to formalize rationality, it makes sense that it would serve as a useful tool in modeling aberrations of reason. If individuals infer conclusions from a set of premises by applying a pre-established category of rules of reasoning, then false conclusions may be arrived at by either starting from false premises or by invalid inferences. The vast majority of literature on schizophrenia and logic address the second of these possibilities, beginning with von Domarus' idea

that patients with schizophrenia consistently use a specific fallacious inference (Von Domarus, 1944). More modern studies have tested patients' abilities to use standard logical inferences (Ho, 1974; Kemp et al, 1997; Watson and Wold, 1981). Related to these are studies linking poor performance on the Wisconsin Card Sorting Task (a rule-generating task) with schizophrenia (Pantelis et al, 1999), and the correlation between delusion thought and a peculiar style of reasoning in which patients "jump to conclusions" (Huq, Garety, Hemsley, 1988). Results from these studies have been inconclusive. Though valuable as preliminary data, Mujica-Parodi, Malaspina, and Sackeim (2000) have argued that these studies are flawed because of the heterogeneity of patient samples, floor effects, and the conflating of different types of logic as if they reflected the same type of reasoning.

Surprisingly, little attention has been paid to the other possibility by which false conclusions may be reached: inappropriate choice of premises. This absence is all the more striking because modern empirical studies of normal cognition suggest a paradigm of reasoning, *mental models*, that is radically at odds with that presupposed by standard tests of logic (Johnson-Laird, 1995). The most obvious difference lies at the level of premises. Tests of deductive logic provide pieces of information that are explicitly described as the material from which conclusions ought to be derived. In the real world, however, our premises are seldom laid out so neatly before us. Instead, a large portion of our mental work must go towards discriminating between relevant and irrelevant information, choosing that from which we will later derive conclusions. Since available premise-groups are usually incomplete, most "conclusions" are actually closer to be being *hypotheses*, over-inclusive sets that are then restricted by confrontation with new evidence. Johnson-Laird's experiments suggest that the capacity for recognizing counter-examples to our provisionary models, and these models' subsequent revision, are just as critical in the formation of belief systems as the inferences that initially give rise to the models (Oakhill and Johnson-Laird, 1985). Since perhaps the most characteristic feature of delusions is not the strangeness of the conclusions reached, but of their perseverance in the face of systemic evidence to the contrary (Jones and Watson, 1997) one would expect the recognition and application of counter-examples to be a cognitive ability that is seriously impaired in patients with delusions. Yet it is a phenomenon that has hardly been studied in this population.

Our central hypothesis is that it is the failure to sort premises: distinguishing relevant from irrelevant information and, in particular, the recognition and application of counter-examples, that is responsible for delusions. We suggest that such a failure may be the result of a normal prioritization of neural resources during periods of emotional stress, inappropriately activated in patients. While it may be natural for healthy individuals to initially form false or partially false models, these models are normally revised in the face of contradictory evidence. In the presence of anxiety or fear, this self-correcting mechanism may be temporarily disabled in order to devote full mental resources to avoiding the cause of threat. Once the threat has passed, the mechanism would become functional once more and false beliefs would be revised. If, in the case of patients, the amygdala (and/or other medial temporal lobe structures responsible for perceiving threat) is hyperactive, then the same process may occur with far less provocation. Under the strain of a more or less continual state of emotional stress, the recognition of counter-examples may become disabled long enough to allow false beliefs to become entrenched. The advantage of grounding the creation of delusions in emotion, rather than the reverse, is that it provides an explanation for the relative thematic uniformity found between different patients' beliefs. The patient who experiences a state of fear or anxiety without a clear referent for it will presumably feel the need to explain that feeling; the explanatory structure that the patient creates, however, will very likely be flawed because of the mechanism hypothesized above.

The view of paranoid delusions as quasi-rational stories that are created to explain pre-existing emotional states is consistent with a wide variety of preliminary clinical evidence connecting psychosis and affect, including vague feelings of fear and anxiety reported during the prodromal (pre-symptomatic) period in schizophrenia (Henmi, 1993; Wiedemann *et al*, 1994) and correlations between levels of perceived stress and preoccupation with delusions (Myin-Germeys, 1999). It has long been known that there is a strong correlation between relapse in schizophrenia and even minor increases in stress (Doering et al, 1998). At a physiological level, schizophrenic patients' MRI's are characterized by lower hippocampal volumes than that of controls (Kegeles *et al*, 2000), these patients appear to have increased cortisol levels (a "stress hormone") (Goldman *et al*, 1993), and increased cortisol levels over sustained periods of time are known to be toxic to the hippocampus (Sapolsky *et al*, 1990). Other studies have linked prenatal damage to the limbic system with later development of schizophrenia (Lipska *et al*, 1993; Hanlon, Astur, and Sutherland, 1999). It may be that a vulnerable amygdala and/or medial temporal lobe abnormalities could be both responsible for the increased cortisol levels as well as for the common generalized feelings of anxiety and fear associated with the emergence of psychosis. It may also be the case that insult to the hippocampus and structures also involved with the circuit associated with arousal, such as cortical regions and the thalamus/hypothalamus, could be at least partly responsible for whatever defect in reasoning is responsible for the development of delusional beliefs. Most provocatively, this line of thought, if valid, could

shed light on the relationship between delusional ideation, clinically defined, and the anecdotal truism that even normally rational individuals become irrational when they are upset (or angry, or fearful, or euphoric, for that matter). It might also eventually provide a link between a particular symptom—delusions—and its neural mechanism among disorders, such as mania, psychotic depression, and schizophrenia, that are currently considered to be unrelated.

For our study, we tested the following hypotheses:

I. Patients with delusions are impaired in their ability to distinguish relevant from irrelevant premises in the formation and restriction of mental models.
II. Patients with delusions use logical inferences equivalently to healthy and patient controls.
III. All individuals (patients and controls) are impaired in their ability to distinguish relevant from irrelevant information when they are subject to emotional stress. We hypothesize that this task of sorting is more vulnerable to the effects of emotional stress than the task of logical inference-making.
IV. Patients are more vulnerable to stress, and therefore require less emotional provocation than do controls in order to reach the level at which this cognitive mechanism is impaired.

The Logical Reasoning Task

Dr. LR Mujica-Parodi and Dr. Harold Sackeim developed a *Logical Reasoning Task* (LRT) that avoids many of the problems present in previous attempts to test logic deficits in patients. Unlike previous tests, this task tests both logical inferences and the choice and evaluation of premises. The evaluation of premises sections are essentially an inverse of the inferences sections, in which the conclusion is given, and the subject is instructed either to identify information that would support the conclusion or to identify information that would contradict it. Items that are identical in form are presented within both affect-neutral and affect-laden contexts, counter-balanced for order. The affect-laden sections use threatening language in order to provoke a state of mild arousal, measured by visual analog scale and skin galvanic response. Responses are circled from a list of possible answers that are randomly spaced along the page. Extensive pilot testing ensured that LRT avoids floor effects by testing only inferences that most (60%-70%) healthy adults without any formal education in logic found to be intuitive and representative of "everyday reasoning." Most importantly, we established that both controls and patients are able to well-tolerate the task. The LRT is comprised of 60 items, 30 for the neutral section and 30 for the affect-laden section. For each section, 10 items test inferences, propositional premise choice, and class (quantifier) premise choice, respectively. The entire LRT takes approximately one hour to complete. Items on the LRT are scored in a manner that permits one to discriminate between errors of premise over-inclusion, errors of premise exclusion, and errors of contradiction. Subjects are able to choose more than one response. A score of 1 point is given for every item that includes the correct answer as long as there is no contradiction entailed by the subjects' responses. In Example 1 shown below (Table 1), the subject's choice of the second and third responses or the third and fourth responses would entail a contradiction. If the subject chooses more responses than are necessary, this is indicated by separate scoring for over-inclusion (with 1 additional point for each additional response). Similar scoring is done for under-inclusion. Separate scoring also records number of contradictions and choice of "not-enough-information" responses (which also indicate, with under-inclusion, degree of premise exclusion). Subjects are given five practice items before beginning the test, three of which have the correct answers marked, and two of which the subject completes.

Table 1: Examples from the Logical Reasoning Task

Example 1: Inferences, Affect-Neutral Condition
If John has missed the bus, then he will be late.
John has missed the bus.
What follows from this?
Nothing follows.
John will not be late
John will be late. ←
John has not missed the bus.
contradiction
contradiction

Example 2: Inferences, Affect-Laden Condition
If they are stabbing me, then they will kill me.
They are stabbing me.
What follows from this?
Nothing follows.
They will not kill me.
They will kill me. ←
They are not stabbing me.

Example 3: Premise Choice, Affect-Neutral Condition (Propositional logic, Counter-example)
John says that he will be late.
What information, together, makes you think that he is wrong?
John is late.
John has missed the bus.
Nothing makes me think that he is wrong.
John has not missed the bus. ←
Only if John is late, will he then miss the bus.
Only if John misses the bus, will he then be late. ←

Study Design

Subjects:
For these preliminary data we looked at responses from 28 patients, divided by cognitive symptom profiles, and 16 healthy controls. Of the patients, 10 had well-developed delusional systems, 5 were thought-disordered,

and 13 were neither delusional nor thought-disordered (with hallucinations as the primary symptom). Our completed data will contain 50 subjects in each of the 3 groups, as well as a group of healthy controls with high degrees of magical ideation. Diagnosis and symptom severity were determined using the Diagnostic Interview for Genetic Studies (DIGS). Patients were matched for symptom severity and medication status. For our final analysis, all three groups will be matched for Verbal IQ (using the Weschler Adult Intelligence Scales), age, and education. For our preliminary analysis, patients and controls were not matched due to the relatively small N, although ANCOVA's determined that covariates of education, gender, age, and education were not significant confounds. Both patient groups and controls were relatively well-educated, averaging two years of college, with no formal training in logic.

In our sample there were more male patients (21) than female patients (7), reflecting the general distribution in schizophrenia, and more female control subjects (10) than male control subjects (6). All subjects signed informed consent for this Institutional Review Board-approved study. Patients were recruited from the New York State Psychiatric Institute's Schizophrenia Research Unit, the Washington Heights Community Unit, and affiliated out-patient clinics. Controls were recruited from the local community, and were screened using the Psychosis Proneness Scales developed by Chapman and Chapman (Chapman et al, 1994).

Procedures:
Control subjects were screened using the Psychosis Proneness Scales. All subjects were administered the LRT and several sections of the WAIS (testing spatial inferences, abstraction without use of counter-examples, vocabulary, and working memory). Blind symptom-profiling for patients was performed post-hoc to avoid bias.

Results:
We performed ANOVA to determine differences between subject groups and test types (with post hoc t-tests), ANCOVA to screen confounds of age, sex, and education, and paired t-tests for individual subjects on affect neutral/laden condition to test the effects of arousal on performance. The results are summarized below in Table 2.

Differences between patient and control groups reached statistical significance for all types of reasoning (inferences: p=.005; premises(prop): p=.024; premises(class): .012). Performance was highest for healthy controls, followed by—in descending order—delusional patients, patients hallucinating only, and thought-disordered patients. This same pattern was present for all three types of reasoning. Healthy controls displayed a slight (non-significant) drop in performance when assessing relevance under mild arousal (premises(class): p=.083/df=15). Delusional patients displayed the same pattern, but in a significantly exaggerated form (inferences: p=.004/df=9; premises(class): p=.033/df=9) This suggests that delusional patients have a relatively intact ability to reason under neutral conditions, with a particular vulnerability toward emotional arousal. Thought-disordered patients displayed an inverse pattern, improving under emotional arousal (premises(class): p=.035/df=4), which perhaps reflects an inability to maintain adequate arousal under normal conditions. Healthy controls, delusional patients, and thought-disordered patients may be viewed as occupying different initial locations on an inverted "U," where—following the Yerkes-Dodson Law— performance initially improves with small degrees of arousal but suffers with increasing amounts of stress. In this case, stress-level is held constant, with different vulnerabilities to arousal accounting for the different locations on the curve. The types of errors made were also different for different groups. Delusional patients generally, and particularly under arousal, showed a tendency to shut out relevant information (p=.067/df=9), again an exaggeration of the healthy controls' response to stress (interestingly, patients who only hallucinated showed even more of an exaggeration in this regard). Thought-disordered patients, on the other hand, were more likely than other groups to assign inappropriate weight to irrelevant information (p=.05/f=2.3).

Table 2: 3 Types of Reasoning x 4 Subject Groups

	Inference	Prop	Class	
Del	0.54±22	0.31±28	0.46±.28	
Th Dis.	0.24±.18	0.11±.09	0.12±.08	**NEUTRAL**
Halluc	0.48±.20	0.29±.15	0.40±.27	**CONDITION**
HC	0.65±.19	0.45±.23	0.62±.28	
	Inference	Prop	Class	
Del	0.35±.24	0.24±.19	0.33±.25	
Th Dis.	0.26±.19	0.15±.10	0.20±.13	**AROUSED**
Halluc	0.41±.25	0.21±.13	0.28±.20	**CONDITION**
HC	0.67±.23	0.41±.24	0.52±.29	

Three important preliminary conclusions to be drawn from this data are that: a) all patients groups show significant deficits in both inferences and cognitive gating relative to controls; b) of all patients, delusional patients infer most similarly to healthy individuals, except in the presence of emotional material, which also seems to affect their reasoning most dramatically; and that c) the "irrationality" of delusional patients (which is affect-driven and shuts out relevant information) appears to be quite different from that of thought-disordered patients (which is affect-independent and reflects and inability to "screen-out" irrelevant information). This last point is of particular relevance because it suggests differences

between symptoms-types that may be relevant not only from the point of view of etiology, but of treatment (delusional patients may benefit from adjunctive benzodiazepines and/or cognitive-behavioral-therapy in a manner that thought-disordered patients may not, for instance). Interestingly, delusional patients' abnormal vulnerability to arousal, combined with healthy controls' less dramatic decline in cognitive gating under arousal, raise provocative questions regarding the degree to which delusional patients' reasoning may resemble normal controls' reasoning when normal controls are under more pronounced levels of stress.

Implications and Future Work

"Cognitive" versus "Sensory" Neural Gating

As shown above, our data suggests that all three patient groups had significant deficits in cognitive gating. In investigating the neurobiological roots to such a deficit, we have considered the possibility that deficits in cognitive gating may be rooted in a more fundamental "lower-level" deficit in "sensory-gating," whose deficits have been shown to be ubiquitous to schizophrenia. While "cognitive gating" is defined as the discrimination between relevant and irrelevant conceptual information, "sensory gating" can be similarly understood as the discrimination between relevant and irrelevant sensory data.

One explanation that could link cognitive and sensory gating is a "hierarchical" hypothesis for information processing, in which sensory data is sorted through a series of neural "filters," traveling first through a "coarse-grained" filter, then through filters that are progressively more "fine-grained" as attentional levels (and presumably levels of abstraction) are increased. This hypothesis is testable, for it predicts that poor performance on tests of higher-order filtering will also entail poor performance on tests of lower-order filtering. However, the converse is not true; performance on tests of lower-order filtering will not entail equivalent performance on tests of higher-order filtering (since information may be adequately filtered at a lower level before stumbling at a faulty higher-level filter). We would expect the brain activation associated with performance to behave equivalently. Thus we would predict that areas of the brain activated during higher-order filtering will entail (i.e., will correlate positively with) activation of areas of the brain associated with lower-order filtering (since all information that that passed through higher-order filters had to be processed through lower-order filters first). However, the converse will not be true; areas of the brain activated during lower-order filtering will not entail areas of the brain activated during higher-order filtering. M.-Marsel Mesulam [1998] proposes a similar hierarchical "critical gateway" model in which "lower" processing of sensory information contributes to "higher" processing of cognitive material along certain pre-established pathways. In Dr. Mesulam's model, the level of neurological impairment (i.e., whether related to "lower-order" global deficits like multimodal anomia or "higher-order" deficits like category-specific anomias) also results from the point in the hierarchy at which processing is disrupted. We are currently conducting a neuroimaging (fMRI) study looking at different information-gating processes (including the Logical Reasoning Task) operating at different "levels" to test this hypothesis.

While prominent, delusions are only one of many cognitive and perceptual symptoms of schizophrenia, which include thought-disorder and hallucinations. The elucidation of filter-level deficits, and their relationship to *specific* signs and symptoms of schizophrenia, is important in responding to a cogent criticism placed by Frith (1979), that the disabling of a sensory filtering mechanism in schizophrenia, if it exists, cannot be at a general level. This is because a generalized gating deficit would result in far more neurological disability than is actually clinically observed. However, the degree to which patients are disabled varies quite a bit, varying between extreme disorganization and intricately-constructed delusional belief systems. As Frith (1979) earlier has suggested, the precise symptomatology of the illness may be based on the *degree* to which gating is impaired. It may be that paranoid patients have relatively well-preserved lower-level filtering, while only higher-order filtering is impaired. Thought-disordered patients, on the other hand, may represent a more severe form of the illness in which lower as well as higher level gating is affected. Drawing these connections will be important not only theoretically, in establishing a unitary model of schizophrenia which accounts for varied symptoms, but also potentially in developing medications that are tailored to treating specific symptoms. If the mechanism associated with neural filtering does exist upon a continuum, ranging from the basic sensory gating involved in attention (at the lowest end), to the cognitive gating required to separate relevant from irrelevant information (at the highest end)—with each level dependent upon the one "beneath" it—then it may be the case that the stage at which filtering is impaired is responsible for the cognitive symptom picture (thought-disordered vs delusional, for instance) with which a schizophrenic patient presents. Higher-order filter deficits, with lower-order sensory gating that is still intact, may produce symptoms that look like belief systems that are flawed because they are constructed based on inappropriate choice of information (including inattention to counter-examples), but which remain fundamentally self-consistent. Patients whose filtering deficits have progressed to include *both* higher and lower-order gating, may produce a more general disorganization in which inferences, and therefore self-consistency, may no longer be possible. This picture is akin to Frith's model (Frith,

1979); he suggests that delusional ideation may exist as a less severe form of the disease, in which some aspects of cognition are still well-preserved. Based on the literature on sensory/sensorimotor gating and selective attention, we will be primarily looking at activation in the dorsolateral prefrontal cortex, hippocampus, striatum, and thalamus/hypothalamus.

Aknowledgments

Support for this research was provided by the National Alliance for Research on Schizophrenia and Depression, the Essel Foundation, the Frontier Fund for Scientific Research, and the National Institute for Mental Health.

Interactions between Frequency Effects and Age of Acquisition Effects in a Connectionist Network

Abstract

The performance of a connectionist network, in which some resources are absent or damaged is examined as a function of various learning parameters. A learning environment is created by generating a set of random "prototypes" and clusters of exemplar vectors surrounding each prototype. An autoencoder is trained on the patterns. The robustness of each learned item is measured as a function of the time at which it was "acquired" by the network and its overall frequency in the environment. Both factors are shown to influence robustness under several learning conditions.

Introduction

For all their shortcomings, feed-forward network models of learning and memory share certain important features with their biological counterparts. Among these are the ability to gradually abstract statistical regularities from their environments by incorporating them into their connectivity structures and the feature generally known as "graceful degradation".

In this paper, the relationship between early learning (acquisition) and degradation of performance through loss of resources is examined in the context of small-scale simulations, in terms of frequency effects, age of acquisition (AoA) effects, prototype effects, and the insertion of noise into the neural network.

The relative influence of AoA compared to frequency on word naming tasks has been argued among cognitive psychologists and linguists for several years now (Brown & Watson, 1987; Morrison et al., 1992; Gerhard & Barry, 1998). Of course, teasing apart the influences of AoA and frequency is confounded by the strong correlation between them. AoA effects have also been reported in other domains, such as object identification and face recognition (Moore & Valentine, 1999). The effects of AoA and frequency on pattern error have been analyzed by Smith, Cottrell, and Anderson (2001). Here, we look at pattern performance in the face of damage to the network, simulating neuronal failure as could occur with aging or trauma.

The robustness of network performance to hidden unit damage has been shown to improve for networks trained with noise among the hidden units (Judd & Munro, 1993). In some cases, this kind of noise has been shown to improve the generalization properties of a network (Clay & Sequin, 1990). Functionally, the hidden representations of the training items settle to states that are further apart in terms of a Euclidean measure.

In this paper, we examine the following three hypotheses:

1. The robustness of an item under loss of network computational resources (analogous to the loss of neurons in humans) is related both to the time at which that item was "acquired", and to the average frequency of the item in the network's experience.

2. Prototypical items are more robust than exemplars, even if they are never explicitly presented to the network, since they share features with populations of exemplars, and thus have high "effective frequencies" in the environment.

3. Early explicit learning of prototypes can result in a more robust set of internal exemplar representations.

Methodology

The training set

A two-step process is used to generate a structured set of bit strings of length L. First, a set of N prototype strings is produced by generating 0 and 1 values

independently with probability 0.5 for each bit having a value 1. In the second step, a set of n_i exemplar strings are generated from the i^{th} prototype P_i by "flipping" bits with a low probability. The result is a set of N pattern "clusters" (see Figure 1). While the network is trained on the exemplar patterns only, the network performance is measured for both the exemplars and the prototypes. In this study, L=100, N=10, and n_i=10, (i=1..10).

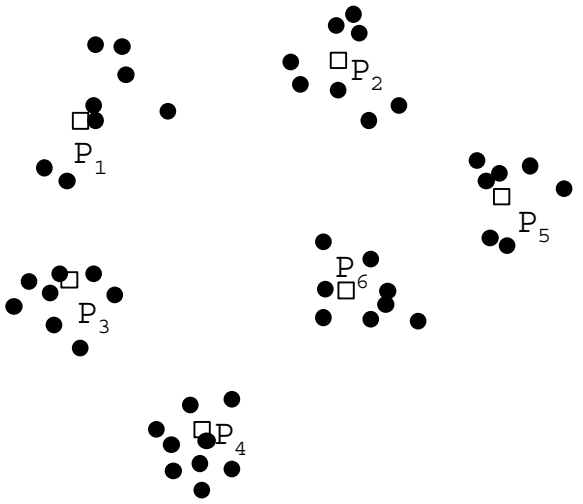

Figure 1. Schematic view of the training patterns. Prototypes (open squares) are randomly generated binary strings. A set of exemplars (filled circles) is generated in the neighborhood of prototype.

In order to analyze the role of frequency, items were selected from the training set according to a ramp distribution; that is, the selection probabilities for the 100 exemplars ranged from approximately 0.0002 to 0.0200 linearly. The probabilities were assigned such that the cluster probabilities also followed a ramp distribution. In other words, the items were ordered according to the parent prototypes and the probability of selecting the k^{th} item was proportional to k. This way, the clusters were also ordered such that the probability of selecting an item from the j^{th} cluster was proportional to j.

Network Architecture

Networks trained by backpropagation to reconstruct their input pattern at the output layer (autoencoders) with a single hidden layer of 40 units are trained using backprop. In some trials, the responses of the hidden units are randomly perturbed to analyze the effect of network noise. An output unit's response is deemed "correct" if it differs from the target by less than a predetermined tolerance level δ. Performance is measured in terms of the number of correct output units. If the network responds with a sufficient number of correct output units to an input pattern, that pattern has been acquired by the network. The point in training at which a pattern is first acquired is called its age of acquisition (AoA). Preliminary studies have shown that in some cases a pattern may briefly be "forgotten" soon after its initial acquisition. In such instances, the forgotten pattern is promptly reacquired; thus, the AoA is defined as the time the pattern is first acquired.

Performance Analysis

After training, the network's response to each training pattern was tested under various damage levels. Damage was implemented by only allowing the output of k of the H hidden units to stimulate the output layer, where k is varied from 1 to H. The minimum number of hidden units required to reconstruct the input pattern (to within a specified degree of tolerance) is recorded as a measure of the pattern's robustness in the network. In some cases, patterns were "forgotten" after initial acquisition. In most such cases, the pattern was reacquired, but not always.

Experimental Conditions

In all the experiments, the acquisition criterion is that 95 out of 100 units should be within 0.2 of their target value (0 or 1). The total training time is either 50000 or 100000 pattern presentations, depending on the condition. Thus, with the ramp distribution, the number of presentations of each individual pattern varies from about 10 to about 2000.

Control Condition (CC) In the control condition, the network is trained with just the 100 exemplars for a period of 100000 pattern presentations.

Head Start Condition (HC) Here, the training set consists a subset of only 10 patterns (one from each cluster) of the full set of 100 exemplars for the first 10000 time steps. This is done to guarantee very low AoAs on some patterns. The training set is expanded to the full set, including the initial subset, for 90000 more presentations. Ellis & Lambon-Ralph (2000) found strong AoA effects in a staged learning condition of this kind.

Noisy Condition (NC) This condition is the same as the previous condition (HC) with "Boolean" noise injected into the hidden layer during the early phase. Here, the activity levels of a small number of hidden units are multiplied by −1. This manipulation is predicted to increase the overall robustness of the full training set.

Prototype Condition (PC) In this variation of HC, the network is trained on only the protoypes during the early phase with no injected noise. Note that prototypes

are never explicitly presented in the previous three conditions.

Results

All conditions show a strong dependence of AoA on frequency. In general, prototype patterns are acquired earlier than exemplar patterns, even if they are not explicitly presented, with the AoA of the prototypes dependent on average frequency of the corresponding exemplars.

Control Condition (CC)

Over the course of 100000 exemplar pattern presentations, 92 of the 100 exemplars were acquired by the network. The eight nonacquired exemplars were all among the 11 least frequent. Of the 10 prototypes, one was not acquired, and eight were acquired in the first 10000 iterations. A scatterplot of AoA vs frequency follows a hyperbolic trend (Fig 2, top). This observation prompted a second scatterplot (Fig 2, bottom), in which AoA is examined vs. $freq^{-1}$. Regression on these data indicates the product of AoA and frequency is about 190 (zero intercept assumed).

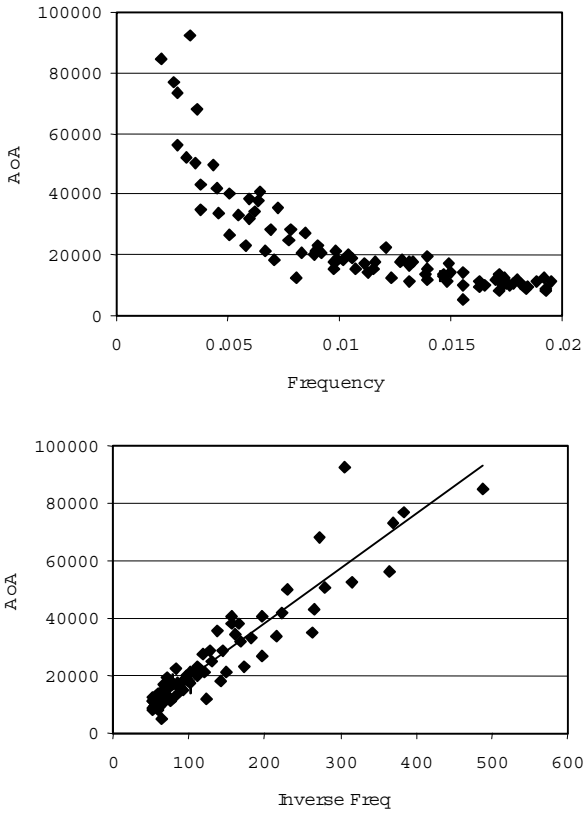

Figure 2: AoA vs Frequency (top) and AoA vs. $Freq^{-1}$ (bottom). The random selection of stimuli in the simulation follows a ramp distribution to give a wide range of frequencies.

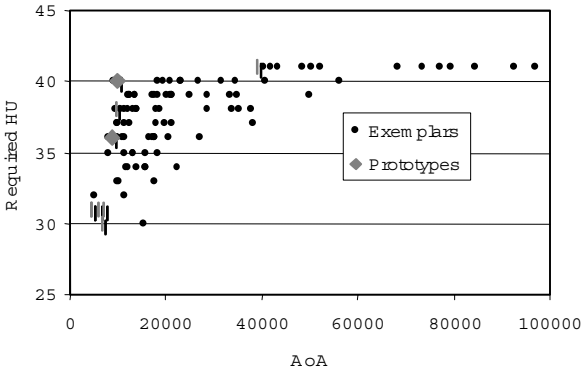

Figure 3. The number of hidden units required to reconstruct the input as a function the AoA. A value of 41 indicates that when the simulation halted, the pattern could not be reconstructed with all 40 hidden units.

The fragility of each item, as measured by the number of hidden units required to reconstruct the pattern tends to be higher for the patterns with later AoA (i.e., earlier patterns are more robust). This is true for both the exemplars and the prototypes (Fig 3). Similarly, items that are more frequent tend to be more robust (Fig 4).

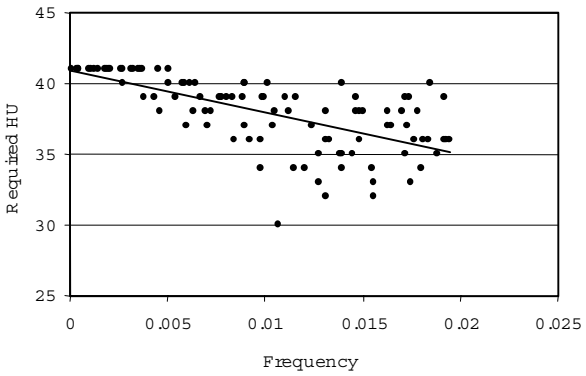

Figure 4. The required number of hidden units vs. frequency. The trendline shows that more frequent items tend to be more robust.

Regression against both variables indicates that the influence of AoA ($p = 0.01139$) is stronger than frequency ($p = 0.03271$) by a factor of almost three.

Head Start Condition (HC)

Here, the first 5000 iterations use only a subset of 10 items (one exemplar from each prototype's "cluster") for training. The network is then exposed to the entire set of 100 exemplars for 45000 subsequent learning trials. Selection of patterns during early exposure also follows a ramp distribution, giving a variety of frequencies within this set.

Early Items. Nine of the 10 items presented alone for the first 5000 time steps are learned before presentation 2000. Four of them are acquired before the earliest prototype (1000 iterations). The least frequent item in this set was never learned. As in CC, AoA and frequency are highly correlated.

Prototypes. The mean AoA for prototypes under HC (12907) is later than it is under CC (10568) and the average prototype is slightly less robust under HC (35.75 HU) than under CC (34.22 HU).

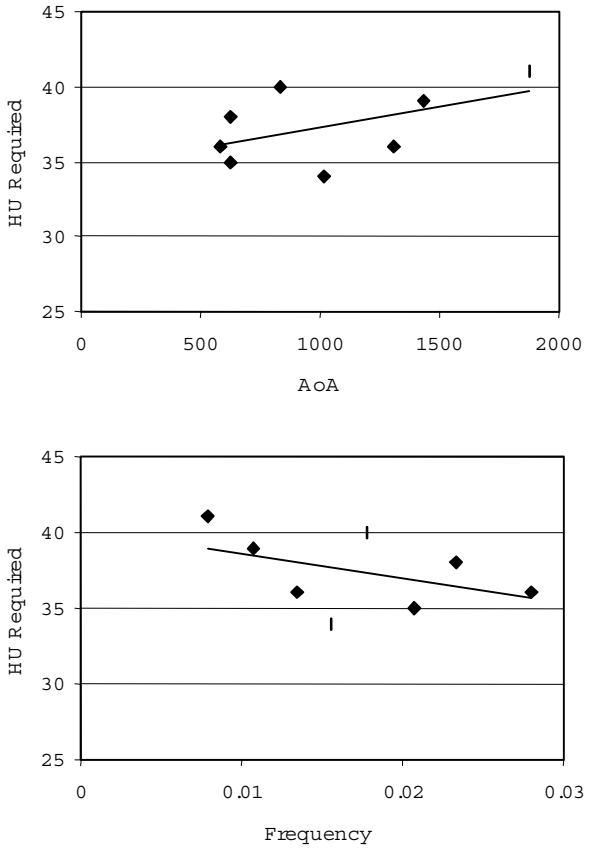

Figure 5. The dependencies of robustness on AoA (top) and frequency (bottom) under HC.

Prototype Condition (PC)

This condition is like HC, except that the ten patterns presented in the early phase are the prototypes of the later patterns. No significant differences in the effects on robustness or AoA were observed in the PC relative to HC.

Noisy Condition (NC)

As in the case of PC, this condition produced mainly negative results. No significant effect of the noise was noticed on the acquisition or robustness of the exemplars. The main observed effect of noise is that the prototypes are acquired much faster. However, the network does not maintain the ability to reconstruct prototypes from the low frequency clusters. Nevertheless, those prototypes that are maintained can withstand more damage to the network.

The bar graphs in Figure 6 display the AoA and robustness (HU required) for the prototype patterns, such that they can be compared with corresponding values in the control condition (black bars=NC, striped bars=CC).

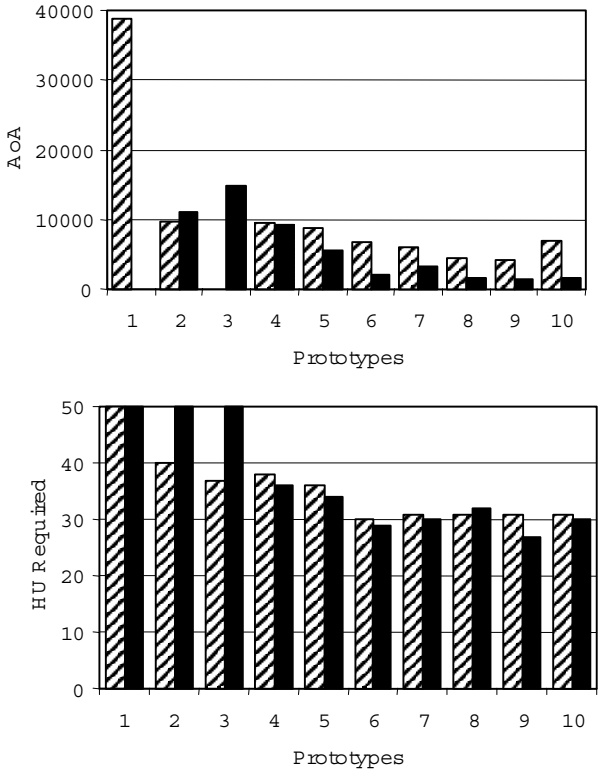

Figure 6. Distributions of AoA (top) and the required number of hidden units (bottom) are displayed for the control condition (striped bars) and NC (dark bars). The 10 items are ranked from lowest (approx. 0.018) to highest frequency (approx. 0.18). The network was never able to reconstruct the lowest frequency prototype (#1), hence there is no bar for this condition. The maximum value for the lower bar graph is the total number of hidden units, 40. A value of 50 means that the network could not reconstruct those prototypes at the end of the simulation.

Conclusions

As a preamble to the data analysis, the relationship between AoA and frequency was examined. These variables were found to be strongly related by a function of the form $a=k/f$, where a is the AoA, f is the frequency, and k is a constant (refer to Fig 2). Even

though this did not bear directly on the hypotheses, it may be the strongest result of this paper!

Our results support the first two hypotheses. The first hypothesis, that both frequency and AoA influence robustness of a learned item is evident from the simulations. Bivariate regression of the robustness variable (HU required) against the two independent variables gave fits that were not very tight (i.e., the p values were too high for the results to be considered significant). Nevertheless, the value corresponding to AoA was consistently lower than that for frequency, indicating a stronger dependence of robustness on AoA.

The second hypothesis, that prototypes are more robust than exemplars was supported by the simulations. The effect is as strong as expected by the measure used here: under CC, prototypes require an average of 34.3 HU, while exemplars require 36.3 HU. Note that this may simply by a byproduct of the AoA effect, since prototypes are acquired much earlier than exemplars. Frequency also plays a role. Even when the prototypes are not explicitly presented, and thus have no frequency per se, the exemplars may be considered distorted versions of the prototypes. Hence, each prototype has an "effective frequency" that depends on the total frequency of its supporting exemplars weighted by the exemplar-prototype distances.

Our simulations did not support the third hypothesis, that early explicit prototype training would result in representations that are more robust. While no such effect has yet been observed, it remains as a subject for future investigation.

Discussion

The issues investigated in this study are the first steps into the exploration of a broader question: How does the adult cognitive structure ultimately depend on the initial stages of learning? This question is quite similar to the age-old debate of nature vs. nurture. Here the issue is whether some potential for later cognitive capabilities is dependent, not on innate factors, but on the content of early experience and the biological mechanisms at work.

The process of acquisition of information, the sequence in which items are presented to the learner, as well as the internal parameters of the learner, may play a determining role in the adult conceptual architecture. It may be that the representations of concepts acquired in childhood, and the associations formed among them construct a foundation on which later concepts are built. Hence, the soundness of this foundation may determine the ultimate robustness of the adult.

Certainly, the importance of early learning on cognitive development has been acknowledged (for example, Catherwood, 1999). In the present work, we have begun to examine this within the connectionist framework, whereby adult cognitive performance might be linked to the statistics of the learning environment in early childhood.

Abstract

The current study examines the modality preference and its change in the course of development. Based on findings from previous research (Balaban & Waxman, 1997; Roberts, 1995; Sloutsky & Lo, 1999), it was expected that the auditory modality would be privileged at a very young age. In the experiment, participants after being trained to select a target image and sound combination were required to select a new combination where the target image was paired with a new sound and the target sound was paired with a new image. It was argued that the selected set would be indicative of whether the image or sound is more salient. Results indicate that the auditory modality was more salient than visual for 4-year-olds, whereas the visual modality was more salient for 5-year-olds and adults.

Introduction

It is well known that linguistic labels play an important role in induction. For example, in Gelman & Markman's (1986) forced-choice task, young children were presented with pictures of a blackbird (Target), flamingo (Test 1), and bat (Test 2) that was perceptually similar to the blackbird. Both the blackbird and flamingo were referred to as "birds," and the task was to induce a property (e.g., "feeds its young with mashed food" vs. "feeds its young with hard food") from one of the Test stimuli to the Target. Results indicated that young children reliably induced biological properties from one bird to another bird, even when both birds were perceptually dissimilar. Other researchers demonstrated large, albeit quantitative, effects of labels using a variety of stimuli and tasks (Sloutsky & Lo, 1999; 2000; Sloutsky, Lo, & Fisher, in press). There are also findings that in categorization tasks linguistic labels supported taxonomical grouping of objects in infants (Balaban & Waxman, 1997; Waxman & Markow, 1995) and in young children (Markman, 1989).

These findings have generated three primary explanations: semantic, phonetic, and general-auditory. The two former explanations argue for specific linguistic effects of labels, whereas the third argues for more general auditory effects.

The semantic explanation (Gelman & Markman, 1986; Markman, 1989) has focused primarily on explaining the effects of labels on induction in young preschool-age children. It has been argued that linguistic labels presented as count nouns denote categories, and, because members of the same category are likely to share many nonobvious properties (two cows are more likely to have similar insides than a cow and a pig) shared linguistic labels support induction.

The phonetic explanation (Balaban & Waxman, 1997) has focused on explaining categorization in young infants. According to this position, young infants are especially attentive to the prosodic components of human speech that distinguish it from other sounds (Balaban & Waxman, 1997, Experiment 3). As a result, when presented with pictures accompanied by auditorily introduced labels, infants attended to linguistic labels and to visual features that correlated with linguistic labels.

Finally, the general auditory explanation suggests that, at least for infants and very young children, the effects of labels may stem from the modality of input (Sloutsky & Lo, 1999). In particular, it is possible that the powerful effects linguistic labels have on categorization and induction are due to the fact that auditory input has a privileged processing and attentional status in younger humans (cf. Roberts, 1995; Roberts & Jacob, 1991). If this is the case, stimuli

presented auditorily should have larger attentional weights than stimuli presented in another modality.

Why would auditorily presented stimuli weigh more for younger children than visual stimuli? One possible explanation is that the auditory system matures earlier than the visual system: in particular, the auditory system starts functioning during the last trimester of gestation (Birnholz & Benaceraff, 1983; see also Jusczyk, 1998, for a review), whereas the visual system does not start functioning until after birth. As a result, even though the neural bases of visual perception are fully developed at quite a young age (e.g., Aslin & Smith, 1988), auditory stimuli may still have a privileged processing status for younger children, thus resulting in larger weights of auditory stimuli. This privileged status of the auditory modality may be functionally important for language acquisition, and, in this case the advantage may start decreasing when the child has (in principle) acquired the task of acquiring language.

The goal of current research is to test this general auditory explanation. Note that support of the general auditory explanation does not rule out the semantic and the phonetic explanations. Because the three explanations are not mutually exclusive, it is possible that linguistic labels may have semantic and phonetic effects above and beyond the general auditory effect.

The overall experimental approach was as follows. Participants were presented with two stimulus sets each consisting of an auditory and a visual component and were trained to consistently select one set over the other. When training was accomplished, they moved to a test phase, in which the trained set was split, such that the visual stimulus of the trained set was paired with a novel auditory stimulus, whereas the trained auditory stimulus was paired with a novel visual stimulus. The participants were asked which of the two was the trained set. It was argued that if participants put more weight on the visual stimulus, they should select the first set, whereas if they put more weight on the auditory stimulus they should select the second one.

Method

Participants

A total of 39 children and undergraduate students participated in the experiment. Participants represented three age groups with 13 participants in each group: (1) 48-month-olds to 57-month-olds, (2) 58-month-olds to 65-month-olds, and (3) undergraduate students at The Ohio State University. The second group was added when the experiment was under way. This was done to provide more dense developmental observations. Children participants were recruited from local childcare centers in the Columbus, Ohio area. Undergraduate students participated as part as part of an introductory psychology course.

Materials

Materials consisted of 24 stimulus sets. Each set was comprised of a visual and an auditory stimulus. The visual stimuli were digitized photographic landscape images. Each image consisted primarily of a different type of green foliage. Images were 4 inches by 4 inches in size. The auditory stimuli were computer generated patterns, each consisting of three unique simple tones. Simple tones varied on flavor (sine, triangle, or sawtooth) and frequency (between 1 Hz and 100 Hz) components. Each simple tone was .3 seconds in duration and was separated by .05 seconds of silence, for total pattern duration of 1 second.

Diagnostics were run to insure the auditory and visual stimuli had high discriminability. This was accomplished using a same-different task. In the task participants were presented with one stimulus for a duration of one second, followed by the presentation of a second stimulus for a duration of one second, and then asked whether the two stimuli were the same. The participants were able to discriminate between all stimuli on over 95 percent of the trials.

Design and Procedure

The experiment included six blocks, each consisting of 8 training trials (a training session) and 6 test trials (a testing session). In each block, 4 out of the 24 stimulus sets were used. Two of these four sets were used in the training session, and the other two were used in the testing session. Children participants were tested in a quiet room within their daycare center. Small toys were used as rewards for participation. Undergraduate participants were tested in a lab on campus. A laptop computer controlled presentation of stimulus sets and recorded all responses. Participants entered the room and sat in a chair in front of laptop. They were told that they would play a game (references to toys were omitted for undergraduate participants), in which they should find the location of a prize. They were then presented on-screen with two stimulus sets each consisting of a visual component (V_1 vs. V_2) and an auditory component (A_1 vs. A_2).

Stimuli were presented in the following manner. First, V_1 and A_1 were presented simultaneously on one side of the screen, followed by the presentation V_2 and A_2 on the other side of the screen. Each image's presentation matched the duration of its sound, and was replaced by a white circle icon at the end of each set's presentation. In short, the child was presented with two stimuli sets V_1A_1 and V_2A_2 and the task was to identify the stimulus set, under which the prize is hidden. The goal of training was to teach the child to consistently

select a particular stimulus set, and, therefore, on each trial the child was provided with yes/no feedback. The positions of each of the two stimulus sets were counterbalanced across the 8 training trials. Participants making correct selections in the final four trials moved into the test session.

The test session followed immediately after the training session, during which participants were presented with two novel stimulus sets: set one (V_1A_{new}) matched the training target's visual component, but had a novel auditory component, whereas set two ($V_{new}A_1$) had a novel visual component, but matched the training target's auditory component. The participants were asked again to identify the one where a prize was hidden. When the participant's selection was made, the experimenter pressed the keyboard key corresponding to the selection, without giving feedback to the participant. The overall structure of training and testing trials is presented in Table 1.

Table 1: The overall structure of training and testing trials.

Training Trial		Testing Trial	
V_1A_1 (Target)	V_2A_2 (Distracter)	V_1A_{new}	$V_{new}A_1$

Results and Discussion

In this section, we analyze participant's choices in the testing phase. Recall that stimulus sets were arranged such that participants could rely either on the visual components of the learned stimulus set (V_1) or on the auditory component (A_1). We first compare overall means of visual and auditory responses across the three age groups. We then report provide a more detailed analysis of participants' performance. In particular, we compare the number of blocks where participants were above chance selecting either the familiar visual or auditory component. We also analyze individual patterns of responses, comparing the number of participants consistently exhibiting auditory responding with those consistently exhibiting visual responding. Note that 48-month-olds to 57-month-olds successfully accomplished 61 out of 78 training sessions (78%), 58-month-olds to 65-month-olds successfully accomplished 65 out of 78 training sessions (84%), and adults successfully accomplished all 78 training sessions. There were also 7 children in the youngest group and 2 children in the older group who did not pass a single training session. These children were eliminated from the analyses and they are not a part of 39 participants whose data are reported here.

Overall means for auditory-based responding were subjected to a one-way ANOVA with age as a factor, followed up by post-hoc Tukey tests. The analyses indicated that these means (65% vs. 22% vs. 2%) differed significantly across the three age groups, F (2, 36) = 19.9, $p < .0001$, and post-hoc Tukey test confirmed that there were significant differences among the groups.

To analyze participants' performance in test sessions, we calculated the number of sessions with above-chance reliance on auditory stimuli, above chance reliance on visual stimuli, and chance performance. Performance was considered above chance if the same choice was made on 5 out of 6 trials (Binomial Test, $p = .09$), otherwise it was considered at chance. Results indicate that in the group of 48-57-month-olds only 9 out of 61 session were at chance, and in the group of 58-65-month-olds 10 out 65 were at chance. All other sessions were above chance. In the group of undergraduate students all test sessions were above chance. Percentages of sessions with above-chance performance by age group and stimulus modality are presented in Figure 1.

Percentages of sessions with above change auditory and responses were subjected to two separate one-way ANOVA with age as a factor. There were significant differences across age groups, both Fs (2, 36) >19, ps < .0001. The post-hoc Tukey tests pointed to the following order differences: 48-57-month-olds were more likely to rely on auditory stimuli and less likely to rely on visual stimuli than 58-65-month-olds or undergraduate students.

Across age groups, there emerged three distinct patterns of responses: (1) participants who were above chance in relying on auditory stimuli (auditory responders); (2) participants who were above chance in relying on visual stimuli (visual responders); and (3) participants who were at chance (mixed responders). Percentages of responders' types across age groups are presented in Table 2.

Table 2. Percentages of responder types by age group.

	Responder Type		
Age Group	Visual	Auditory	Mixed
48-57-month-olds	15.38	61.53	20.07
58-65-month-olds	76.92	15.38	7.69
19-year-olds	100.00	0	0

Numbers of auditory and visual responders in each age were subjected to a chi-square analysis. The analysis pointed to significant differences among the groups, both χ^2s (2, N =39) > 13.4, $p < .001$. The analysis of standardized residuals indicated that 48-57-month-olds were more likely to exhibit an auditory-based pattern than 58-65-month-olds or 19-year-olds, whereas 58-65-month-olds or 19-year-olds were more likely to exhibit a visual-based pattern of responses (all zs > 3.1, ps < .001).

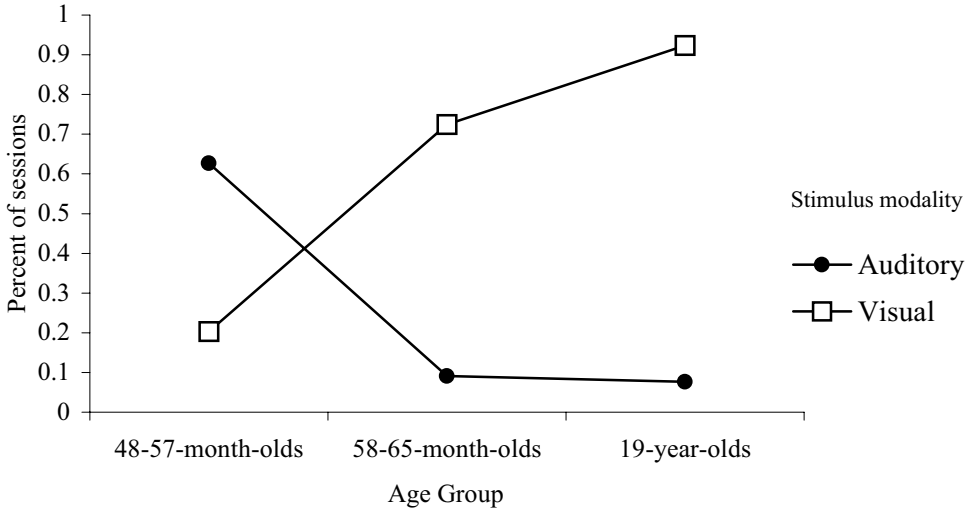

Figure 1. Percent of test seccions at above-chance performance by age group and stimulus modality

In short, the reported data indicate that for 48-57-month-olds auditorily presented stimuli weighed more than visually presented stimuli. These data support the auditory explanation predicting larger weights of auditory stimuli weights for younger children, but not for older children or adults. Of course, the support of the general auditory explanation does not rule out either the phonetic or the semantic explanations. These explanations will be further examined in our future research.

There is also a possible alternative explanation for the significant differences between 48-57-month-olds and the two other groups. First, the younger children's selections may be due to differential complexity of the stimuli. Each auditory stimulus contains far fewer features as compared with the visual stimuli, and, for this reason, the auditory stimuli are simpler to encode and process. Therefore, it is possible that children in the youngest group prefer simpler stimuli that happened to be auditorily presented, rather than prefer auditory stimuli per se. Of course, this explanation would have a hard time explaining the sudden shift from the larger weight of auditory stimuli observed in 48-57-month-olds to the larger weight of visual stimuli observed in 58-65-month-olds, however our current hypothesis also does not have an acceptable explanation for the shift. As mentioned above, there are two possible reasons for audition having priority at a young age. The auditory modality is functional before birth, and it is clear that at birth it is the dominant modality. Perhaps, it is not until the late 4's that the visual modality gains its privileged status. The privileged status of audition may also be related to language acquisition. It is possible, that the auditory modality is privileged during the period where a child's vocabulary acquisition is at its highest. In both cases, our experiments are likely to capture the very end of the period when auditory modality is privileged and the transition to the privileged status of the visual modality. To clarify this issue additional experiments with young infants are needed.

In future research, we plan to examine the above mentioned alternative explanations suggesting that the observed results stem from different computational complexity of stimuli, with impoverished auditory patterns being more simple than more rich and elaborated visual scenes. The next phase of the study will be to reverse the complexity of the stimuli and present participants with impoverished visual stimuli and complex elaborated auditory stimuli. The visual stimuli will be computer-generated two-dimensional geometric figures. The auditory stimuli will be compressed pieces of Celtic music. If the 48-57-month-old group continues to make selections that favor audition, this will provide evidence for the privileged status of auditory processing for young children. If the 48-57-month-olds' selections favor visual stimuli, this will instead provide evidence that young children use stimulus information that is easier to process.

Following this second experiment, it will be useful to examine whether introducing human speech has any effect on the percentage of auditory selections. In this experiment, sounds will be comprised of three phonemes (e.g. "ba te do"). The results of this

experimentation, considered with the results from experiment one, should elicit the attentional weights given to language-rich and auditory stimuli in general.

Finally, it will be necessary to test younger children and infants to determine if preference for auditory stimuli decreases monotonically with age. It is possible that the relation is an inverted U-type, and the auditory modality only becomes dominant during the "explosion" period of language development.

While these alternatives will be tested in the future, research presented here indicates that under these conditions, auditory stimuli weigh more than visual stimuli for 48-57-month-olds, whereas visual stimuli weigh more than auditory for older children and adults. These results support the hypothesis that for young children auditory input may have privileged processing status.

Clustering Using the Contrast Model

Daniel J. Navarro and Michael D. Lee

South Australia, 5005, AUSTRALIA

Abstract

An algorithm is developed for generating featural representations from similarity data using Tversky's (1977) Contrast Model. Unlike previous additive clustering approaches, the algorithm fits a representational model that allows for stimulus similarity to be measured in terms of both common and distinctive features. The important issue of striking an appropriate balance between data fit and representational complexity is addressed through the use of the Geometric Complexity Criterion to guide model selection. The ability of the algorithm to recover known featural representations from noisy data is tested, and it is also applied to real data measuring the similarity of kinship terms.

Introduction

Understanding human mental representation is necessary for understanding human perception, cognition, decision making, and action. Mental representations play an important role in mediating adaptive behavior, and form the basis for the cognitive processes of generalization, inference and learning. Different assumptions regarding the nature and form of mental representation lead to different constraints on formal models of these processes. For this reason, Pinker (1998) argues that "pinning down mental representation is the route to rigor in psychology" (p. 85). Certainly, it is important that cognitive models use principled mental representations, since the *ad hoc* definition of stimuli on the basis of intuitive reasonableness is a highly questionable practice (Brooks 1991, Komatsu 1992, Lee 1998).

One appealing and widely used approach for deriving stimulus representations is to base them on measures of stimulus similarity. Following Shepard (1987), similarity may be understood as a measure of the degree to which the consequences of one stimulus generalize to another, and so it makes adaptive sense to give more similar stimuli mental representations that are themselves more similar. For a domain with n stimuli, similarity data take the form of an $n \times n$ similarity matrix, $\mathbf{S} = s_{ij}$, where s_{ij} is the similarity of the ith and jth stimuli. The goal of similarity-based representation is then to define stimulus representations that, under a given similarity model, capture the constraints implicit in the similarity matrix by approximating the data.

Goldstone's (in press) recent review identifies four broad model classes for stimulus similarity: geometric, featural, alignment-based, and transformational. Of these, the two most widely used approaches are the geometric, where stimuli are represented in terms of their values on different dimensions, and the featural, where stimuli are represented in terms of the presence or absence of weighted features. The geometric approach is most often used in formal models of cognitive processes, partly because of the ready availability of techniques such as multidimensional scaling (e.g., Kruskal 1964; see Cox & Cox 1994 for an overview), which generate geometric representations from similarity data. The featural approach to stimulus representation, however, is at least as important as the geometric approach, and warrants the development of techniques analogous to multidimensional scaling.

Accordingly, this paper describes an algorithm that generates featural representations from similarity data. The optimization processes used in the algorithm are standard ones, and could almost certainly be improved. In this regard, we draw on Shepard and Arabie's (1979) distinction between the psychological model that is being fit, and the algorithm that does the fitting. We make no claims regarding the significance of the algorithm itself (and certainly do not claim it is a model of the way humans learn mental representations), but believe that the psychological representational model that it fits has three important properties. First, it allows for the arbitrary definition of features, avoiding the limitations of partitioning or hierarchical clustering. Second, it uses a more general model of featural stimulus similarity than has previously been considered. Third, it generates featural representations in a way that balances the competing demands of data-fit and representational complexity.

Featural Representation

Within a featural representation, stimuli are defined by the presence or absence of a set of saliency weighted features or properties. Formally, if a stimulus domain contains n stimuli and m features, a featural representation is given by the $n \times m$ matrix $\mathbf{F} = f_{ik}$, where

$$f_{ik} = \begin{array}{ll} 1 & \text{if stimulus } i \text{ has feature } k \\ 0 & \text{otherwise,} \end{array} \quad (1)$$

together with a vector $\mathbf{w} = (w_1, \ldots, w_m)$ giving the (positive) weights of each of the features.

The Contrast and Ratio Models

Tversky's (1977) Contrast Model and Ratio Model of stimulus similarity provide a rich range of possibilities for generating featural representations that have been significantly under-utilized. Using the assumption that the similarity between two stimuli is a function of their common and distinctive features, the Contrast Model measures stimulus similarity as:

$$\hat{s}_{ij} = \theta F(\mathbf{f}_i \quad \mathbf{f}_j) - \alpha F(\mathbf{f}_i - \mathbf{f}_j) - \beta F(\mathbf{f}_j - \mathbf{f}_i), \qquad (2)$$

where $\mathbf{f}_i \quad \mathbf{f}_j$ denotes the features common to the ith and jth stimuli, $\mathbf{f}_i - \mathbf{f}_j$ denotes the features present in the ith, but not the jth, stimulus, and $F(\,)$ is some monotonically increasing function. By manipulating the positive weighting hyper-parameters θ, α and β, different degrees of importance may given to the common and distinctive components. In particular, Tversky (1977) emphasizes the two extreme alternatives obtained by setting $\theta = 1, \alpha = \beta = 0$ (common features only), and $\theta = 0, \alpha = \beta = 1$ (distinctive features only). A different approach is given by the Ratio Model, where similarity takes the form:

$$\hat{s}_{ij} = \frac{\theta F(\mathbf{f}_i \quad \mathbf{f}_j)}{\theta F(\mathbf{f}_i \quad \mathbf{f}_j) \quad \alpha F(\mathbf{f}_i - \mathbf{f}_j) \quad \beta F(\mathbf{f}_j - \mathbf{f}_i)}. \qquad (3)$$

While the Contrast Model and the Ratio Model provide great flexibility for measuring similarity across featural representations, the only established techniques for generating the representations from similarity data are additive clustering algorithms (e.g., Arabie & Carroll 1980; Lee 1999, in press; Mirkin 1987; Shepard & Arabie 1979; Tenenbaum 1996), which rely exclusively on the common features version of the Contrast Model. This means that only one special case of one of these approaches has been used as the basis of a practical technique for generating representations.

The paucity of available techniques is serious, given the recognition (e.g., Goodman 1972; Rips 1989; see Goldstone 1994 for an overview) that similarity is not a unitary phenomenon, and the way in which it is measured may change according to different cognitive demands. Direct empirical evidence that featural similarity judgments can place varying emphasis on common and distinctive features is provided by the finding that items presented in written form elicit common feature-weighted judgments, whereas pictures tend to be rated more in terms of distinctive features (Gati & Tversky 1984; Tversky & Gati 1978).

A Symmetric Contrast Model

Although the Contrast Model has three hyper-parameters, α and β remain distinct only when $s_{ij} = s_{ji}$. While it is certainly the case that real world domains display asymmetric similarity, modeling techniques based on similarity data generally assume that similarity is symmetric. Further, if the similarity ratings are assumed to lie between 0 and 1, the remaining hyper-parameters α and θ can be incorporated into one parameter, $\rho = \theta \quad (\theta \quad \alpha)$, which represents the relative weighting of common and distinctive features, with $0 \quad \rho \quad 1$. Setting the functional form $F(\,)$ using the same 'sum of saliency weights' approach as additive clustering yields the similarity model

$$\hat{s}_{ij} \quad = \quad \rho \sum_k w_k f_{ik} f_{jk} - \frac{1-\rho}{2} \quad \sum_k w_k f_{ik} \left(1 - f_{jk}\right)$$

$$\sum_k w_k (1 - f_{ik}) f_{jk} \qquad c. \qquad (4)$$

It is this symmetric version of the Contrast Model that is used in this paper to develop general featural representations. It allows for any relative degree of emphasis to be placed on common and distinctive features and, in particular, subsumes the additive clustering model ($\rho = 1$) and the distance-based feature-matching similarity model ($\rho = 0$). Technically, it is worth noting that the additive constant c used in additive clustering, which is added to all pairwise similarity estimates in both additive clustering and Contrast Model clustering representations, is not treated as a cluster, and thus is not weighted by ρ.

Limiting Representational Complexity

Shepard and Arabie (1979) have noted that the ability to specify large numbers of features and set their weights allows any similarity matrix to be modeled perfectly by a featural representation using the common features version of the Contrast Model. The same is true for the majority of Tversky's (1977) similarity models, and is certainly true for Eq. (4). While the representational power to model data is desirable, the introduction of unconstrained feature structures with free parameters detracts from fundamental modeling goals, such as the achievement of interpretability, explanatory insight, and the ability to generalize accurately beyond given information (Lee 2001a).

This means that techniques for generating featural representations from similarity data must balance the competing demands of maximizing accuracy and minimizing complexity, following the basic principle of model selection known as 'Ockham's Razor' (Myung & Pitt 1997). Data precision must also be considered, since precise data warrants a representation being made more detailed to improve data-fit, while noisy data does not.

In practice, this means that featural representations should not be derived solely on the basis of how well they fit the data, as quantified by a measure such as the variance accounted for,

$$\text{VAF} = 1 - \frac{\sum_{i<j}(s_{ij} - \hat{s}_{ij})^2}{\sum_{i<j}(s_{ij} - \bar{s})^2}, \qquad (5)$$

where $\bar{s}$ is the arithmetic mean of the similarity data. Rather, some form of complexity control must be used

to balance data-fit with model complexity. Most established algorithms strike this balance in unsatisfactory ways, either pre-determining a fixed number of clusters (e.g., Shepard & Arabie 1979; Tenenbaum 1996), or predetermining a fixed level of representational accuracy (e.g., Lee 1999).

Recently, Lee (in press) has applied the Bayesian Information Criterion (BIC: Schwarz 1978) to limit the complexity of additive clustering representations. Unfortunately, an important limitation of the BIC is that it equates model complexity with the number of parameters in the model. While this is often a reasonable approximation, it neglects what Myung and Pitt (1997) term the 'functional form' component of model complexity. For featural representations, parametric complexity is simply the number of features used in a representation. Functional form complexity, however, considers the feature structure **F**, and is sensitive to the patterns with which stimuli share features (see Lee 2001a), as well as any difference arising from the relative emphasis given to common and distinctive features.

It is important to account for functional form complexity with featural representational models that can vary their emphasis on common and distinctive features. Figure 1 shows the results of fitting featural representations, assuming different levels of ρ, on similarity data that were generated using either entirely common features ($\rho = 1$), entirely distinctive features ($\rho = 0$), or an even balance of the two ($\rho = 0.5$). These results are averaged across five different similarity matrices, each based on a five-feature representation, and show one standard error about the mean level of fit.

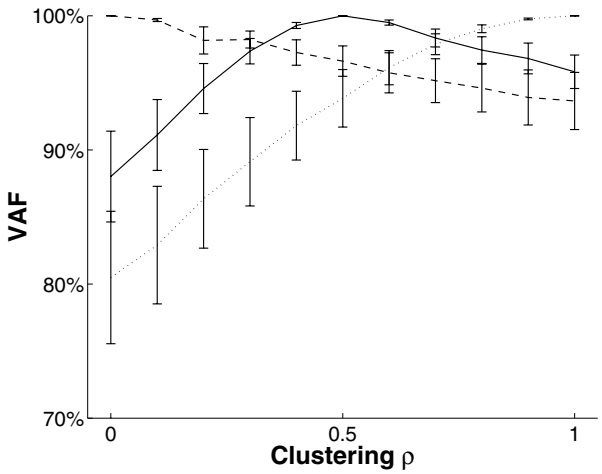

Figure 1: The change in VAF value, as a function of the assumed balance between common and distinctive features, for the entirely common (dotted line), entirely distinctive (dashed line) and balanced (solid line) similarity data.

As expected, the best-fitting featural representations have ρ values matching those that generated the data. More interestingly, Figure 1 shows that the level of fit for the entirely common features data deteriorates more rapidly than for the entirely distinctive features data when the wrong ρ value is assumed. Similarly, for the evenly balanced data, the fit is greater when too much emphasis is placed on common features in the assumed similarity model. These results imply that common features-weighted models are more able to fit data when they are wrong than are distinctive features-weighted models. In the language of model complexity, the common features functional form is more flexible than the distinctive features functional form, and this extra complexity improves the fit of incorrect models. For this reason, it is important to derive featural representations using a measure that is sensitive to functional form complexity.

A Geometric Complexity Criterion

Myung, Balasubramanian, and Pitt (2000) have recently developed a measure called the Geometric Complexity Criterion (GCC) that constitutes the state-of-the-art in accounting for both fit and complexity in model selection. The basic idea is to define complexity in terms of the number of distinguishable data distributions that the model can accommodate through parametric variation, with more complicated models being able to index more distributions than simple ones. Using Tenenbaum's (1996) probabilistic formulation of the data-fit of a featural model, and extending Lee's (2001a) derivation of the Fisher Information matrix for the common features case of the Contrast Model, it is a reasonably straightforward exercise to derive a GCC for the current similarity model. The final result is:

$$\text{GCC} = \frac{1}{2s^2}\sum_{i<j}(s_{ij}-\hat{s}_{ij})^2 \quad \frac{m}{2}\ln\frac{n(n-1)}{4\pi s^2} \quad \frac{1}{2}\ln\det G, \tag{6}$$

where s denotes an estimate of the inherent precision of the data (see Lee 2001b), m is the number of features, n is the number of stimuli, and G denotes the $m \times m$ *complexity matrix* for the feature structure. The xy-th cell of the complexity matrix is given by,

$$\sum_{i<j} e_{ijx}e_{ijy} \tag{7}$$

where e_{ijx} equals ρ if x is a common feature, $-(1-\rho)$ 2 if x is a distinctive feature, and 0 if neither i nor j possesses the feature x.

An interesting aspect of the complexity matrix, and the GCC measure as a whole, is that it is independent of the parameterization of the model. That is, the complexity of a featural representation is dependent only on the feature structure, and not the saliencies assigned to the features. We should make two technical points about the GCC. First, this derivation is based on the assumption that ρ is a fixed property of a model, and not a free parameter.

An alternative would be to modify the GCC so that it accommodated ρ as a model parameter. Second, since the additive constant is not weighted by ρ, the terms in the complexity matrix corresponding to the additive constant behave as if $\rho = 1$.

Algorithm

In developing an algorithm to fit featural representations using the Contrast Model, we were guided by the successful additive clustering algorithm reported by Lee (submitted). Basically, the algorithm works by 'growing' a featural representation, starting with a one-feature model, and continually adding features while this leads to improvements in the GCC measure. For any fixed number of features, the search for an appropriate assignment of stimuli to features is done using stochastic hill-climbing, with the best-fitting weights being determined using a standard non-negative least squares algorithm (Lawson & Hanson 1974). The algorithm terminates once the process of adding features leads to representations with GCC values that are more than a prespecified constant above the best previously found, and the featural representation with the minimum GCC value is returned.

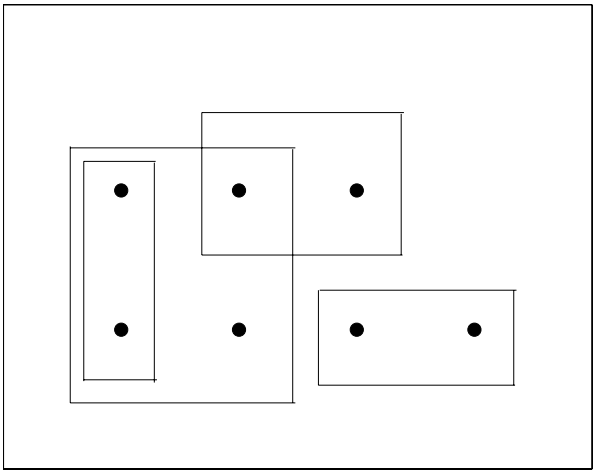

Figure 2: The artificial featural representation containing seven stimuli and four features.

To test the ability of this optimization algorithm to fit similarity data, we examined its ability to recover a known featural representation. This representation had seven stimuli and four features, and included partitioning, nested, and overlapping clusters, as shown in Figure 2. Using this representation, similarity data were generated assuming entirely common features, entirely distinctive features, or an even balance between the two. Feature weights were chosen at random subject to the constraint that they resulted in positive similarity values. Each of the similarity values was perturbed by adding noise that was independently drawn from a Normal distribution with mean 0 and standard deviation 0.05.

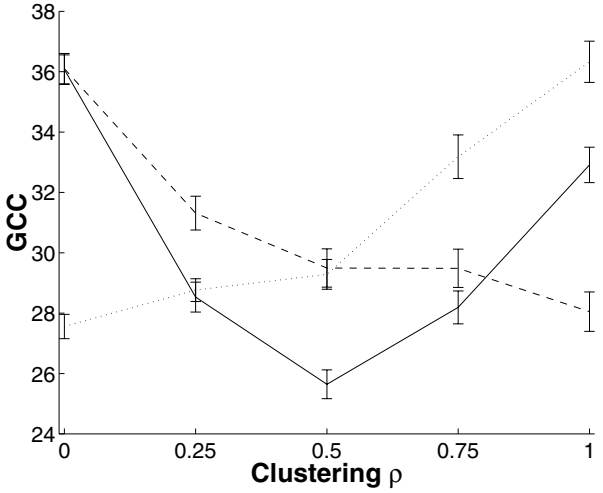

Figure 3: The change in GCC value, as a function of the assumed balance between common and distinctive features, for the entirely common (dotted line), entirely distinctive (dashed line) and balanced (solid line) similarity data.

The algorithm was applied to this similarity data under different assumptions regarding the balance between common and distinctive features, using ρ values of 0, 0.25, 0.5, 0.75 and 1. In calculating the GCC measure, a data precision value of $\sigma = 0.05$ was assumed, in accordance with the known level of noise. Figure 3 summarizes the results of 10 runs of the algorithm for each of the three similarity conditions, across all of the assumed ρ values. The mean GCC value of the 10 derived representations is shown, together with error bars showing one standard error in both directions.

Figure 3 shows that the GCC is minimized at the correct ρ value for all three similarity conditions. An examination of the derived representation revealed that the correct featural representation was recovered 25 times out of 30 attempts: nine times out of ten for the entirely distinctive data, and eight times out of ten for the evenly balanced and the entirely common data. It is interesting to note that Figure 3 is far more symmetric than Figure 1, suggesting that the GCC has successfully accounted for the differences in functional form complexity between the common and distinctive feature approaches to measuring similarity.

Additional Monte Carlo simulations with other featural representations, based on particular structures reported by Tenenbaum (1996, Table 1) and Lee (1999, Table 5), also suggested that the algorithm is capable of recovering known configurations when more stimuli or more features are involved, although problems with local minima are encountered more frequently.

Table 1: Representation of Rosenberg and Kim's (1975) kinship terms domain.

STIMULI IN CLUSTER	WEIGHT
aunt uncle niece nephew cousin	0.319
granddaughter grandson grandmother grandfather	0.291
mother daughter grandmother granddaughter aunt niece sister	0.222
sister brother cousin	0.221
father son grandfather grandson uncle nephew brother	0.208
mother father daughter son sister brother	0.163
mother father daughter son	0.136
daughter son granddaughter grandson niece nephew sister brother	0.128
mother father grandmother grandfather aunt uncle sister brother	0.091
additive constant	0.563
VARIANCE ACCOUNTED FOR	92.7%

An Illustrative Example

To demonstrate the practical application of the algorithm, we used the averaged similarity data reported by Rosenberg and Kim (1975), which measures similarity of English kinship terms. A data precision estimate of $s = 0.09$ was made based on the sample standard deviation of the individual matrices. Since the data was obtained by having participants sort items into different stacks, we might expect a model that provides a weighting of common and distinctive features to provide a better fit than one allowing only for common features. Using ρ values of 0, 0.1, 0.2, ..., 1.0, the representation with the minimum GCC was found at $\rho = 0.4$.

This representation contained the nine features detailed in Table 1, and explained 92.7% of the variance in the data. Interpreting most of the features in Table 1 is straightforward, since they essentially capture concepts such as 'male', 'female', 'nuclear family', 'extended family', 'grandparents', 'descendants', and 'progenitors'. While this representation is very similar to the nine-feature representation generated by additive clustering (Lee submitted, Figure 2), it explains more of the variance in the data, suggesting that participants did indeed use both common and distinctive features in assessing similarity.

Conclusion

We have developed, tested, and demonstrated an algorithm that generates featural stimulus representations from similarity data. Unlike previous additive clustering approaches, the algorithm uses a symmetric version of Tversky's (1977) Contrast Model that measures similarity in terms of both common and distinctive features. A particular strength of the algorithm is its use of the Geometric Complexity Criterion to guide the generation process, which allows the desire for data-fit to be balanced with the need to control representational complexity. Importantly, this criterion is sensitive to the functional form complexity of the similarity model, preventing an overemphasis on the inherently more complicated common features approach.

In terms of future work, it should be acknowledged that the symmetric version of the Contrast Model is certainly not the only possibility for combining common and distinctive features approaches to measuring similarity. Tenenbaum and Griffiths (in press) provide a compelling argument for the use of the Ratio Model in the context of their Bayesian theory of generalization. It would also be worthwhile to examine featural representations where each feature is assumed to operate using entirely an distinctive or an entirely common approach. The distinctive similarity features would be those that globally partition the entire stimulus set, as for the feature 'male', which implies the existence of the complementary feature 'female'. The (more prevalent) common similarity features would be those that captured shared properties, such as eye or hair color, where no broader implications are warranted.

Abstract

People are active experimenters, constantly seeking new information relevant to their goals. A reasonable approach to active information gathering is to ask questions and conduct experiments that minimize the expected state of uncertainty, or maximize the expected information gain, given current beliefs (Fedorov, 1972; MacKay, 1992; Oaksford & Chater, 1994). In this paper we present results on an exploratory experiment designed to study people's active information gathering behavior on a concept learning task. The results of the experiment suggest subjects' behavior may be explained well from the point of view of Bayesian information maximization.

Introduction

In scientific inquiry and in everyday life, people seek out information relevant to perceptual and cognitive tasks. Whether performing experiments to uncover causal relationships, saccading to informative areas of visual scenes, or turning towards a surprising sound, people actively seek out information relative to their goals.

Consider a person learning a foreign language, who notices a particular word, "tikos," used to refer to a baby moose, a baby penguin, and a baby cheetah. Based on those examples, she may attempt to discover what tikos really means. Logically, there are an infinite number of possibilities. For instance, tikos could mean *baby animals*, or simply *animals*, or even *baby animals and antique telephones*. Yet a few examples are often enough for human learners to form strong intuitions about what meanings are most likely.

Suppose the learner could point to a baby duck, an adult duck, or an antique telephone, to inquire whether that object is "tikos." What question would she ask? Why do we think that pointing to the telephone is not a good idea, even though from a logical point of view, a phone could very well be tikos? In this paper we present a normative theoretical framework, to try to predict the questions people ask in concept learning tasks (Fedorov, 1972; MacKay, 1992; Oaksford & Chater, 1994).

A Bayesian concept learning model

In the approach presented here, we evaluate questions in terms of their information value. Formally, information is defined with respect to a probability model. Here we use a Bayesian framework in the sense that we model internal beliefs as probability distributions. In order to quantify the information value (in bits) of a person's questions, we first need a model of her beliefs, and the way those beliefs are updated as new information is obtained. Tenenbaum (1999, 2000) provides such a model of people's beliefs, for a number concept learning task. While Tenenbaum (1999, 2000); and the first and last authors of the present paper, in a pilot study, found that his model described subjects' beliefs well, there were some deviations between model predictions and subjects' beliefs. The concept learning model used in the present study, which we describe below, is based on Tenenbaum's original model, but extended in ways that reduce previously observed deviations between model predictions and study participants' beliefs.

We formalize the concept learning situation described by the number concept model using standard probabilistic notation: random variables are represented with capital letters, and specific values taken by those variables are represented with small letters. The random variable C represents the correct hidden concept on a given trial. This concept is not directly observable by study participants; rather, they infer it on the basis of example numbers that are consistent with the true concept. Notation of the form *"C=c"* is shorthand for the event that the random variable C takes the specific value c, e.g. that the correct concept (or "hypothesis") is *prime numbers*. We represent the examples given to the subjects by the random vector X. The subject's beliefs about which concepts are probable prior to the presentation of any examples is represented by the probability function $P(C=c)$. The subject's updated belief about a concept's probability, after she sees the

examples X=x, is represented by *P(C=c|X=x)*. For example, if *c* is the concept *even numbers* and *x* the numbers "2, 6, 4", then *P(C=c|X=x)* represents the subject's posterior probability that the correct concept is *even numbers*, given that 2, 6, and 4 are positive examples of that concept. Study participants are not explicitly given the true hidden concept; rather, they infer it from examples of numbers that are consistent with the true concept.

The number concept model includes both *arithmetic* and *interval* concepts. Interval concepts are sets of consecutive integers between *n* and *m*, where $1 \le n \le 100$, and $n \le m \le 100$, such as *numbers between 5 and 8*, and *numbers between 10 and 35*. Thus, there are 5050 interval concepts. Arithmetic concepts include *odd numbers*, *even numbers*, *square numbers*, *cube numbers*, *prime numbers*, *multiples of n* ($3 \le n \le 12$), *powers of n* ($2 \le n \le 10$), and *numbers ending in n* ($1 \le n \le 9$). There are 33 arithmetic concepts.

Inferences are made with respect to the following model of how examples are generated: A concept is first chosen at random according to a prior probability distribution. The prior probability distribution of the model is designed to reflect the human intuition that a concept like *multiples of 10* is more plausible than a concept like *multiples of 10 except 30*. A portion of total prior probability is divided evenly into the arithmetic concepts, with the exception of *even numbers* and *odd numbers*. To reflect the higher salience of the concepts *even numbers* and *odd numbers*, each of those concepts is given five times the prior probability of the other arithmetic concepts. Among the interval concepts, prior probability is apportioned according to the Erlang distribution

$$P(H = h) \propto \frac{|h|}{\sigma^2} e^{\frac{-|h|}{\sigma}}$$

according to the concept's size $|h|$. (The concept *numbers between 15 and 30* is size 16.) Sigma gives the optimal interval length. In the simulations described in this paper we set σ to 15, although in principle, σ is a free parameter to fit to the data. Interval concepts of a given length, such as *numbers between 25 and 35*, and *numbers between 89 and 99*, receive the same prior probability, irrespective of their endpoints.

Once a concept is chosen, examples are randomly and independently generated, with equal probability, from the set of numbers in that concept. Thus, the likelihood of a particular vector of m examples X=x, given the concept h,

$$P(X = x \mid H = h) = \frac{1}{|h|^m},$$

if all m examples are in the concept *h*, and zero otherwise.

This generating assumption reflects the human intuition that although a given set of example numbers is typically compatible with more than one concept, it may be more representative of some concepts than others. For instance, although the example numbers 60, 80, 10, and 30 are compatible with both *multiples of 10* and *multiples of 5*, that set of numbers is a better example of the concept *multiples of 10* than it is of the concept *multiples of 5*, because it is much more likely to be observed as a random sample from the more specific hypothesis *multiples of 10*.

The generative model described above can be used to compute the probability that a new element *y* belongs to the hidden concept *C* given the examples in *x*:

$$P(y \in C \mid X = x) = \frac{\sum_{h: y \in h} P(X = x \mid H = h) P(H = h)}{\sum_{h} P(X = x \mid H = h) P(H = h)}$$

An ideal concept learning model would assign some prior probability to every possible concept, according to each concept's plausibility to human learners. The main difference between the concept learning model used in the current paper, and the model introduced in Tenenbaum (1999, 2000), is our inclusion of a large number of random "exception" concepts, which are formed by replicating and slightly changing, or "mutating," concepts from the basic model. Here, we include 50,830 exception hypotheses -- on average, 10 exception concepts for each concept in the basic model. To form an exception concept (or "hypothesis"), a concept is first picked from the basic model, according to the prior probability of concepts in the basic model. We include a parameter μ for the average number of changes to the original concept, and divide these changes equally, on average, into additions of new numbers and exclusions of existing numbers. The probability of each existing number being excluded from a concept is $\frac{\mu}{2|h|}$, and the probability of each currently excluded number (between 1 and 100) being added to the concept is $\frac{\mu}{2(100 - |h|)}$.

Each exception hypothesis receives a constant share of the total proportion of prior probability assigned to the exception hypotheses. In the simulation of the model reported in this paper, 60% of prior probability

was assigned to the exception hypotheses, and μ was set to 6. It takes approximately 30 minutes to simulate the set of trials in the study, for any setting of model parameters, and we are just beginning to explore the parameter space. Early exploration suggests that a wide range of parameters in the extended number concept model can improve on the basic model's correspondence to human beliefs.

Information-maximizing sampling

In the experiment reported in this paper, we allowed subjects to actively ask questions about number concepts, instead of making inferences solely on the basis of the examples given to them. For example, on one trial the subject was given the number 16 as an example of the hidden underlying concept, and then was allowed to test another number, to find out whether it was also consistent with the true, hidden concept.

In our formalism, the binary random variable Y_n represents whether the number n is a member of the correct concept. For example, $Y_8=1$ represents the event that 8 is an element of the correct, hidden concept, and $Y_8=0$ the event that 8 is not in that concept. Asking "is the number n an element of the concept?" is equivalent to finding the value taken by the random variable Y_n, in our formalism.

We evaluate how good a question is in terms of the information about the correct concept expected for that question, given the example vector $X=x$. The expected information gain for the question "Is the number n an element of the concept?" is calculated with respect to the learner's beliefs, as approximated with the extended number concept model described above. Formally, expected information gain is given by the following formula:

$$I(C, Y_n \mid X = x) = H(C \mid X = x) - H(C \mid Y_n, X = x),$$

where the uncertainty (entropy) about the hidden concept C given the example numbers in x,

$$H(C \mid X = x) = -\sum_c P(C = c \mid X = x) \log_2 P(C = c \mid X = x),$$

and the expected remaining uncertainty about the hidden concept C, given the example numbers in x and the answer to the question Y_n:

$$H(C \mid Y_n, X = x) = -\sum_{v=0}^{1} P(Y_n = v \mid X = x) \sum_c P(C = c \mid Y_n = v, X = x) \log_2 P(C = c \mid Y_n = v, X = x)$$

We consider only binary questions, of the form "is n consistent with the concept?" so the maximum information value of any question in our experiment is one bit. Note how information value of questions is relative to subjects' internal beliefs, which we approximate here by using the expanded number concept learning model. An information-maximizing strategy prescribes asking the question with the highest expected information gain, e.g., the question that minimizes the expected entropy, over all concepts.

Another strategy of interest is confirmatory sampling, which consists of asking questions whose answers are most likely to confirm current beliefs. In other domains it has been proposed that people have a bias to use confirmatory strategies, regardless of their information value (Klayman & Ha, 1987; Popper, 1959; Wason, 1960).

The active sampling concept game

Twenty-nine undergraduate students, recruited from Cognitive Science Department classes at the University of California, San Diego, participated in the experiment. Subjects gave informed consent, and received either partial course credit for required study participation, or extra course credit, for their participation. The experiment began with the following instructions:

> Often it is possible to have a good idea about the state of the world, without completely knowing it. People often learn from examples, and this study explores how people do so. In this experiment, you will be given examples of a hidden number rule. These examples will be randomly chosen from the numbers between 1 and 100 that follow the rule. The true rule will remain hidden, however. Then you will be able to test an additional number, to see if it follows that same hidden rule. Finally, you will be asked to give your best estimation of what the true hidden rule is, and the chances that you are right. For instance, if the true hidden rule were "*multiples of 11*," you might see the examples 22 and 66. If you thought the rule were "*multiples of 11*," but also possibly "*even numbers*," you could test a number of your choice, between 1-100, to see if it also follows the rule.

On each trial subjects first saw a set of examples from the correct concept. For instance, if the concept were even numbers, subjects might see the numbers "2, 6, 4" as examples. Subjects were then given the opportunity to test a number of their choice. Subjects were given feedback on whether the number they tested was an element of the correct concept.

We wrote a computer program to simulate the expanded number concept model, and to compute the information value of each possible question, given each set of examples. By considering beliefs and questions together, we may evaluate the information value of participants' questions, as well as that of information-maximizing and confirmatory sampling strategies. We define the confirmatory strategy as testing the number (excluding the examples) that has the highest posterior probability, as given by the extended number concept

model, of being consistent with the correct hidden concept.

Results

We discuss two types of trials, grouped according to the posterior beliefs of the extended number concept model, after all the example numbers have been seen. These results should be considered preliminary, as 29 data points on each trial are not sufficient for estimation of statistically reliable sampling distributions over the range of possible queries from 1 to 100.

Arithmetic trials

On some trials, the model is dominated by arithmetic concepts, and exception hypotheses based on arithmetic concepts. On each of these trials, good agreement between a number's information value and subjects' propensity to sample that number was observed. The information value of the confirmatory strategy was near to that of the information-maximizing strategy on these trials.

Consider the trial with the examples 81, 25, 4, and 36, in which the concept with the highest posterior probability is *square numbers*. Generalization behavior of the model, and beliefs of subjects, are shown in Figure 1. Note that the model and subjects alike assign certain, or near certain, probability to each of the example numbers, but less than certain probability to the other square numbers. Relative to the model's beliefs, the most informative numbers to test are non-example square numbers, such as 9, 16, 49, 64, or 100 (Figure 2). In fact, 20 of 29 subjects tested one of these numbers. Other subjects' samples do not show a clear pattern, except for testing the number 10 (5 of 29 subjects), which is unpredicted.

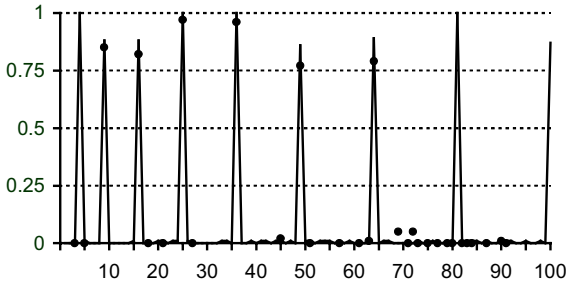

Figure 1. Generalization probabilities, given the examples 81, 25, 4, and 36. Model probabilities are given by the line. Subjects' probabilities, for the 30 probe numbers subjects rated, are given with circles.

Good agreement between subjects' samples and rated information value is also observed on the trial with the examples 16, 8, 2, and 64. The most informative numbers to test are non-example powers of two, 4 or 32. Most (16/29) subjects tested these numbers.

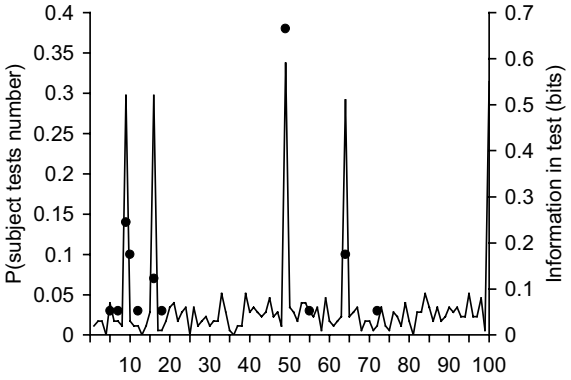

Figure 2. Information value of questions (line), and subjects' questions (circles), given the examples 81, 25, 4, and 36.

Finally, we may consider the trial with the examples 60, 80, 10, and 30, in which the hypothesis *multiples of 10* receives the highest posterior probability; multiples of 5 also receive moderate probability (Figure 4). On this trial, non-example multiples of 10, such as 20, and odd multiples of five, have the highest information value. Multiples of 10 were tested by 21 of 29 subjects; an additional 5 subjects tested odd multiples of five

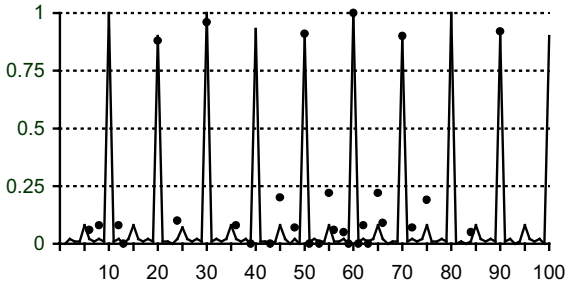

Figure 3. Generalization probabilities given the examples 60, 80, 10, and 30.

The difference between the first two arithmetic trials, and the trial with the examples 60, 80, 10, and 30 appears to be that a clear alternate hypothesis -- multiples of five -- receives moderate posterior probability in the multiples of 10 trial, but not on the other trials.

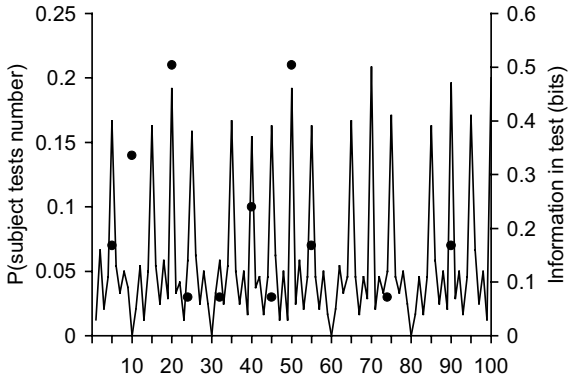

Figure 4. Information value of questions, and subjects' questions, given the examples 60, 80, 10, and 30.

Interval trials

On these trials, several examples of numbers of similar magnitude, such as 16, 23, 19, and 20, are given (these numbers are points where model probabilities are 1.00, Figure 5, and Figure 7). The model is certain that the example numbers themselves are consistent with the true concept. The model is fairly sure that non-example numbers within the range spanned by the examples, like 17, 18, 21, and 22, are consistent with the true concept. Finally, the model assigns decreasing probability to numbers as they move away from the range of observed examples (Figure 5).

It should be noted that there is some variability from one run of the model to the next. The general pattern of results, however, holds from run to run. In particular, (1) numbers slightly outside of the range of the observed examples are most informative, (2) information value of numbers decreases with increasing distance from the observed examples, and (3) there is moderate information value in non-example numbers within the range of observed examples.

Most subjects tested numbers outside of, but near the observed examples (Figure 6). About one-third of subjects tested (non-example) numbers within the range spanned by the examples. On the other interval trials -- with example numbers 60, 51, 57, and 55; and 81, 98, 96, 93 (illustrated in Figure 7 and Figure 8)-- similar patterns emerged.

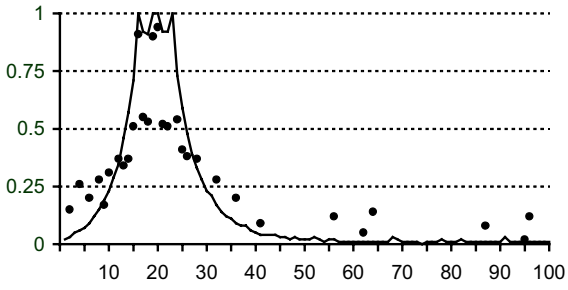

Figure 5. Generalization probabilities, given the examples 16, 23, 19, and 20.

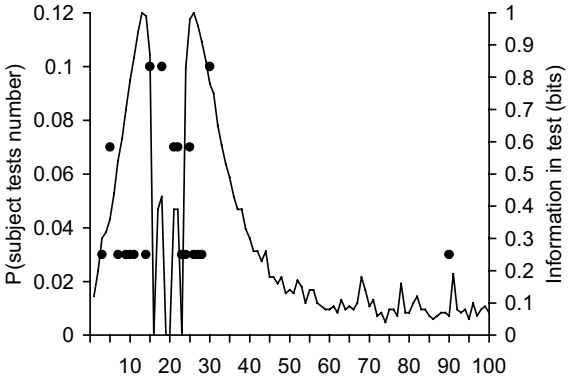

Figure 6. Information value of questions, and subjects' questions, given the examples 16, 23, 19, and 20.

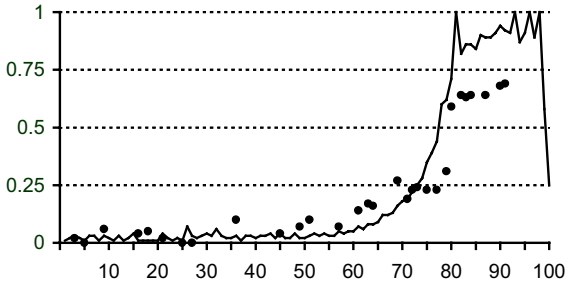

Figure 7. Generalization probabilities, given the examples 81, 98, 96, and 93.

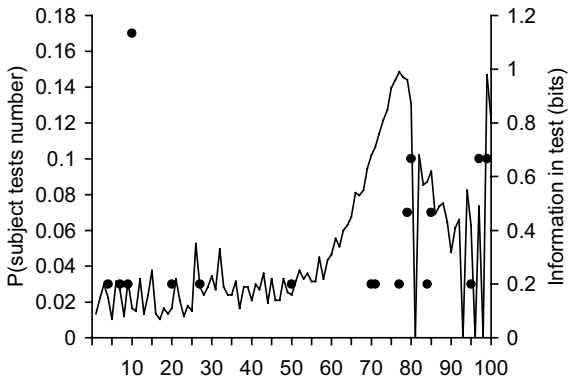

Figure 8. Information value of questions, and subjects' questions, given the examples 81, 98, 96, and 93.

Discussion

This paper presents work in progress to analyze active inference in concept learning from the point of view of the rational, probabilistic approach to cognition (Anderson, 1990). In the rational study of information-gathering behavior, the current research adds to existing analyses of Wason's (1966, 1968) selection task (Oaksford & Chater, 1994, 1998), and Wason's (1960) 2-4-6 task (Ginzburg & Sejnowski, 1996).

We found that a normatively inspired criterion of optimal sampling -- maximizing average information gain -- predicts human behavior well on a relatively unconstrained task. This result is strengthened by the fact that the extended number concept model we employed, as a proxy for subjects beliefs, was not originally developed with the goal of serving as a model for sampling. Nor were our extensions to it ad hoc. To the contrary, our extended model now has a better fit to data from earlier studies.

If rational theories of cognition are to explain thought and behavior in natural environments, then optimal sampling agents should also exhibit the systematic "biases" traditionally associated with human behavior. Indeed, we found that on many trials, a confirmatory sampling strategy approximates the information-maximizing strategy.

A final point is that whereas information gain, calculated with respect to the extended number concept model, predicts study participants' questions fairly well, information gain with respect to the original number concept model does not do so. This illustrates that particular queries are not informative or uninformative on their own, but only in relation to a particular probability model. To understand people's questions, or build artificial sampling systems that come closer to meeting human competence, developing appropriate probability models is critical.

Abstract

Successful problem solving depends on a dynamic interplay of resources between agent, task, and task environment. To illuminate these interactions we studied how participants added a series of single-digit numbers presented on a computer screen. We distinguished between four different user interfaces, each implementing a different mode of interaction with the displayed addends: look only, point, mark, and move. By collecting and analysing complete interaction protocols we were able to integrate overall performance measures with fine-grained behavioural process data on the strategies engendered by the different user interfaces. We discovered reliable differences in the chosen sequences of addends, which can be understood in terms of the cost-benefit structures provided by the interactive resources of the user interfaces.

Introduction

Successful problem solving is an embedded and embodied process and crucially depends on a dynamic interplay of resources and constraints between agent, task, and task environment.

The importance of feedback loops, wherein actions on the world provide new information to the problem solver, was recognized in the earliest cognitive accounts of human problem solving (e.g. Miller, Galanter and Pribram, 1960; Newell and Simon, 1972). Yet until relatively recently, the interactive properties of the task environment have seldom been the focus of attention. Thus, the traditional literature on problem solving has been concerned primarily with planning, search strategies and heuristics (see e.g. Mayer, 1992, for an overview).

Recently, however, it has become increasingly clear to many investigators that interactions between mental processes and external objects play a crucial role in human problem solving. This interactive perspective has led to recent analyses of, for example: the importance of constraints provided by the properties of external representations (Larkin and Simon, 1987; Zhang and Norman, 1994; Zhang, 1997); the role of the display as a resource in human-computer interaction (Payne, 1991; Monk, 1998; Gray and Fu, 2001); the effect of the cost of implementing operators on the interplay between planning and action (O'Hara and Payne, 1998).

In this article, we extend this general approach to investigate the way in which the nature of available interactions in the task environment determines the discovery and use of strategies in a rather simple problem solving task: adding a series of numbers.

This work builds on the empirical work of Kirsh and colleagues (1995a, 1995b, Kirsh & Maglio, 1994), who, in a series of empirical studies, have shown that problem solvers often spontaneously manipulate the external world in order to reduce cognitive load.

In studying the interactive video game "Tetris", Kirsh and Maglio (1994) showed that expert players physically rotated falling pieces more than was required by their goal orientation. Kirsh (1995) demonstrated that people were reliably faster and more accurate at counting coins when they were allowed to move the coins around as they counted. Similarly, Maglio et al. (1999) found that people generated more anagrams when they were allowed to rearrange Scrabble tiles as they worked.

The experiment reported in the current article exemplifies an empirical approach that has three characteristics:

First, we study a problem solving task in which the atomic components are relatively simple and well understood, so that strategy differences (as well as outcome differences) may be easier to observe and explain.

Second, we design several user interfaces to the same problem, allowing subtle manipulations to the interactive resources that are available to problem solvers. This enables a more refined investigation of the relationship between resources and strategies.

Third, we independently manipulate problem complexity, so that we can assess relations between problem characteristics and interactive resources.

Interaction in Addition

Consider a simple serial addition like 1+2+9+7 presented, as here, linearly on a visual display. As with many cognitive tasks, we could solve this entirely "in our heads". But this does not warrant the conclusion that environmental interactions cannot play important roles.

Despite the linear presentation format, the law of commutativity allows us to add the four addends in any of 4!=24 different orders. Whilst all potential solution paths result in a total sum of 19 their cognitive demands may vary considerably. Within the context of this study, two sequences are of particular interest: By first adding 1 plus 9 before adding 2 and 7 to the result, one could exploit the fact that within the arabic base 10 number system the two addends 1 and 9 form what we call a *pair*,

i.e., they add up to the next bigger unit, a "round number". Likewise, someone might first add 1+2 but then spot 7 to make an intermediate sum of 10 before adding 9. In this case, the single addend 7 *complements* the current intermediate sum 3 to make a round number.

Both strategies exploit the same rationale: Two numbers, which add up to a round number are easy to add, and, when adding series of numbers, it is easier to add another number to round intermediate sums. The difference between a pair and a complement strategy is that pairs combine two external addends, whereas complements combine an internal intermediate sum with an external number.

However, both strategies come at a cost. As neither the pair nor the complement in the above example is available with adjacent elements of the linear left to right sequence, their detection requires visually searching ahead through the problem display, as well as some way of keeping track of used and skipped numbers. Thus, the use of a pair and complement strategy facilitates calculation at the expense of other resources. We hypothesize that the specific structure of this trade-off depends on the triad of factors noted above: The skill and memory capacity of the problem solver, the difficulty of the problem, and the availability of interactive resources.

Pilot Study In a pilot study we observed that the ability to rearrange or manipulate numbers on paper cards improved performance in simple addition. Furthermore, the availability of a pencil encouraged participants to use both the pair and the complement strategy, particularly with increasing problem difficulty and when numbers were presented in a 2-dimensional array. However, particular ways of using the pencil varied greatly (and included pointing, marking, copying, as well as recording intermediate sums), obstructing precise analysis of the underlying effects. Consequently, in the current study, we use computer interfaces to isolate specific interactive resources.

Method

Participants' interactions with the problem of adding numbers were operationalized as mouse actions and visual feedback on a standard computer interface. Four different *interactive modes* were distinguished:

1. *Look only*: Numbers had to be added without being able to point at them, as the mouse cursor was disabled during stimulus presentation.
2. *Point*: The mouse cursor was enabled and participants were instructed to click on numbers when adding them. When a number was clicked, a brief tone provided auditory feedback.
3. *Mark*: Mouse pointer and instructions were exactly as in 2. However, when a number was clicked, it also changed its colour from dark red to grey, thereby visually marking numbers that had been processed.
4. *Move*: Numbers could be moved on the screen using a drag-and-drop procedure.

Table 1: Examples of linear stimulus lists allowing for pairs, complements, or neither at positions x_1-x_2, y_1-y_2, and z_1-z_2.

Type	Stimulus list	Sum
Pair list:	4 3 9 7 8 6 5 4 2 1 5 9	63
Complement list:	3 1 8 6 5 3 9 4 5 7 2 9	62
Neutral list:	9 4 5 8 9 6 3 2 1 5 7 2	61
Structure:	$a\ x_1\ b\ x_2$ $c\ y_1\ d\ y_2$ $e\ z_1\ f\ z_2$	

Materials A total of 72 lists of 4, 8, or 12 single-digit numbers were generated by a Prolog program. Each list consisted of one, two, or three building blocks of the form ax_1bx_2. Three types of linear lists were distinguished: For *pair lists* x_1 and x_2 added up to 10 and the list allowed for no complements within a lookahead span of three digits. Analogically, for *complement lists* the value of x_2 plus the intermediate sum at x_1 resulted in a round number, and the list contained no pairs within a lookahead span of three digits. *Neutral lists* allowed for neither pairs nor complements within the same lookahead span. Note that none of the linear lists contained any adjacent pairs or complements (see Table 1 for some examples of stimuli). In contrast to linear lists, the elements of *spatially distributed lists* were scattered pseudo-randomly over the screen. Lists within each level of the list-length and -type factors were matched for their sums and number of possible pairs.

Stimuli presentation and data collection were controlled by a MS Windows Visual Basic program. All stimuli were displayed on a 17" computer screen using a 20pt Arial bold font of dark red colour against a white background.

Design The experiment used a mixed design, with *interactive mode* as a between-subjects manipulation and *list length* and *list type* as within-subjects factors.

Procedure Forty-four Psychology undergraduates (with a mean age of 20.3 years) took part in the experiment to receive course credit and were randomly assigned to one of the four interactive modes.

After the completion of four practice trials and a letter task to familiarize participants with their respective interactive resources, participants were instructed to add as fast as they could without making any errors. For each trial, participants pressed a button when they had added all numbers and then entered the result on another screen using a mouse-operated number pad.

Since erroneous trials were repeated at the end of the randomized sequence of trials, the experiment continued until the participant correctly added all 36 different lists (i.e. three different lists of each of three lengths and four types). On average, participants completed the experiment within 25 minutes.

Predictions The first and most basic prediction is that participants will benefit from interactive resources. In particular, following the findings of Kirsh and colleagues (1994, 1995a, 1995b), we predict that the *move* condition will elicit better performance than the *look only* condition. We also make a specific prediction concerning the comparison between the *point* and *mark* conditions. Because the latter provides an external memory for already-processed addends, it reduces the cognitive costs associated with the more sophisticated strategies of exploiting pairs and complements. Thus we predict more use of these strategies in the *mark* condition than the *point* condition, and more efficient performance as a result.

Results

Analyses of time and accuracy for the practice trials showed no differences between experimental groups at the pre-test stage. In the following report, we first focus on performance measures before considering more detailed process characteristics.

Performance

Accuracy The overall rate of errors was 13.87%. A one-way between subjects ANOVA confirmed that the number of erroneous trials in the four experimental groups differed between interactive modes [$F(3,40)=5.8$, $p=.002$, $MSE=15.2$, see Table 2 for descriptive data].

Planned comparisons revealed that participants in the *look only* condition indeed had significantly more erroneous trials than those who could *move* numbers ($t=3.28$, df=40, $p=.002$). Likewise, participants in the *point* condition made significantly more errors than those in the *mark* condition ($t=2.57$, df=40, $p=.014$). Thus, both of our specific predictions were confirmed for accuracy data.

Latency As differences in accuracy could be due to a speed-accuracy trade-off error rates and response latencies must be considered in parallel. Since the total time participants spent on the experiment is trivially longer when they made more errors we divided it by the actual number of trials for each participant to obtain an overall measure of average time per trial.

The comparison of accuracy and latency data (see Table 2) shows that no speed-accuracy trade-off contaminated the between-groups comparisons: In addition to being less accurate, participants in the *point* condition were significantly slower than those in the *mark* condition ($t=3.03$, df=40, $p=.004$), whereas the three other groups did not differ with respect to overall latency (Tukey pairwise comparisons).

Table 2: Mean number of erroneous trials and latencies per trial in seconds (and their respective standard deviations). Each interactive mode included 10 participants.

	Interactive mode			
	look only	*point*	*mark*	*move*
Errors:	8.6 (5.9)	7.8 (3.8)	3.6 (2.6)	3.2 (2.3)
Latencies:	13.8 (2.9)	17.8 (4.4)	13.3 (3.2)	12.6 (3.6)

Table 3: Mean latencies of correct solutions in seconds (a) by list length (each cell contains 132 data points) and (b) by list type (each cell contains 99 data points).

		Interactive mode			
		look only	*point*	*mark*	*move*
(a) length	4:	4.7	7.2	6.9	4.7
	8:	12.8	16.3	12.9	11.3
	12:	21.8	27.4	19.0	20.4
(b) type	pair:	13.8	18.0	12.4	11.5
	complement:	13.6	16.9	12.7	12.5
	neutral:	13.2	17.8	12.5	12.0
	spatial:	11.8	15.2	14.0	12.5

Moderating Factors

So far, we have shown that overall performance measures varied across different interactive modes. However, this standard assessment of performance based on error rates and latencies does not distinguish between different task characteristics and thus cannot uncover potential interactions between tasks and interactive resources. To analyze how performance is modulated by problem features we now qualify the global between-subjects effects by the factors of list length and type.

Accuracy The effects of list length on the frequency of errors are as expected and consistent for all interactive modes: The longer the list, the more likely participants were to add it incorrectly. Also, it made no difference to the average error rate whether a stimulus was a pair, complement, neutral, or spatially distributed list.

Since any error in calculation could effectively alter the type and length of a list, all subsequent analyses examining the effects of list length and type will be based on correct trials only.

Latency A mixed ANOVA using a 4x3x4 design was conducted to assess the effects of interactive mode, list length, and list type. Apart from significant main effects of interactive mode [$F(3,40)=4.9$, $p=.005$, $MSE=125.8$] and list length [$F(2,80)=511.6$, $p<.001$, $MSE=22.96$] it yielded significant interactions between interactive mode and list length [$F(6,80)=5.6$, $p=.001$, $MSE=23.0$] and interactive mode and list type [$F(9,120)=5.3$, $p<.001$, $MSE=6.1$].

To interpret the results of subsequent simple main effects the mean latencies are shown in Table 3. Unsurprisingly, the time needed to add a list increased for all interactive conditions as the lists' length increased (see columns of Table 3a). However, the slope of this increase

was much steeper in the *point* condition. For lists of four numbers, participants in the *look only* and *move* conditions were faster than the two other groups.

Of the eight possible simple main effects for the rows and columns of Table 3b five are significant. However, the *absence* of significant differences in three cases is more instructive: For spatially distributed lists the effects of different interactive modes levelled out [$F_{A@b4}(3,40)=2.0$, $p=.124$], which is due to the participants in the *look only* and *point* conditions being slightly faster than for other list types. Likewise, the differences between the mean latencies in the *mark* and *move* conditions for different list types failed to reach statistical significance [$F_{B@a3}(3,129)=2.3$, $p=.076$; $F_{B@a4}(3,129)=1.0$, $p=.402$], suggesting that the ability to mark and move numbers allowed participants of the corresponding groups to somehow transcend the linear and spatial constraints imposed by different list types.

Strategies

Having established that there *are* differences in performance we have to explain their genesis. We will attempt this by addressing strategy differences between groups which are reflected by features of the actual problem solving process. For this purpose, participants' cursor movements and mouse clicks in the *point*, *mark* and *move* conditions provided a rich source of fine-grained process data.

Mouse Moves per Trial When analyzing mouse cursor data, we use the term "move" to signify the physical movement from a number x_1 to a different number x_2. As each number has both value and location, moves can be characterized in terms of their distance and type, i.e., neutral, complement, pair, and triple. (In analogy to pairs, we defined a *triple* as three consecutive addends with a sum of 10.)

To obtain a measure of the amount of activity on each trial we computed the total sum of distances of all consecutive moves for each trial. A mixed 3x4x4 ANOVA on the total distance of moves per trial yielded a significant interaction between the two within-subjects factors list type and length [$F(6,180)=4.0$, $p=.010$] as well as a significant interaction between interactive mode and list length [$F(4,60)=3.5$, $p=.037$]. Whereas the first interaction merely reflects stimulus characteristics (e.g. that longer and spatially distributed lists afford longer moves) the second illustrates the modulation of moves by different interactive modes and lengths (see Table 4).

Table 4: Mean distances of cursor movements per trial in twips (1 twip = 0.05 pt = 0.01764 mm). Each cell contains 132 data points.

		Interactive mode		
		point	*mark*	*move*
length	4:	7 100	7 492	404
	8:	18 281	22 363	18 176
	12:	24 972	40 650	38 994
Total:		16 784	23 502	19 191

Table 5: Mean frequency (and standard deviations) of pairs, complements, triples, and neutral additions. Each cell summarizes data from 396 correct trials.

	Type of Move			
	Pair	*Compl.*	*Triple*	*Neutral*
point:	29.3 (14.0)	6.9 (3.2)	10.2 (7.5)	205.3 (14.7)
mark:	65.3 (38.3)	2.9 (3.2)	7.5 (2.8)	175.5 (10.3)

Whilst the increase in average move distances with longer lists was to be expected, it is notable that the slope of this increase is much steeper for the *mark* and *move* conditions. However, simple effect tests for the rows of Table 4 yielded a significant value only for lists of four numbers [$F_{A@b1}(2,30)=240.8$, $p<001$]. The lower value of the *move* condition at this length suggests why the corresponding latency was identical to the *look only* condition (see first line of Table 3a): Participants mostly chose *not* to move anything when adding short lists, but made use of their interactive potential when adding longer lists.

As the distances of moves in the *mark* and *move* conditions did not significantly exceed those in the *point* condition, activity per se cannot account for the reported differences in performance. To further illuminate potential strategy differences between groups, we have to consider process data on a within-trial level.

Choice of Next Addend At every non-last number within a stimulus participants faced the potential choice of which number to add next. We now examine the type of these choices and the corresponding move distances for the *point* and *mark* conditions, who had identical instructions (and differed only by the colour change of clicked numbers in the latter group) and both provided data on the complete paths of the chosen sequence of addends.

Table 5 contains the mean frequency of pairs, complements, triples and neutral moves chosen within correct trials. To appreciate the overall frequency of non-neutral moves we have to bear in mind that a participant had to select one or two neutral addends before being able to reach a round number and that none of the linear stimulus lists contained an adjacent pair, triple, or complement.

Pairs were the most frequent type of "rounding" move for both groups. T-tests for independent samples showed that participants in the *mark* condition chose more pairs [$t(12.6)=2.9$, $p=.012$] and fewer complements [$t(20)=2.9$, $p=.009$] than those in the *point* condition, whereas the number of triples did not significantly differ between groups [$t(14.9)=1.4$, $p=.181$].

When adjusting the frequency data for the number of *possible* pairs and complements on each particular trial, we found that participants in the *mark* condition in fact

chose to add 62.3% of all possible pairs and 2.3% of all possible complements, whereas participants in the *point* condition chose 31.4% of all possible pairs and 5.8% of the possible complements. As pair and complement strategies compete for the same addends, it is likely that the increase in complements for the *point* condition is a mere by-product of the more persistent selection of pairs in the *mark* condition.

As with the performance measures above, the differential effects of move choices were modulated by the task characteristics of list length and type. Specifically, participants in the *mark* condition predominantely pursued pairs regardless of list length and type, whereas those in the *point* group only used pairs when stimuli were short or spatially distributed.

Distance of Next Addend Additional support for the special attractiveness of pairs can be obtained when considering move distance data at the within-trial resolution.

When choosing which number to add next, participants had to balance the costs and benefits associated with the numerical value and the physical distance of each addend. If our main hypothesis about interactive problem solving applies on this micro-level, how far someone ventures in order to select a specific next number ought to vary as a function of interactive resources and number value.

Because the physical distance of moves varies trivially as a function of list length and layout, we determined how many physically closer numbers a participant skipped on each move in order to choose the next addend. By dividing the number of moves to the physically nearest unprocessed number by the total number of moves for each trial we gained a "proximity index". Its value represents the percentage of moves to the closest number per trial and ranges from 100% (indicating that the closest neighbour was always selected) to $(n\text{-}1)^{-1}$% (as at least one of the n-1 moves within a stimulus of n addends leads to a next number). The average proximity index for the *point* condition was found to be 71%, compared to a value of 61% in the *mark* condition [$t(782.3)=5.9$, $p<.001$], which indicates that marking led to a decreased likelihood to select the nearest neighbour.

To answer the question *why* participants prioritized spatially more remote addends in the other 29% or even 39% of all cases, we have to combine data on move distances and types. To quantify the price of spatial relocation a participant was willing to pay in order to make a particular type of move, we counted the number of physically closer numbers skipped for each move. Average scores of 2.20 for pairs, 1.12 for complements and 0.53 for neutral moves indicate that, to reach a pair, participants skipped about twice as many numbers than to reach a complement, whose selection still led participants to ignore about twice as many closer numbers than a neutral addend.

Moving Pairs Is there any evidence that the preference for a pair strategy generalized to the *move* condition?

Because the interactive mode of this group differed from the *look only* and *mark* conditions in that it permitted the problem solver the freedom *not* to interact, we lack the data on complete sequences of addends. However, as we observed many participants of this group either re-arranging numbers pairwise on the screen or positioning one addend of a pair physically close to the other, we computed the total distance between all possible pairs at the beginning and end of each trial. Since a mere decrease of distances between pairs could also be caused by someone moving *all* items closer together, we divided the pre- and post-trial distances between all possible pairs by the corresponding sums of distances of all possible non-pairs. A significant decrease of this ratio from initially 0.14 to 0.10 [$t(395)=12.2$, $p<.001$] allows the conclusion that pairs were moved closer towards each other than non-pairs.

Discussion

The experimental manipulation of interactive resources resulted in reliable differences in performance, which were systematically modulated by task characteristics.

Participants in the *look only* condition did well when adding short lists, but became unreliable as the number of addends increased. A similar error rate and even more pronounced increase in latencies to add long lists showed the participants in the *point* condition to be at an even greater disadvantage—presumably because they paid the additional price for interacting (clicking) without receiving the benefit of marking. As both groups had to mentally keep track of the numbers added, their strategies were more conservative and reflected specific stimulus characteristics.

In contrast, members of the *mark* and *move* groups exploited their interactive resouces to transcend the constraints imposed by stimulus and task characteristics and actively implemented a facilitative pair strategy. Their significantly faster and more reliable performance emerged as a consequence of systematic differences on a behavioural micro-level.

This finding of spontaneous adaptation to the structure of costs and benefits at the user interface supports recent attempts to describe interactive behaviour within a rational analysis framework (O'Hara and Payne, 1998; Gray and Fu, 2001). In Gray and Fu's study, a subtle increase to the cost of external information (an eye-movement or a single mouse-click) led to users of a simulated VCR relying on imperfect memory. In our study a relatively subtle change to the information display reduces internal memory load and thus enables a more sophisticated strategy for ordering addends. What is important about studies like these is not so much that small changes to the task environment can produce reliable shifts in behaviour but that an analysis of the interactions between physical and cognitve costs and benefits can predict and explain the particular behaviours that emerge.

In the current experiment, the additional resources provided by the more powerful interactive modes were all available relative cheaply (as are the so called

"epistemic" and "complementary actions"—like rotating objects or moving coins—in the studies by Kirsh, as cited above). What happens when complementary actions become more expensive, in terms of time or mental effort? Even in the current study, the results from the *move* condition suggest that disuse of interactive resources can sometimes be adaptive. In future work, we propose to investigate such questions by directly manipulating costs, following the methodology of O'Hara and Payne (1998), and by asking participants to explicitly choose between modes of interaction, using the choice-no-choice paradigm of Siegler and Lemaire (1997).

In this experiment, participants spontaneously, and almost instantly adopted a strategy which was tuned to their interactive resources. This contrasts with findings that people often are very inflexible in their behavioural routines, and continue to use dysfunctional strategies even when more efficient alternatives are available (Carroll & Rosson, 1987). To address this apparent discrepancy between rapid adaptation and rigid perseverance future studies will have to incorporate issues of learning and transfer.

The implications of this line of research are manifold:

On a theoretical and conceptual level, a strong version of the interactive perspective challenges the distinction between agent and environment, and promises to bridge the gap between cognition and action (Clark, 1997; Kirsh, 1996).

Methodologically, the dynamic interplay of factors illustrates that studies of interactive cognition have to strive for a very fine-grained resolution. To study the features of an agent, task, or task environment in isolation would fail to capture the multi-faceted nature of effects and misrepresent the complex balancing act of successful problem solving.

Finally, the study of interactive problem solving promises practical applications. Several studies have now shown that subtle changes in interactional resources can lead to substantial differences in performance. The challenge for interface design is to understand the complex structure of costs and benefits imposed by different environments, and to use this understanding to produce information displays that encourage effective interactions.

On the Normativity of Failing to Recall Valid Advice

David C. Noelle (NOELLE@CNBC.CMU.EDU)

Pittsburgh, PA 15213 USA

Abstract

Instructed category learning tasks involve the acquisition of a categorization skill from two sources of information: explicit rules provided by a knowledgeable teacher and experience with a collection of labeled examples. Studies of human performance on such tasks have shown that practice categorizing a collection of training examples can actually interfere with the proper application of explicitly provided rules to novel items. In this paper, the normativity of such exemplar-based interference is assessed by confronting a model of optimal memory performance with such a task and comparing the "rational" model's behavior with that exhibited by human learners. When augmented with a rehearsal mechanism, this optimal memory model is shown to match human responding, producing exemplar-based interference by relying on memories of similar training set exemplars to categorize a novel item, in favor of recalling rule instructions.

Introduction

Contemporary studies of human category learning have tended to focus on the acquisition of general knowledge about a new concept exclusively from exposure to a collection of labeled examples. In common learning environments, however, students attempting to learn a categorization skill are frequently provided with more than a set of training examples. In particular, learners are often explicitly instructed in the nature of a new category before being presented with instances. They are provided with definitional sentences and explicit rules (e.g., "an equilateral triangle has at least two sides of the same length" or "bugs with six legs are insects"). Direct instruction of this kind can rapidly provide a basic understanding of a new category, while experience with examples can further shape and refine that initial understanding (Klahr and Simon, 1999).

While it is common for the process of explicit instruction following and the process of induction from examples to cooperate to produce quick and robust learning, there are situations in which these two learning processes actually compete. Specifically, practice at classifying a set of training examples can cause learners to violate explicitly provided categorization rules when classifying novel items. Extensive experience with examples can lead learners to categorize novel instances according to similarity to training items, rather than according to categorization rules communicated through explicit instruction. Thus, novel items which are highly similar to training examples from another category come to be misclassified as a result of practice.

This exemplar-based interference effect, in which experience with examples interferes with proper instruction following, was investigated by Allen and Brooks (1991), as well as others (Brooks et al., 1991; Neal et al., 1995; Noelle and Cottrell, 2000). Such interference in category learning is mirrored by similar difficulties in a wide variety of learning contexts, such as when students come to solve math or science problems by analogy to previously seen problems, rather than by application of formal principles and techniques communicated through direct instruction. Learners appear to have a tendency to disregard perfectly valid explicit advice in favor of knowledge induced from experiences with examples.

Exemplar-based interference might be seen as the result of limitations of the cognitive system, such as imperfect working memory efficacy (Noelle and Cottrell, 2000) or difficulties recalling and applying abstract, linguistically encoded, rules. There is another alternative, however. It is possible that human learners neglect explicit instructions in favor of experienced exemplar-similarity information because the latter form of information tends to be more reliable in a wide variety of learning contexts. Exemplar-based interference may be the result of an essentially normative process of weighting sources of category information according to the previously established utilities of those sources.

There are many aspects of common learning situations which may encourage students to rely more heavily on examples than on explicit rules. Consider, for example, how the instructions provided by teachers are frequently approximate and heuristic. Advice is often implicitly limited to a particular range of circumstances, and there are often exceptions, even within this range, to explicitly provided rules. Also, teachers are sometimes in error. In short, human learners may have strong reasons to doubt the perfect accuracy of offered categorization rules. In comparison, exemplar similarity may be seen as a highly reliable indicator of category membership. Most categories, after all, involve clusters of similar objects, suggesting that similarity might be the best tool for predicting the category labels of novel instances.

Even if considerations of teacher reliability are ignored, there are other rational reasons for a learner to

rely preferentially on training experiences. In general, recalling past experiences with features similar to those of the current situation is often more useful than recalling dissimilar experiences. Thus, when faced with the task of categorizing a novel stimulus item, learners may be naturally inclined to recall other similar items rather than an explicit rule, which, due to its linguistic encoding, may bear little surface similarity to the situation at hand. Also, the recollection of experiences which are recent and frequently recurring is, on average, more useful when facing a novel challenge than recalling rare experiences from one's distant past. Thus, when performing an instructed category learning task, it may be reasonable for a learner to selectively recall the training items which were recently and repeatedly studied in favor of a briefly presented rule. In short, we may conjecture that exemplar-based interference arises from a rational tendency to rely on similar, recent, and frequent past experiences when faced with a novel situation.

In order to evaluate this conjecture, this paper reports on the modeling of the exemplar-based interference results of Allen and Brooks (1991) using the normative, or "rational", account of memory formulated by Anderson (1990). The goal is to investigate the degree to which exemplar-based interference can be explained in terms of a Bayes optimal learning process, given some assumptions about the common demands placed on human memory. The human performance results are reviewed first, followed by a description of Anderson's optimal memory model. The results of applying the model to this domain are then presented.

Human Performance

Allen and Brooks (1991) performed a number of experiments demonstrating the way in which experience with labeled training exemplars can interfere with instructed rule following. In their Experiment 1, learners were asked to categorize cartoon illustrations of fictional animals into one of two categories, based on how the animals were said to construct their homes: the "builders" and the "diggers". The appropriate category for each animal was strictly determined by it's physical features. Each animal was composed of specific selections for five binary attributes: angular body shape or rounded body shape, spots or no spots, short legs or long legs, short neck or long neck, and two legs or four legs. Only three of these attributes were ever relevant for classification, however: body shape, presence or absence of spots, and leg length. The animals were always depicted against color backgrounds, displaying four different outdoor environments. From this space of $2^5 \times 4 = 128$ different possible stimuli, only 16 were actually used. These 16 items were carefully chosen to include two animals with each possible level of the three relevant attributes. The irrelevant features were selected so that each stimulus item would have exactly one "partner" item — an item which differed from it only in the presence or absence of spots. Otherwise, each animal differed from each other animal in at least two attributes.

Experimental participants were provided with explicit categorization rules for discerning the "builders" from the "diggers". These always took the form of "2 of 3" rules, in which a target category was described as all animals with at least two of a list of three features (e.g., builders have two or more of the following features: angular body shape, spots, long legs). The rules were carefully chosen so that the 16 stimuli were equally split between the two categories. Also, the exemplars were partitioned into a training set and a testing set so that no two "partnered" items were in the same set. This resulted in exactly half of the testing set items having their partner items in the opposite category. These testing items were the ones for which interference was predicted.

The learners were presented with a training phase which consisted of seeing each of the 8 training set items five times, presented in a random order, for a total of 40 trials. When a stimulus image appeared on the screen, learners were to categorize it as quickly as possible, without sacrificing accuracy. Then, a sequence of two slides would be shown, illustrating how the animal actually constructed its home, identifying it as a builder or a digger. A subsequent testing phase involved soliciting categorization responses from the participants without providing any form of feedback on their decisions. During this testing phase, each training set stimulus was presented 4 times and each testing set stimulus was presented once, for a total of 40 testing trials.

There were two main results of this experiment. First, accuracy on the items whose "partners" were in the opposite category was much worse than on the other testing set items — around 55% correct as compared to 80%. This was a strong indication of exemplar-based interference. Second, the response time for correctly classified items was much larger for items whose "partners" were in the opposite category. This was interpreted as extra caution on the part of the learners when facing these "tricky" stimulus items. In other words, even when exemplar-based interference did not cause error, it at least caused a slowing of behavior.

Allen and Brooks argued that explicit memories for individual stimulus items played an important role in the production of this interference effect. The presentation of a testing set stimulus was seen as provoking a recollection of that item's "partner" in the training set, with the category label of that training set item often being assigned to the new stimulus in lieu of a label based on explicit rule application. Following this intuition concerning the centrality of memory to this effect, we have attempted to model these data using a previously explicated account of optimal memory performance.

Anderson's Rational Memory

The hypothesis explored here is that the behavior of the learners examined by Allen and Brooks can be characterized as normative — as the natural result of employing a memory system which is optimal in a Bayesian sense. This raises the question of how an optimal memory system would respond in this domain. Anderson and Mil-

son (1989) have proposed a "rational" model of memory which might be employed to address this question.

Initially, one may think that an optimal memory is a perfect memory. *Everything* is to be stored in every detail, without degradation, for an unlimited amount of time. This overlooks one very important function of memory, however, and that is to recall only those memories which are relevant to the current task. Without this ability of selective recall, a memory is essentially useless, even if (or especially if) it contains every detail that was ever experienced. Thus, the task faced by an optimal memory is the identification of those memory traces which would be most useful in the current situation.

In Bayesian terms, the goal is to determine, for each memory trace, the probability that that trace would be useful in the current situation. In Anderson's model, this is called the "need probability" of a trace. An optimal memory is seen as one which retrieves exactly those traces with the highest need probabilities in the current context. The question then becomes one of calculating the need probability for each memory trace.

In this model, the need probability is seen as a function of two components: the *desirability* of the trace and the *association* between the trace and the current context. The desirability of a memory trace is a measure of the average utility of the trace — a kind of base rate of appropriateness. The desirability of a trace is to be induced from its history of use. Recent and frequent retrieval of a memory trace is indicative of high desirability. The association between the trace and the current context is a kind of normalized likelihood of the context given that the trace is needed. This term increases the need probability with increased similarity between the context and the trace. Both of these components of the need probability are seen as normative properties of the situation, unbiased by predispositions of the agent. In brief, the optimal memory system computes the need probability of each memory trace, conditioned on the current context and on the history of past retrievals of that trace.

Mathematically, if A represents the event that a given memory trace is needed in the current context, H_A represents the complete retrieval history of that trace, and Q is the current context, then the conditional need probability is $P(A|H_A \ \& \ Q)$, which may be decomposed as follows:

$$P(A|H_A \ \& \ Q) \ = \ P(A|H_A) \times \frac{P(Q|A)}{P(Q)}$$

Note that this assumes that Q and H_A are both independent and conditionally independent with respect to A. If Q is taken to be composed of a collection of mutually independent features, then this expression may be written as:

$$P(A|H_A \ \& \ Q) \ = \ P(A|H_A) \times \prod_{i \in Q} \frac{P(i|A)}{P(i)}$$

This formulation allows for the separate calculation of a *history factor*, $P(A|H_A)$, and a *context factor* which measures the association between the memory trace and each feature of the current context, $P(i|A)$.

The calculation of the history factor requires some assumptions about the desirability of memory traces. Each trace is taken to start at some desirability level, λ_0, when it is first generated. Over the range of memory traces, these initial desirabilities are assumed to have a gamma distribution with parameter b and index ν. This means that no traces have an initial desirability of zero, most have some small initial desirability, and a very few have a high value for this variable. Furthermore, desirability is assumed to decay exponentially over time, with a decay rate of δ, where this rate of decay varies over the traces. It is assumed that δ is exponentially distributed with parameter α. Together, these assumptions paint a picture of memory traces with various initial desirabilities, decaying exponentially over time at various rates. Some memory traces start out with a high desirability and decay only slowly, like, say, the trace for your own name. Other traces start out with a low probability of use, like instructions on how to help a heart attack victim, but the desirability does not decay much with time. Some memories are very important but only for a short time, such as the memory for how much money was handed to a cashier before receiving change. Most trivia start out with a low desirability and decay rapidly.

One phenomenon not captured by this characterization is the way in which certain memory traces might become very useful again, after a long period of unimportance. To remedy this oversight, it is assumed that memory traces occasionally experience "revivals", at which time their desirabilities are returned to their original levels. The probability of a revival of a memory trace is assumed to decay exponentially with the time since the trace's introduction, with rate β.

This formulation provides a characterization of the probability distribution of possible trajectories of desirability over time. Recall, however, that what is needed is the distribution of histories of actual trace retrievals:

$$P(A|H_A) \ = \ \frac{P(A \ \& \ H_A)}{P(H_A)}$$

If we assume that a trace is retrieved with a probability proportional to its desirability, we can compute $P(H_A)$ by integrating over all possible values of initial desirability, decay rate, and revival history. This value is:

$$P(H_A) \ = \ \int\int \ P(H_A|\delta \ \& \ R) \ p(\delta) \ p(R) \ \ d\delta \, dR$$

where δ is a decay rate and R is a particular revival history. Note that, in this expression, the initial desirability has already been integrated over. The main term in this double integration has the form:

$$P(H_A|\delta \ \& \ R) \ = \ \frac{b^{\nu}(n+\nu-1)!}{D^{n+\nu-1}(\nu-1)!} \ \prod_{i=1}^{n} e^{-\delta(H_i - r_i)}$$

where n is the number of retrievals in H_A, H_i is the time of the *ith* retrieval, r_i is the time of the revival which most

immediately preceded the *ith* retrieval, and D is:

$$D = b + \frac{1}{\delta} \sum_{j=0}^{m} \left(1 - e^{-\delta(R_{j+1} - R_j)}\right)$$

where m is the number of revivals, and R_j is the time of the *jth* revival. All other variables in these expressions are parameters from the previously discussed probability distributions. In short, an expression for the value of $P(H_A)$ is available in the form of the double integral above.[1] This double integral ranges over an infinite space of δ values and possible revival histories. In order to estimate the value of this expression, a Monte Carlo integration may be performed, sampling decay rates and revival histories from their respective distributions. In this way, an estimate of $P(H_A)$ can be calculated.

Note that $P(A \ \& \ H_A)$ can be calculated in exactly the same fashion as $P(H_A)$ simple by including an additional retrieval of the memory trace at the current moment. As previously noted, the ratio of these two probabilities is the needed history factor, $P(A|H_A)$.

The calculation of the context factor is much easier to perform, mostly due to some simplifying assumptions. To compute the contribution of the association between the trace and the current context, it is assumed that the trace is composed of features which contribute independently to the need probability of the trace. These features are assumed to be mutually independent, even when conditioned on any feature of the current context. Thus, the context factor can be written as:

$$\prod_{i \in Q} \frac{P(i|A)}{P(i)} = \prod_{i \in Q} \frac{P(A|i)}{P(A)} = \prod_{i \in Q} \prod_{x \in A} \frac{P(x|i)}{P(x)}$$

All that remains is to determine the associative strengths between features of the current context and features of the memory trace, expressed as $P(x|i)$, which may be selected in a manner sensitive to the specific stimuli used.

Anderson and Milson (1989) showed that this optimal memory model matched human performance in many ways. This calculation of the probability of retrieval was found to predict recency and frequency effects, and the model was shown to be consistent with effects arising from varying the temporal spacing between the presentations of stimuli. This complex retrieval probability computation accounted for effects of word frequency on the memorization of word lists, priming effects, and various fan effects. Most all of these calculations were performed with fixed values for the distribution parameters: $b = 100$, $\nu = 2$, $\alpha = 2.5$, and $\beta = 0.04$.

Modeling Exemplar-Based Interference

Following the theorizing of Allen and Brooks (1991), their instructed category learning task can be viewed as a memory task. When initially given the explicit rule for categorizing the fictional animals, the learner must remember this rule, and it must be recalled when it is needed to categorize a stimulus item. The rule need not always be recalled, however, as it will be sufficient in many cases to simply remember a previous presentation of the specific stimulus being viewed and its corresponding category label. This characterization of the task makes Anderson's rational memory model applicable to an optimality analysis of instructed category learning.

A computer program was written which simulated the performance of Anderson's rational memory on the experimental task examined by Allen and Brooks (1991). Initial instruction involved the creation of a memory trace for the given categorization rule, and the retrieval of that trace for ten consecutive time steps, representing a study period. After this instruction period, the training set items were presented to the optimal memory, one at a time, in the same manner as they were presented to human participants. With each presentation, the need probability of each existing memory trace was estimated in the context of the current stimulus. The memory trace with the highest need probability among those traces that contained a category label was retrieved from the memory.[2] The category label of the retrieved memory trace was taken to be the response provided by the optimal memory system to the current stimulus. Note that the memory trace for the explicit rule was seen as containing the correct category label for every stimulus item.

During the training phase, the solicitation of a categorization judgment from the memory was followed by the incorporation of performance feedback information. The memory system responded to feedback by immediately retrieving the memory trace corresponding to the current stimulus, or, if this was the first presentation of the given item, by generating and retrieving a new trace for the stimulus, marked with the given category label.

After the training phase, the optimal memory experienced a testing phase equivalent to that presented to the human learners, involving a mix of training set items and new testing set items. The protocol for memory trace retrieval during the testing phase was the same as during training, except that none of the newly generated memory traces contained category label information, as no feedback was provided to the humans during this phase. Categorization errors made by the memory system during the testing phase were examined for signs of exemplar-based interference: relatively poor accuracy on those testing set stimuli whose "partner" items in the training set were in the opposing category.

To calculate the history factor of the need probabilities, the same parameters that were used by Anderson and Milson (1989) were used in this simulation: $b = 100$,

[1] Note that this expression is different than that provided in the appendix of Anderson and Milson (1989). When this error was brought to the attention of the authors, they provided the software that they had used to perform their calculations. It was discovered that the error was only in their appendix and not in their software.

[2] During the testing phase it was possible that the memory trace with the highest need probability would be a memory of a previous presentation of an unlabeled item. Such a memory would not be of much use for making a categorization judgment. Thus, this retrieval was restricted only to those memory traces which contained explicit category information.

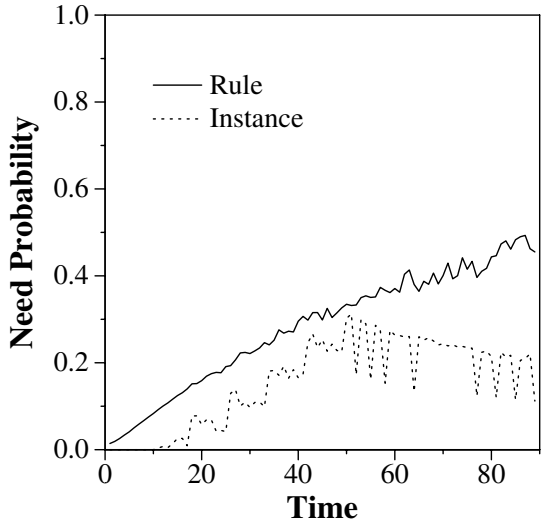

Figure 1: Results from the Optimal Memory Model: The need probability of the rule memory trace is plotted against the maximum need probability among the traces for the training set items. Note that the training phase ran from time step 11 through 50, and the testing phase ran from time 51 through 90.

$\nu = 2$, $\alpha = 2.5$, and $\beta = 0.04$. To calculate the context factor, the presentation of a stimulus was seen as providing a context consisting of 5 binary features (i.e., the attributes of the fictional animals) and one 4-ary feature (i.e., the background). Memory traces were seen as containing these six features, plus an optional category label. The associational strength between context and trace features was taken to be $P(x|i) = 0.65$. These features were taken to be pictorial in nature, so the memory trace for the explicit verbal rule contained none of these features. The Monte Carlo integration process employed by the optimal memory model consistently used $100,000$ samples in the calculation of each need probability estimate.

A summary of the results of this computation are shown in Figure 1. Plotted in that graph is the calculated need probability of the explicit rule memory trace and the highest need probability over the training set exemplar traces, both over time. Note that the training phase began at time step 11 and ended at time step 50, and the testing phase ran from time step 51 through time step 90. The primary result shown in this graph is that the rule always dominated over the exemplars. This meant that the rule was always retrieved in preference to traces for previously viewed items. In other words, the optimal memory produced perfect rule following behavior with no sign of interference. Even when the optimal memory system was modified to stochastically retrieve traces in a manner proportional to their need probabilities (rather than always retrieving the trace with the highest need probability), errors on stimulus items with "partners" in the opposite category averaged only 12%, as compared to the 45% error exhibited by humans.

These results were found, however, to be very sensitive to the associational strength that was used, $P(x|i)$. If this value was substantially increased above 0.65, then the memories for the training set items would immediately and persistently dominate over the trace for the rule. Under such higher settings of the associational strength, the optimal memory model would produce interference during the appropriate portions of the testing phase, but it would not produce expected behavior early in the session. In particular, the explicit rule would almost never be used. In short, this initial simulation of the optimal memory model of instructed category learning did not match human performance very well at all.

Anderson had some similar problems with his rational memory model when he compared its performance to human behavior (Anderson, 1990). While human responding matched his rational memory calculations in a number of domains, there were some aspects of human performance which could only be fit by the model with the help of an additional assumption. This assumption was that the system would covertly rehearse recently retrieved traces. He added to the memory model a rehearsal buffer which contained the 4 most recently retrieved memory traces. On each time step, each trace in the rehearsal buffer had a 0.2 probability of being rehearsed on that time step. Rehearsal simply involved the retrieval of that trace from memory. Increasing the number of retrievals of a trace through rehearsal would expand its retrieval history, H_A, and would thereby increase the history factor, $P(A|H_A)$, for that trace. Anderson added this rehearsal strategy, admitting that it stepped beyond the bounds of an optimality analysis. Still, such an augmented analysis was considered worthwhile, since it could show that human performance is optimal up to the inclusion of such rehearsal strategies. Indeed, that was exactly what Anderson demonstrated for a number of memory phenomena.

Following Anderson's lead, the optimal instructed category learning simulation was augmented with a 4 element rehearsal buffer. As in Anderson's work, the probability of rehearsal for each item in the buffer was set to 0.2 per time step. The memory trace for the instructed rule was allowed to occupy the buffer and be rehearsed, just like any other memory trace. The associational strength parameter was kept at 0.65.

Adding this rehearsal mechanism had a substantial impact on the behavior of the optimal memory, as shown in Figure 2. With rehearsal, the explicit rule maintained its perceived utility through much of the training phase, but was overcome by exemplar similarity by the time the testing items were presented. This produced consistent errors on those stimuli whose "partners" were in the opposite category. When traces were retrieved stochastically, in proportion to their need probabilities, the frequency of error on such items was 42%, comparing favorably to the 45% error exhibited by human learners. Thus, the rational memory model, when augmented with rehearsal, appears to be consistent with the observed in-

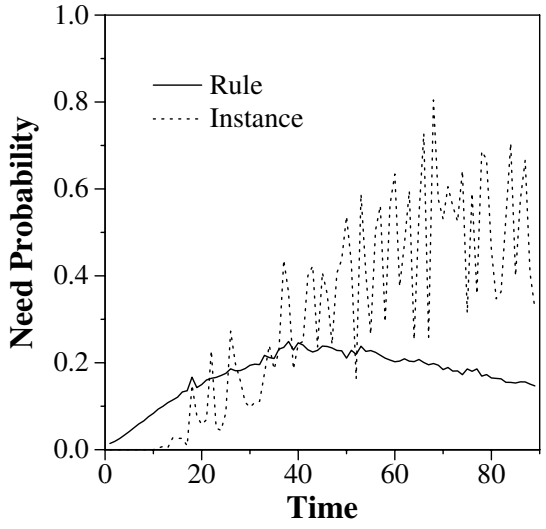

Figure 2: Results from the Optimal Memory Model With Rehearsal: Once again, the need probability of the rule memory trace is plotted against the maximum need probability among the traces for the training set items.

terference effect in instructed category learning.

Discussion

In many situations, it is more useful to remember a highly similar episode from the past than to recall generally applicable instructions. The rational memory model of Anderson and Milson (1989) is a formalization of the process of optimally predicting when such a situation has arisen. The unaugmented optimal memory model specifies that, within the experimental design of Allen and Brooks (1991), the explicit rule should almost always be preferred if similarity is not very predictive (i.e., when the associational strength is low), and a memory for specific instances should almost always be preferred if similarity is sufficiently predictive (i.e., when the associational strength is high). This is not consistent with human performance, however, where errors on "tricky" testing set items appeared only 45% of the time.

However, if the rational memory model is augmented with a rehearsal mechanism, as is needed to explain performance on other memory tasks (Anderson, 1990), the resulting need probabilities match human performance much more accurately. This suggests that the interference effect of interest may arise in the interaction between an optimal memory mechanism and a rehearsal strategy. One prediction of this calculation is that experimental manipulations which hinder rehearsal will reduce exemplar-based interference.

Note that, in these simulations, the memory trace for the explicit rule shared no features with the stimulus presentation contexts. This was intended to model the fact that the stimuli were pictorial, while the rule was linguistic. In fact, if the features itemized in the explicit rule are associated with the corresponding stimulus features with the same associational strength as used elsewhere in these simulations (0.65), the explicit rule comes to dominate over exemplar memory traces, even in the augmented model. It is a surprising fact is that this property of the model actually reflects human responding. Exemplar-based interference virtually disappeared when Allen and Brooks (1991) presented the animal stimuli not as pictures but as word lists — allowing the stimulus features and the explicit rule terms to literally match.

In summary, while this analysis does not rule out other potential explanations of exemplar-based interference, it offers the tantalizing possibility that the human tendency to ignore explicit instructions in favor of information provided by example experiences may be essentially adaptive when considered within the context of the common demands placed on the cognitive systems responsible for learning and memory.

Abstract

Several theories of learning have been proposed to account for the acquisition of abstract, generative knowledge including schema theory, analogical learning and implicit learning. However, past research has not compared these three theories directly. In the present studies we instantiated each theory as a learning scenario (i.e., direct instruction, analogy training and implicit training) and then tested all three training groups on a common problem. Results show that the analogy training groups and one of the direct instruction groups performed significantly better than the other groups on problem solving performance. The findings are interpreted in terms of opportunity to practice generating a response of the relevant type.

Theories of Deep Learning

In order to solve complex, novel problems one must be able to retrieve previously learned information from memory and apply it to the current situation. For instance, students learning geometry need to be able to apply mathematical formulas acquired during study to novel problems encountered at test. Although surface features of the problems change (e.g., specific values: a=5 to a=15) the abstract operators used to solve the problems stay the same (e.g., the Pythagorean theorem: $a^2 + b^2 = c^2$). Thus, in order for the knowledge gained from study to be helpful on the test it must be both abstract and generative. How such deep knowledge is acquired remains a central question for researchers in psychology, philosophy and education.

Several theoretical explanations have been proposed as to the origin of such abstract, generative knowledge including: schema theory (Marshall, 1995; Thorndike, 1984), analogical learning (Gentner, 1983; Holyoak & Thagard, 1988) and implicit learning (Reber, 1989).

Research on schema theory has shown that abstract knowledge is constructed during various types of higher-order cognitive activities including text comprehension (e.g., Kintsch & van Dijk, 1978; Thorndike, 1977), problem solving (e.g., Marshall, 1995) and direct instruction (e.g., Ohlsson & Hemmerich, 1999; Ohlsson & Regan, in press). For the purposes of this paper we are not concerned with the induction hypothesis of schema acquisition but instead with whether a schema can be taught directly (Ohlsson & Hemmerich, 1999). Although schema theory has provided much insight into the nature and form of abstract knowledge representations (e.g., Bobrow & Collins, 1975) it has done little to articulate a specific theory for how abstract schemas are acquired.

A second major theoretical proposal is the analogical learning hypothesis. Research on analogical learning suggests that one acquires deep knowledge through a systematic process in which a person retrieves an analog from memory and maps the underlying conceptual structure to a novel problem (Gentner, 1983; Holyoak & Thagard, 1988). In a typical analogical learning experiment participants first solve a source problem (e.g., story problems: Gick & Holyoak, 1983; or algebra problems: Reed, 1987) and then solve a test problem that has different surface features (i.e., a different context) but retains the deep relational features of the source problem. When participants are given the hint to use the source problem to solve the test problem they perform better than a control group who did not receive prior training, indicating that explicit knowledge of the prior solution procedure facilitates subsequent problem solving.

In contrast to the prior two theories research on implicit learning suggests that knowledge acquisition is a passive, inductive process that is independent of any intention to learn (Reber, 1989; Seger, 1994). In the training phase of artificial grammar learning – a typical implicit learning paradigm – the participants memorize letter strings that are generated from an artificial grammar. Participants are not informed of the rule-based nature of the memorization strings until after the training phase. In the test phase, the participants are given a classification task in which they are asked to judge whether or not new letter strings, half generated by the relevant grammar and half violating one or more of the rules, are like those memorized during the training phase. A large amount of evidence (Reber 1989; Seger; 1994; Stadler & Frensch, 1998) shows that participants perform better than chance in the test phase, indicating that they have acquired some knowledge of the underlying grammar.

These three theories present a complicated if not contradictory picture of knowledge acquisition. Each theory has a history of empirical support, experimental paradigms and explanatory problems associated with it. In order to

further explore and understand the relationship between these theories comparative empirical studies are essential. In the present studies we examine all three theories via a single experimental paradigm. This allows us to compare and examine the type of the knowledge generated by the various learning scenarios associated with each theory. How does that knowledge function on subsequent tasks? Is the knowledge representation abstract? Is it generative?

We instantiate each theory as a different type of learning scenario (i.e., direct instruction, analogical training and implicit training) and then test all three training groups on a common problem, Thurstone's sequence extrapolation task (Thurstone & Thurstone, 1941).

Sequence extrapolation problems have been studied from a cognitive perspective by Kotovsky and Simon (1973) and Simon (1972), among others. In this type of problem, the problem solver is given a sequence of symbols (usually letters) generated in accordance with some complex pattern and asked to extrapolate it. In order to solve the problem, he or she must first *discover* the pattern in the given segment of the symbol sequence and then articulate that pattern to *generate* the next N positions of the sequence.

In the current studies, experiments were divided into a training phase and a test phase. Participants in the implicit training condition memorized letter strings that had the same abstract pattern as that used in the test phase. Participants in the analogy training condition solved source problems that had the same abstract pattern as that used in the test problems. Participants in the instruction condition read a general tutorial on how to solve sequence extrapolation problems and studied the abstract rules of the pattern for each target problem.

In the test phase of the experiments all participants solved two types of extrapolation problems, a target problem and a transfer problem. The *target problem* had the same deep structure (i.e., the relations between the elements of the pattern) as that used in the sequences of the training procedures. The *transfer problem* was generated from the target problems by 'stretching' relations between letters, e.g., "forward 1 step in the alphabet" becomes "forward 2 steps" and "backwards 1" becomes "backwards 2" (see Table 1).

The goal of the present studies is to examine the nature and function of the knowledge created by each of the three training scenarios. If the knowledge gained is generative (i.e., can articulate a sequence of temporally related actions) and abstract (i.e., not bound to surface features) then performance should be facilitated on the target task. If the knowledge is of a higher level of abstraction it should facilitate problem solving performance on the transfer problem.

Experiment 1: Analogy vs. Implicit Training

Experiment 1 compares the effect of different types of analogical training (i.e., solving 1 problem three times vs. solving 3 structurally similar problems once) to different levels of implicit training (i.e., memorizing 6 vs. 18 instances of the pattern) on problem solving task performance.

Method

Participants One hundred and twenty seven undergraduate students from the University of Illinois at Chicago participated in return for course credit.

Materials The target tasks were two sequence extrapolation problems with a periodicity of six items for problem 1 and seven items for problem 2. Each task was instantiated as both a target and transfer problem; see Table 1. Target and transfer problems were related in that they contain similar over-arching pattern types but differed in the particular instantiation of the relations (i.e., manipulating some of the relations of the target pattern by a magnitude of 2 for transfer problems). To enable participants to detect the pattern, the given segments were 12 items long for task 1 and 14 items long for task 2. That is, they covered two complete periods of the underlying pattern. The extrapolation problems were created specifically for this experiment with a design similar to the problems used by Kotovsky and Simon (1973).

Table 1. Two sequence extrapolation problems and their associated transfer problems.

Problem Type	Given letter or number sequence & the correct 8-step extrapolation
Problem 1	
Target	E F D G C O F G E H D P G H F I E Q H I
Transfer	E G D I C O G I F K E P I K H M G Q K M
Problem 2	
Target	A C Z D B Y Y D F X G E W W G I V J H U U J
Transfer	A E Z G C X X G K V M I T T M Q R S O P P S

There were also three extrapolation *training* problems for each target task. The three training problems followed the exact same pattern as the associated target problem; see Table 2a for an example. Training problems were constructed so they do not overlap (i.e., do not share any of the surface features) with each other or the target problems. The single analog group was trained on the first of the three training problems and the multiple analog group was trained on all three.

In addition, there were 36 letter training strings consisting of 12 letters for task 1 and 14 letters for task 2, eighteen strings for each problem. The eighteen strings

associated with each problem followed the exact same pattern as the given sequence for that problem; see Table 2b for an example. The low implicit participants were trained on six strings per task and the high implicit participants were trained on eighteen strings per task.

Table 2. Two training sequences for Problem 1.

Example	
A. Source Problem:	I J H K G S J K I L H T
B. Training String:	M N L O K W N O M P L X

Each participant was tested on a Macintosh computer with a 14' color monitor, standard keyboard and mouse. All stimuli were presented in black 30pt font in the center of the screen. The experiment was designed and generated using PsyScope software. Target and transfer problems and associated training stimuli were counter-balanced across all conditions.

Design and procedure The participants were randomly assigned to one of four groups: *single analog* (n = 25), *multiple analog* (n = 23), *low implicit* (n = 26), *high implicit* (n = 23). In addition, a separate *control group* (n = 30) was tested on the target and transfer problems to provide a measure of baseline performance.

In the analogy training groups, participants solved letter sequence extrapolation training problems that conformed to the same patterns as those used in the target problems. The single analog group solved one and the same training problem three times and the multiple analog group solved three different training problems once each. Each of the multiple analog problems had different surface features but they all shared the same underlying pattern. In both implicit learning groups, participants memorized letter strings that conformed to the same patterns as those in the target extrapolation problems. The low implicit group memorized six training strings and the high implicit group memorized eighteen training strings. In the control group participants received no training.

General procedure. Participants were tested in groups of 1-4 people. The procedure consisted of *two cycles*. Each cycle was composed of problem training followed by solving target and transfer problems.

Procedure for analogy groups. Participants were first given general instructions on how to solve sequence extrapolation problems. Next, they were presented with the first extrapolation training problem. They were given 6 minutes to solve each problem. After participants had finished solving a problem or max time had elapsed, they were presented with the next problem. After participants solved all three training problems they were presented with the target problem instruction. Target problem instructions were the same as the training instructions except that they added the hint that if participants noticed a pattern on any of the prior problems it would help them solve the target problem. They were then presented with the target problem and were given 6 minutes to solve it. Finally, they were given the transfer problem and instructed to solve it in the same manner as the target problem. The second cycle proceeded in the same manner. The entire procedure took between 60-80 minutes.

Procedure for implicit learning groups. The participants were instructed to memorize and recall each letter string one by one; six strings for the low implicit group and eighteen strings for the high implicit group. They were then given 45 seconds to memorize each string. After 45 seconds the string disappeared and they were given 30 seconds to recall and type in the string. After they finished recalling the string or 30 seconds elapsed, participants were presented with the next string. This procedure was continued through all of the training strings. Next, participants were instructed to write down whether or not they noticed a pattern in the memorization strings. If they noticed a pattern they were instructed to describe it as best they could. Participants were then given general instructions on how to solve the sequence extrapolation problems. They were presented with the target sequence extrapolation problem and given the hint that if they noticed a pattern from the memorization strings it might help them on problem solving. They were given 6 minutes to solve the problem. Finally, they were given the transfer problem and were instructed to solve it in the same manner as the target problem. The second cycle proceeded in the same way. The entire procedure took approximately 70-90 minutes.

Results

The central question of interest is whether or not the various training scenarios facilitated performance on the target and transfer problem tasks. The problem solving score was the number of letters correctly extrapolated in each problem solving task. Because the participants were asked to continue the sequence to eight places their problem solving scores varied between 0 and 8.

Initial analyses revealed non-significant differences within both the implicit and analogy groups and all subsequent analyses collapsed across them, $F(1, 46) = .922$, ns and $F(1, 47) = .02$, ns respectively. Figure 1 shows the mean problem solving scores for the analogy, implicit and control groups on target and transfer problems.

A 3 (treatment: analogy vs. implicit vs. control) by 2 (problem-type: target vs. transfer) mixed analysis of variance (ANOVA) revealed a main effect for both treatment and problem-type, $F(1, 124) = 7.88$, $MSE = 12.96$, $p < .05$ and $F(1, 124) = 14.26$, $MSE = 1.86$, $p < .05$ respectively. The interaction was not significant, $F(1, 124) = .32$, ns. The main effect of problem-type shows that the participants performed better on the target problems than on the transfer problems. Follow up comparisons on treatment showed that the analogy

group performed significantly better than both implicit and control groups, F (1, 95) = 13.77, MSE = 12.35, p < .05 and F (1, 77) = 8.39, MSE = 14.23, p < .05. The implicit group did not significantly differ from the control F (1, 76) = 0.02, ns.

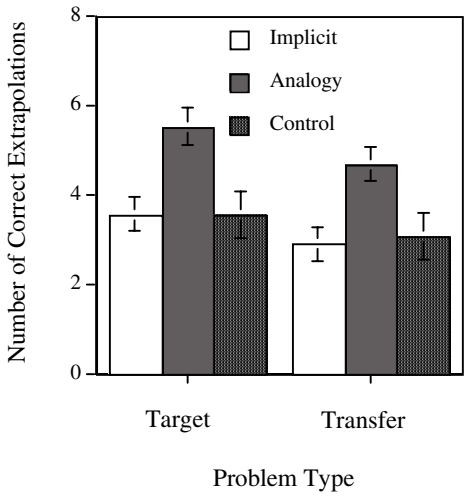

Figure 1: Problem solving as a function of training condition.

In addition, a simple comparison of target vs. transfer was conducted for the control group to provide a measure of baseline performance for problem-type. The analysis revealed a non-significant difference indicating that control participants performed equally well on both target and transfer problems, F (1, 29) = 2.77, ns.

We next compare analogy training to direct instruction.

Experiment 2: Analogy vs. Direct Instruction

Both analogy and implicit learning are indirect training methods. Is it possible to teach a sequential schema directly, by simply telling the participants what the pattern is? Experiment 2 compares different types of analogy training (single vs. multiple analog training) to different levels of direct instruction (high vs. low) on problem solving task performance.

Method

Participants One hundred and nineteen undergraduate students from the University of Illinois at Chicago participated in return for course credit.

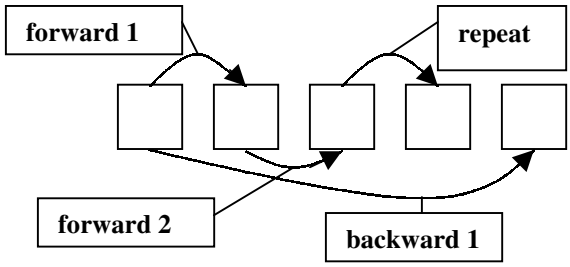
Materials The test problems and the analogy training problems were exactly the same as those used in experiment 1.

In addition, there were two extrapolation problem tutorial booklets, one for low instruction training (12 pages) and one for high instruction training (14 pages). Both tutorials consisted of general instructions for how to *find* pattern sequences as well as detailed descriptions of the component relations of patterns (e.g., forward, backward, repeat and identity relations). The high instruction tutorial had two additional pages of general instruction describing how to *extrapolate* or *continue* sequence patterns. There was also a general tutorial test that consisted of four recall questions and two comprehension questions.

In addition, there were two diagrammatic illustrations of the underlying pattern relations for each of the target problems as well as two blank diagrammatic recall sheets (see Table 3 for an example of a diagrammatic pattern illustration). There were also two distractor tasks that consisted of three multiplication problems each.

Table 3. A sample diagrammatic pattern illustration.

Example: *square boxes represent letter positions*



The test problems and analogy training problems were presented via computer with the same specifications as experiment 1. Direct instruction training material was presented on sheets or in booklet form. Target and transfer problems and associated training stimuli were counter-balanced across all conditions.

Design and procedure The participants were randomly assigned to one of four groups: *single analog* (n = 30), *multiple analog* (n = 31), *low instruction* (n = 28), *high instruction* (n = 30). The same *control condition* (n = 30) was used from experiment 1 as a measure of baseline performance.

In the instruction training conditions participants first read general tutorials, then memorized and recalled the abstract patterns for each target task. The only difference between high and low instruction groups was that the high instruction participants were given two additional pages in the tutorial which provided specific step by step instructions for how to extrapolate a problem.

Procedure for analogy groups. Procedure was exactly the same as in experiment 1.

Procedure for direct instruction groups. Participants were tested in groups of 1-4 people. The procedure consisted of *two cycles*, a training phase and a test phase. Before the training phase cycle all participants were given the general tutorial text to read (max time allowed = 18 minutes) after which they were given the tutorial test (max time = 6 minutes). At the beginning of the training cycle participants were given 3 minutes to memorize the first diagrammatic pattern illustration. Next, participants were presented with

the diagrammatic blank recall sheet and instructed to recall and write down the relations of the pattern (max time = 3 minutes). Participants were then given the distractor task (max time = 3 minutes). Next, participants were presented with the general instructions for the test problems. They were then given 6 minutes to solve the target problem. Finally, they were given the transfer problem and were instructed to solve it in the same manner as the target problem. The second cycle proceeded in the same way. The entire procedure took approximately 70-90 minutes.

Results

Again, the question of interest pursued here is whether or not training facilitated problem solving performance on the test tasks. The problem solving score was calculated in the same manner as experiment 1.

Initial analysis revealed a non-significant difference between analogy groups and all subsequent analyses collapsed across them, F (1, 59) = .51, ns. Figure 2 shows the mean problem solving scores for the analogy, high instruction, low instruction and control groups on target and transfer problems.

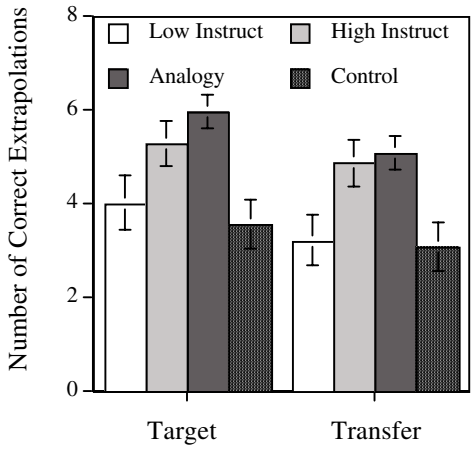


Figure 2: Problem solving as a function of training condition.

A 4 (treatment: analogy vs. high instruction vs. low instruction vs. control) by 2 (problem-type: target vs. transfer) mixed ANOVA revealed a main effect for both treatment and problem-type, F (1, 145) = 6.18, MSE = 14.45, $p < .05$ and F (1, 145) = 18.56, MSE = 1.49, $p < .05$ respectively. The interaction was not significant, F (1, 145) = .70, ns. The main effect of problem-type shows that the participants performed better on the target problems than on the transfer problems. Follow up comparisons on treatment showed that both the analogy and high instruction group performed significantly better than the low instruction and control groups, F (1, 87) = 9.19, MSE = 15.13, $p < .05$, F (1, 89) = 13.11, MSE = 14.77, $p < .05$, and F (1, 56) = 4.37, MSE = 13.94, $p < .05$, F (1, 58) = 6.78, MSE = 13.43, $p < .05$ respectively. The analogy group did not significantly differ from the high instruction group and the low instruction group did not significantly differ from control, F (1, 89) = .60, ns and F (1, 56) = .15, p = ns respectively.

Discussion

So how is abstract, generative knowledge acquired? The present study suggests that there are at least two ways to acquire such knowledge, one through analogical problem solving and the other through direct instruction.

Experiments 1 and 2 showed that participants in the analogy and high instruction training conditions performed better than participants in the implicit, low instruction and control conditions on both target and transfer problems. Target problem performance indicates that the knowledge acquired from analogy and high instruction training was both *generative*, in that the representation could be used to continue a sequence of temporally related actions, and *abstract*, in that the knowledge was flexible and could be applied to novel stimuli. This result supports typical findings on analogical transfer in problem solving (e.g., Gentner & Markman, 1998; Gick & Holyoak, 1983; Reed, 1987).

The analogy and high instruction groups also performed better than implicit, low instruction and control groups on the transfer problems indicating that the knowledge representation was generalizable to similar types of problem structures. However, there was a main effect for problem-type showing that analogy and high instruction participants performed better on target than on transfer problems. In contrast, the control group performed no differently on target than on transfer. These results show that the difference in performance on the target and transfer problem was a function of knowledge gained from training and not of differences in problem stimulus.

These results suggest at least two plausible explanations. One possibility is that some of the participants in the analogy and high instruction groups acquired a knowledge representation of a higher-level abstraction that facilitated their performance on the transfer problem whereas the others did not. Individual differences within the groups would account for the acquisition of a more abstract representation for only a portion of the participants. A second possibility is that participants in addition to learning the abstract pattern from the training stimuli also learned general problem solving heuristics for solving sequence extrapolation problems (i.e., employing specific pattern finding strategies such as searching for repetitions or backward relations). In this case, although knowledge of the specific abstract pattern facilitated performance on target problems it failed to transfer to the transfer problems and participants resorted to more general (and less accurate) problem solving heuristics.

Why did analogy and high instruction training facilitate problem solving and the other training conditions fail? The

prior analysis of the properties of a successful knowledge representation – abstraction and generativity – also reveals the potential components for failure in problem solving including failures of generativity and abstraction.

The failure of implicit training can be explained by either of the above components. Previous research does not provide definitive support for either component. For example, in a prior study we investigated implicit learning in sequence extrapolation problems and found that the knowledge created from the training procedures was of a moderate level of abstraction but was also potentially generative (Nokes & Ohlsson, 2000). Further research is needed to differentiate between each of these components.

The reason for the failure of low instruction can be investigated by examining the differences between the high and low instruction training materials. The only difference between the two training scenarios was that the high instruction tutorial had two additional pages of instruction describing in detail how to *extrapolate* sequence patterns. This description included one example problem that was worked through step by step in detail. This difference in training materials suggests that the low instruction group failed to construct a knowledge representation that was generative.

This hypothesis is also supported by other results in the literature. For example, Ohlsson and Regan (in press) used an intervention paradigm to teach participants several abstract concepts relating to the structure of DNA and facilitated subsequent use of those concepts on a discovery problem. They had participants practice *generating* their own concrete examples of the concepts in the training phase in addition to being given an example from the experimenter. Since low instruction participants in the current study never practiced articulating the abstract schema this component of the knowledge representation was not strengthened.

Thus a commonality that ties both implicit and low instruction together is the lack of practice in *articulating* the abstract schema. Although both learning scenarios had participants memorizing and recalling exemplars, whether they were letter strings or abstract rules, the participants never studied or practiced using these knowledge representations. In contrast, the analogy groups practiced generating pattern sequences on three separate occasions and the high instruction group studied pattern articulation in depth. It is proposed here that it is the practice of pattern articulation of an abstract schema that gives the analogy and high instruction groups their advantage over the other two learning scenarios.

Abstract

Shillcock, Kirby, McDonald and Brew demonstrate that there is a significant global relationship between word form and meaning across a substantial part of the lexicon of English. Here, 1705 words were studied to establish how their history in the language related to their participation in the correlation between meaning and form. It was found that the meaning-form correlation was significantly stronger for words with earlier dates of entry into the lexicon, implying that an individual word's meaning-form correlation may develop over time. Changes to individual words may be contingent on the word meanings and word forms in the rest of the lexicon.

Introduction

What is the relationship between a word's form and its meaning? And does age matter to the closeness of a relationship?

This paper addresses the second of these questions by building on previous work which addresses the first. The rest of this section introduces general background to the first question; the next section introduces the specific work upon which we build, and our current hypothesis; subsequent sections outline the methods and results of the current study, and draw a general conclusion.

Kelly (1995) suggested that "the hypothesis that phonological cues are unavailable or that people are not sensitive to them have no 'sound' basis in fact". On the one hand, the interaction between phonological and semantic representations has been widely discussed. On the other, the seemingly intuitive idea that there is a structure-preserving relation between these two aspects of words' representations has been largely ignored.

For instance, Dorffner and Harris (1997) report a model predicting that "although the mapping between word form and meaning is arbitrary… novel pseudo-words will prime concepts corresponding to words that are orthographically similar". They go on to discuss findings that showed that when English speakers are presented with pseudo-words, they tend to have associations with English words similar in terms of form. However, Dorffner and Harris dismiss possible relations between orthographic and semantic representations, and this implies that they see no connection between phonological form and the meaning of words. Yet no strong evidence is put forward to support this claim. Whereas priming effects could certainly exist in the absence of meaning-form relations, there is no reason to suggest that useful phonological cues to meaning cannot be utilised.

Indeed, Kelly (1992) had previously investigated how phonological cues—in terms of number of syllables, word duration, and pronunciation of certain syllables—were involved in category assignment. The study indicated that phonetic cues could be used to infer gender in a number of different languages, including French, Hebrew and Russian.

Continuing from this work, Cassidy, Kelly and Sharoni (*in press*) studied how phonological cues can be used to interpret gender, and how this information might be used by English speakers. A connectionist model was trained to classify novel names as male or female, solely on the basis of phonological cues, and succeeded in classifying 80% of names correctly. Experiments were undertaken which showed that four-year-old children had the ability to infer gender from pseudo-names, and that names that are phonologically typical of either gender are classified significantly more quickly than less typical examples.

In addition, Kelly (1998) studied "blend structure", which concerns the manner in which aspects of two words can be combined to produce a fresh word, in terms of cognitive and linguistic principles. Clearly, such cases help enhance the relationship between meaning and form for the words involved. Blended words such as *brunch* may become embedded in the lexicon due to their phonological evocativeness.

The Relationship Between Meaning and Form

Shillcock, Kirby, McDonald and Brew (2001) report a study in which they generated a semantic hyperspace from a large corpus of English, effectively defining the meaning of each word in terms of its contexts of occurrence. The semantic distance between any two words could be quantified using this hyperspace. In addition, they defined the phonological distance between any two words in terms of an edit distance (the number of features that it would be necessary to change to turn one word in the other).

For a set of 1733 monosyllabic, monomorphemic words, they obtained the meaning distance and the form distance between each word and every other word. They demonstrated that there was, overall, a significant relationship between these two distances: words that are phonologically more similar tend to be semantically more similar.

Further, for each word they calculated the correlation between the two pairs of distances between that word and each of the remaining 1732 words. This gave a value of r_{mf} (the correlation between meaning and form) for each word. When these individual values were ranked, important psychological differences between words emerged between different parts of the ranking. A high value for r_{mf} can be seen as the rest of the lexicon conspiring to support the relation between meaning and form for that particular word. Shillcock et al. claim that the communicatively important words predominantly occurred at the top of the list. In contrast, words with a small or negative r_{mf} value are often more specific and "propositional", for example, *priest* or *plight*. Shillcock et al. postulated that this relation is an example of a tendency towards structure-preserving mappings by the brain.

This ranked list of the relation between words' meaning and form provides the basis for the current study.

With reference to studies on the role of phonology and similarities between lexical neighbours, Shillcock et al. suggested that even very different words can be related in "a model that assumes the whole lexicon may influence the processing of any one word". They go on to demonstrate how the variability of monomorphemic, monosyllabic words in terms of length and phonological similarity can relate to semantic meanings, due to a tendency whose results resemble the compositionality normally present only at the higher levels of linguistic structure.

The Age-Complicity Hypothesis

Suppose the meaning-form correlation is, as hypothesised, a quantifiable aspect of a representational strategy employed by the brain. Then we can suggest that the correlation for each word is open to change over time, as groups of phonetically similar and semantically similar words become established. Further to this effect, it is also likely that words with strong individual meaning-form correlations are more likely to *remain* established, whereas words with weak individual meaning-form relations could be subject to semantic drift, and would be more likely to take on new meanings, losing their original ones. Therefore, the meaning-form correlation would tend to be strongest for words that have been longest in the lexicon. We call this prediction the Age-Complicity Hypothesis.

Method

The current study was based on the list of 1733 words ranked according to their individual relationship between meaning and form (r_{mf}), produced by Shillcock et al. Using information obtained from the Oxford English Dictionary on the first non-obsolete date of entry, a total of 1705 of these words were analysed, once words with no dictionary entry had been discarded. This produced a database of 1705 words with information on first non-obsolete date of entry and r_{mf} scores.

Correlation between r_{mf} rank and date of first entry was measured using Kendall's Tau B. The data were further analysed by comparing how the r_{mf} correlation differs within sections of the ranked list partitioned in terms of r_{mf} rank and age.

Results and Discussion

The Age-Complicity hypothesis predicted that words with long established meanings would have high r_{mf} values. This prediction was convincingly supported by these results. Figure 1 gives an overall view of the data, but although certain interesting features are visible, it is not possible to discern the trends in the data. Figure 2 charts averaged data, and trends become visible.

As Table 1 shows, there was a highly significant correlation ($\tau = 0.08$, $p < .001$) between the meaning-form relation and the first date of entry over all the data.

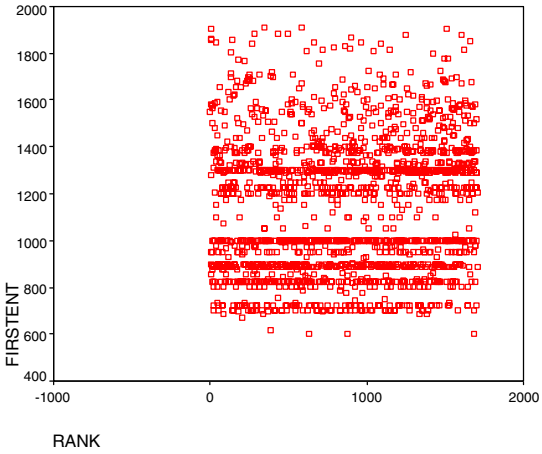

Figure 1: Graph of r_{mf} rank versus date of entry

On the basis of r_{mf} rank, the data were divided into three sections for further analysis: the top ranked 500 words, the middle ranked 500 words and the lowest ranked 500 words. The correlations between first date of entry and r_{mf} are given in Table 1.

There was a negative correlation for the top 500 words in the ranking: the words that were higher in the ranking by r_{mf} had the more recent dates of entry for this subset, contrary to the overall correlation. This feature of the results is probably a reporting phenomenon. The very top of the ranking by r_{mf} contains a number of items such as speech editing terms (*um*, *er*), swear words, and shortened proper names (*Mick*). These kinds of items may have been relatively unlikely to be written down—and hence given a date of first entry—in earlier times.

The middle section showed a non-significant correlation between rank order of r_{mf} value and date of first entry, although this time with a positive correlation. Finally, the lowest entries showed a correlation between rank and first date of entry which mirrored that in the total survey. In summary, despite the anomaly at the top of the ranked list, the results displayed an overall pattern of words' individual meaning-form relationships correlating with age, with words with a high value of r_{mf} having an earlier date of entry.

Table 1: Correlation (τ) between r_{mf} values and date of entry, sorted by r_{mf} rank

Entries 1-1705	Entries 1-500	Entries 600-1099	Entries 1206-1705
0.080 ($p < 0.000$)	-0.056 ($p < 0.033$)	0.032 ($p < 0.148$)	0.080 ($p < 0.004$)

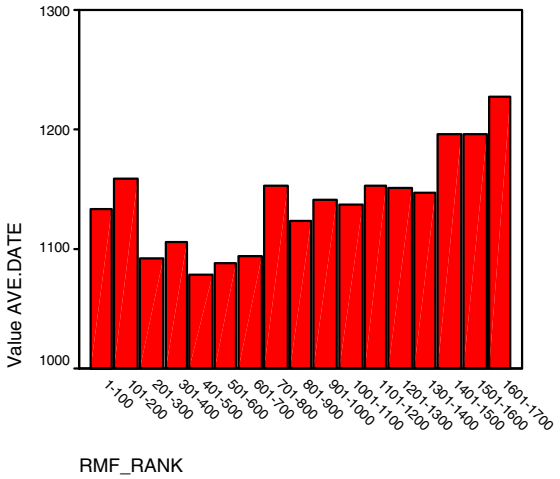

Figure 2: Graph of average first date of entry versus ranked r_{mf} entries

What happens when we think primarily in terms of dates? To provide another view onto the hypothesis, the data were again split into three sections, this time according to dates of entry. The three sections correspond to dates of entry between the years 601 and 897, 972 and 1297, 1303 and 1911, respectively.

Table 2 shows a non-significant (but negative) correlation between r_{mf} rank and date of entry for the section of words with the earliest dates of entry. The positive overall correlation is best reflected in the "middle-aged" words.

We have just seen, in Table 1, the reversal of the correlation for the more recent words, and the same explanation applies to Table 2. A good example is the new entry *yeah* (a colloquial form first recorded in 1905) with a very high r_{mf} value (ranked 8th). If this is due to a reporting phenomenon, then *yeah* could have been important in speech for a long time, and simply not captured in text, to be reported by the OED. On the other hand, it remains possible that *yeah* is just a recent, successful innovation. Then, the entry into the language of such a modified word could be attributed to their meaning-form correlation being stronger than their competitor, (*yes* is ranked 89th in terms of r_{mf}). Figure 3 charts the averaged data.

Table 2: Correlation (τ) between r_{mf} values and date of entry, sorted by date

All Dates 1-1705	Dates ranked 1-476	Dates ranked 599-1100	Dates ranked 1238-1705
0.080 ($p < 0.000$)	-0.043 ($p < 0.091$)	0.064 ($p < 0.023$)	-0.053 ($p < 0.045$)

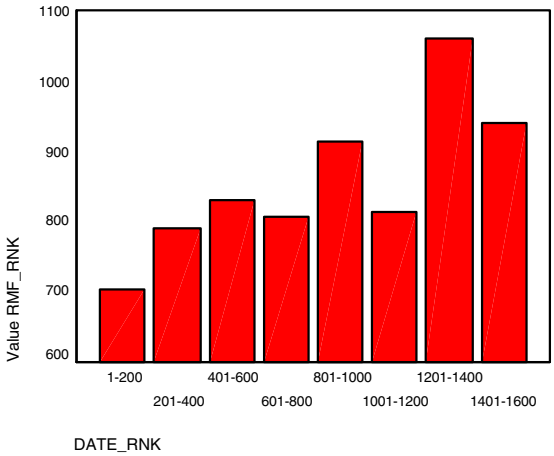

Figure 3: Graph of average r_{mf} rank versus date of entry.

Conclusion

From the results, it seems that there are anomalies amongst the (apparently) youngest, and oldest recorded words in our study. Nonetheless, a moderate interpretation of the Age-Complicity hypothesis has real support: the closeness of the relationship between form and meaning is related to its age.

More specifically, this study has produced evidence of a relationship between the history of an individual word in the language and that word's participation in the overall relationship between meaning and form in the lexicon. If a word has a high value of $r_{mf,}$ then it may be that it resists any change in its own meaning-form relationship; the rest of the lexicon is in effect supporting that relationship. Such a meaning-form relationship is adaptive; it means that the form and the meaning of the word can be partly inferred, one from the other—a clear advantage in language acquisition and processing. At the same time, that individual word may be helping to change the form and/or the meaning of words with weaker values of r_{mf}.

These findings have implications for studies of a number of aspects of human language. Principally, they offer data to substantiate an explanation of why some words become established in the lexicon while others do not. In other words, one of the contributing factors which can help a word become established is "sounding right", i.e. that its form resembles that of words with similar meanings.

We suggest that computational modelling might be used to simulate the data we have presented. It is not possible to obtain sufficient historical data to resolve all the possible reporting biases that may be present in data of the kind we have considered. Computational modelling may help to resolve some of these issues.

Finally, we have shown that it is possible to construe some of the data about language change from historical linguistics in cognitive terms, and specifically in terms of an adaptive relationship between meaning and form in the mental lexicon.

Abstract

In two studies we examined arguments for singular and general causal claims. The first study, a content analysis of newspaper articles, revealed characteristic distributions for mechanistic, statistical, and counterfactual argumentations in singular and general problems. In a second experimental study, subjects formulated arguments from different perspectives on general and singular problems. The results show that subjects are sensitive to the singular-general distinction as well as to related argumentative roles and backgrounds of knowledge. This supports a rhetorical model of causal cognition.

Introduction

Causal arguments consist of causal claims or conclusions and premises which support the causal claims as reasons. The claims may be general (e.g. "smoking causes cancer") or singular (e.g. "John's cancer was caused by his smoking") in nature. Various reasons can be given for such claims: statistical data (e.g. "because smokers take a much higher risk of getting cancer"), counterfactuals (e.g. "because John would not suffer from cancer, if he had not smoked") and mechanistic explanations (e.g. "because the tobacco carcinogen BPDE damages the P53 gene which is critical in the development of lung cancer"). Statistical (Cheng 1993), counterfactual (Lipe, 1991), and mechanistic arguments (Ahn, Kalish, Medin, & Gelman, 1995) have been the mostly discussed justifications for causal claims, but there are other arguments in addition (Oestermeier & Hesse, 2000). Our main question here is: are there systematic relationships between the generality of the claim and the provided arguments?

Several researchers (e.g. Ahn & Kalish, 2000; Hilton, 1995) have stressed the difference between general and singular causal problems, i.e. cases where causal statements are in need of further justification. Unfortunately, the distinction between singular and general problems is not a clear cut one. In the literature on causal cognition this distinction is often illustrated by general phenomena that occur in all relevant contexts alike (e.g. physical laws) on the one hand and particular instances that only occur at specific points in time and place (e.g. a particular car accident) on the other hand. These are, however, only the extremes of a continuum because causal problems range from single events about limited series of occurences to universal general problems. In the following we count only those causal problems as singular where single (or very few events) at a specific point in time and place are involved, and we count all other as general. Several car accidents at different times at a specific junction, for instance, are considered as a general problem albeit a single property of the junction could be the cause of the multiple accidents. Thus our criterion roughly corresponds to the use of singular and plural in the formulation of the causal problem (e.g. "car accident" vs. "car accidents"). The question then is whether this distinction between the singular and general is indeed a crucial one and whether it shows up consistently in varieties of ordinary argumentative discourse. More specifically, we address the following questions: What are the characteristic arguments for general and singular problems? Do subjects expect different arguments from persons with specific argumentative roles and epistemic backgrounds (i.e. general or singular knowledge)?

Previous Research

Answers to these questions directly contribute to the research about causal attribution and argumentation (see Brem & Rips, 2000, for a recent overview). It is an often replicated finding (Kuhn, 1991; Ahn et al. 1995; Slusher & Anderson, 1996) that empirical evidence, i.e. covariation information and statistical data, plays a limited role in the justification of causal claims. Subjects seem to find information about explanatory mechanisms much more useful and convincing. Brem and Rips (2000), however, found that the formulation of empirical evidence increases if the subjects can cite evidence from whatever source they find appropriate. Under such an ideal condition they produce more empirical backings than in those cases were they rely on their own limited knowledge. Brem and Rips (2000) conclude that the neglect of empirical evidence may be largely due to pragmatic restrictions of the availability of appropriate data.

Table 1: A taxonomy of causal arguments

Argument type	Argument schema	Example
Circumstantial evidence	*A caused B, because*	*The poison killed him, because*
1. Spatio-temporal contiguity	B happened at A	a poison bottle was found near the corpse.
2. Co-occurrences	A often occurred together with B	several people taking this poison died.
3. Similarity of cause & effect	A is similar to B	the corpse smells like the poison.
Contrastive evidence		
3. Covariation	B changes with A	the more he took the more ill he became.
4. Statistical covariation	A increases the probability of B	this poison increases the risk to die.
5. Before-after-comparison	B exists after A but not before A	he became ill after taking it.
6. Experimental comparison	action A led to B, action ´A to ´B	poisoned rats died in the experiment.
7. Counterfactual	B would not have happened without A	he would not have died, if he had not taken it.
Causal evidence		
9. Mechanism/causal explanation	A led to C via the process/mechanism B	the poison impaired the metabolism.
10. No alternative	there is no better explanation for B	no other cause leads to such a painful death.
11. Typical effect	B happened and B is a typical effect of A	the colour of the skin is typical for this poison

The cited research remains indeterminate with respect to the relative impact of counterfactual, covariation, and statistical arguments in singular (e.g. a car accident and the death of a plant) and general (e.g. AIDS, unemployment) problems. There are, however, findings that can be taken as a starting point. Kuhn (1991) used general problems and found that subjects formulate mechanistic arguments much more often than covariation arguments, whereas counterfactuals formulations remained nearly non-existent. In singular problems, on the other hand, most subjects also ask for information about mechanism and not for covariation data (Ahn et al. 1995). Lipe (1991), however, found a preference for counterfactual over covariation information and alternative explanations if counterfactual information was available in particular cases.

These findings are compatible with the following hypotheses: Mechanistic arguments occur more often than statistical and counterfactual arguments in general (Kuhn, 1991) and singular cases (Ahn et al., 1995) alike because both kinds of problems are mainly solved on the basis of prior causal knowledge. Counterfactuals are restricted to singular cases because the relevant contrast cases are easier to imagine in concrete cases than in more diffuse global problems (Sherman & McConnell, 1996). Statistical arguments are inherently general and thus restricted to such problems (Ahn & Kalish, 2000, but see Cheng, 1993). With these hypotheses from the literature in mind we looked at newspaper corpora with a great diversity of causal problems.

Study 1: Singular and General Problems

Method

The content analysis of these newspaper articles was based on our taxonomy of causal arguments (see Oestermeier & Hesse, 2000). This taxonomy was developed from several sources: the general philosophical, rhetorical and psychological literature on causation, Kuhn's (1991) interview study, a content analysis of 42 newspaper articles and a pilot study of our own. Table 1 shows the core of our taxonomy, other parts are beyond the scope of this paper.

The first corpus for the taxonomic analysis was taken from the ECI/MCI CD-Rom (the Multilingual Corpus 1 of the European Corpus Initiative). All Frankfurter Rundschau articles were electronically scanned for the keyword "verursach*" (German for "to cause"). This scan of thousands of articles led to a sample of 1024 articles. From this collection a random subsample of 60 articles was drawn. These articles were classified by two independent raters. Cohen's kappa was calculated for the agreement on implicit and explicit causal claims (.81), the segmentation of causal arguments, i.e. whether the text provided complete claim-ground structures (.74), the classification of complete arguments according to our taxonomy (.66), the singular or general nature of the causal problem (.69). The rest of this corpus was analyzed by a single rater.

The method of electronic scanning for a keyword has serious limitations: synonyms, counterfactuals and implicit causal statements are ignored. Besides that all articles of this sample dated from 1992 to 1993. In order to overcome these restrictions two additional printed samples of other newspapers were read by a single rater. One sample of 10 newspaper was randomly drawn from the Schwaebisches Tagblatt (a local newspaper) of the year 1996, another sample of 30 newspapers randomly from the Koelnische Volkszeitung of the year 1903. The rater was instructed to read all articles for all causal arguments with singular and general conclusions and to omit only the parts without journalistic content (like obituary notices, tables etc.)

Results and Discussion

Table 2 shows the frequencies of the argument patterns across singular and general problems. Arguments from explanatory mechanisms were by far the most common ones (75.1%) in both conditions. They were followed by unspecific covariation arguments (4.3%)

and statistical covariations comparing multiple observations (3.5%). All other arguments for causal claims, including counterfactuals, remained below 3%.

72% of the described problems were singular in nature. This gives some support to the hypothesis that singular causal problems are more important for laypeople than general ones (Hilton, 1995). Besides that, singular and general causal problems seem to rely, at least in part, on different reasoning patterns. Explanations of mechanisms dominated singular and general problems alike, but spatio-temporal contiguity (argument 1), experimental comparisons (7) and no alternatives (10) were offered as arguments for causal claims nearly exclusively in single case problems, whereas statistical arguments (5) remained completely restricted to general problems. They occurred only once in the newspaper from 1903. This observation can be best explained by the relatively late penetration of life with statistics which took place after 1900. Argumentations in newspaper certainly reflect historical developments. We would, however, put not too much weight on this hypothesis from one isolated finding.

Some non-findings are also interesting. From the literature we expected that necessary and sufficient conditions should often be used as arguments for causal claims (e.g. Einhorn & Hogarth, 1985). Astonishingly this was not the case, we found no uses of arguments of the form "X caused Y, because all X are followed by Y" or "X caused Y, because Y never happens without X" in the corpora. Even arguments based on counterfactual necessity, although considered as essential for causal reasoning by many researchers (e.g. Lipe, 1991), were rare. The latter may be due to the fact that counterfactuals can be considered as implicit causal arguments that provide at the same time a ground and a claim, whereas our content analysis looked for causal arguments with distinct claims and grounds.

In sum, the data show that singular and general problems cannot be reduced to the same set of argument patterns. Mechanistic or causal explanations that infer causal claims from prior causal knowledge are abundant in both cases, but inductive and abductive arguments are dependent on the problem type. Especially covariation and statistical arguments seem to be restricted mainly to general problems.

Study 2: Roles and Epistemic Backgrounds

The distributions of arguments in the newspaper corpora can only in part be explained by chance and the question is whether subjects are sensitive to these characteristic distributions. Such a sensitivity would be very useful. Argumentation is a complex social activity in which subjects try to defend their interests and gain acceptance by others. The ability to anticipate different arguments from people with different backgrounds of knowledge would offer distinctive advantages in debates. By anticipating certain arguments, for instance, one can prepare the appropriate counter-arguments in advance and thus be in a better position to convince an audience from one's own perspective.

It is clear, however, that subjects can show this rhetorical competence only in settings were it is demanded. Law suits are especially demanding in this respect and therefore we used selected juridical causal problems with various argumentative points of view (plaintiff, defendant) and various backgrounds of knowledge (witnesses, experts).

Hypotheses

We assumed that participants should be able to take the epistemic backgrounds into account and thus expect more often arguments with a reference to concrete spatio-temporal relations from witnesses than from experts.

Table 2. Singular (S) and general (G) causal arguments in three newspaper corpora

Arguments	Volkszeitung (1903)	Rundschau (1992/3)	Tagblatt (1996)	Totals	
	S:G	S:G	S:G	S:G	S+G in %
Circumstantial evidence					
1. Spatio-temporal contiguity	3:0	2:0	5:0	10:0	1.7
2. Co-occurrences	1:1	2:3	0:1	3:5	1.3
3. Similarity of cause and effect		1:0		1:0	0.2
Contrastive evidence					
4. Covariation	5:7	2:4	2:6	9:17	4.3
5. Statistical covariation	0:1	0:10	0:10	0:21	3.5
6. Before-after-comparison	4:2			4:2	1.0
7. Experimental comparison	2:1	8:0	4:0	14:1	2.5
8. Counterfactual	5:4	1:0	1:0	7:4	1.8
Causal evidence					
9. Mechanism	67:26	183:40	94:45	344:111	75.1
10. No alternative	5:0	4:0	1:0	10:0	1.7
11. Typical effect	2:0		2:0	4:0	0.7
Other causal arguments	9:1	21:5	1:4	31:10	6.7
Total S:G	103:43	224:61	110:65	437:169	(100)

In general problems subjects should expect more statistical arguments from experts than from witnesses because it is unlikely that a witness shares the expert's knowledge about statistics. In other words, the participants' arguments should reflect their (perhaps tacit) knowledge that witnesses typically know only about the particular circumstances, whereas experts know about many different cases.

As a generalization of previous findings we expected that mechanistic arguments should dominate singular and general problems alike, because these arguments mirror directly the familiarity of subjects with everyday causal explanations and theories. But singular and general problems should be different with respect to statistical arguments, i.e. arguments that compare multiple observations. We expect more statistical arguments in general than in singular problems, because they abstract from particular circumstances and are inherently general. According to Sherman and McConnell (1996) counterfactual arguments should be occur more often in singular than in general problems.

Method

Participants. The participants were 40 paid volunteer students from various faculties of the University of Tuebingen (16 participants were male and 24 were female; ages varied between 18 and 44 years with a median of 24). Each subject was paid 30 DM. Participants were tested in groups from 3 up to 6 persons and required between 90 and 120 min to complete the paper and pencil tasks. One participant was removed from the data set because of difficulties to understand the instructions and questions in German.

Procedure. We used a mixed repeated measurement design. As a between subject factor 19 subjects had to work on general problems, 20 on corresponding singular ones. The subjects were randomly assigned to these two conditions. As within-subject variables every participant had to work on three different problem contents (food poisoning, allergic reactions, and car accidents) and several perspectives on the case at issue (plaintiff's, defendant's, witness', expert's view and the participant's own pros, cons and final justification). The problem contents and issues were based on real newspaper reports and reformulated for the sake of the experiment. The order of tasks was randomized.

Each participant read three problem descriptions and the related questions. The description of the singular food poisoning case, for instance, read as follows:

> "The organizer of the last year's public festival at the Rhine promenade was sued for compensation for personal suffering at the inferior court Duesseldorf. The plaintiff Oliver K. (36), a visitor of the festival, had suffered from a serious food poisoning. He had taken a snack at one of the snack stands. The vendor could be identified but went into hiding several month ago. An investigation of the case revealed that the vendor had no official license to sell food.
>
> In the last year, the organizer had granted numerous commercial licenses to vendors of snacks and peddlers without checking for the necessary official licenses and health certificates. This was not disputed by the organizer.
>
> At issue between the parties was the cause of the food poisoning. The question of guilt and responsibility was set aside for the moment, at issue was only the question, which cause lay behind this incident."

The first paragraph of the general food poisoning problem read as follows:

> "Several members of the spontaneously founded interest group 'Festival without Fear' brought an action against the municipality of Duesseldorf at the administrative tribunal Duesseldorf in order to lay the city under an obligation to choose another organizer for the traditional yearly public festival at the Rhine promenade. At the last festival numerous visitors had suffered from serious food poisonings. The investigation of these cases revealed that many vendors had no official license to sell food."

The other two paragraphs were identical with the former ones with the exception that plural constructions were used where appropriate.

After the description of the problem scenario the participants were asked for free formulations of causal claims and justifications from different point of views and juridical roles. Single and general case versions were identical except for number and gender:

> "What is the cause of the food poisoning in the plaintiff's [defendant's] point of view? Which justification do you expect from the plaintiff [defendant] for his position?"

In addition, the subject was asked for his own conjecture about the cause and possible pros and cons that would speak for or against his/her conjecture. Each question was followed by three empty lines to allow for free answers in complete sentences. The next sheet started with a causal claim from the plaintiff's view and asked for possible arguments from a witness' and expert's point of view:

> "The plaintiff argues, that the missing controls caused the food poisoning. He cites a witness and an expert.
>
> Which justification(s) do you expect from a witness, who worked at the festival, [an expert, who was procured by the court] for the claim that the missing controls caused the food poisonings?"

Finally, the subject was asked for his/her opinion about the cause and a final argument. The justifications that were freely formulated by the participants were classified in terms of our taxonomy by two independent raters. On a subset of five randomly chosen survey booklets, we calculated Cohen's kappa as a measure of rater agreement. When coding non-causal arguments as a default category (i.e. "other") the result was fair (.54). A second agreement measure was calculated solely for the categories within the taxonomy, i.e. those cases where both rater agreed that the argument in question

was causal in the sense of our taxonomy. This agreement was .76. Non-causal arguments (e.g. arguments from authority) were ignored later on. Differences in classification of arguments were resolved by discussion.

Results and Discussion

Table 3 gives a summary of the results. The overall number of causal arguments which were produced by the participants across all three tasks varied considerably from 5 to 33 with a median of 19.2. To compensate for this, we computed the relative percentages of each produced argument type per person. With the percentages of (a) statistical, (b) counterfactual, and (c) mechanistic arguments as dependent variables we calculated three 2x3x7 (type of task x content x perspective) mixed analyses of variance (ANOVA) with general and singular problems as a between factor and task content and perspective serving as repeated measures.

(a) Statistical arguments were less often formulated (in total 36 formulated arguments) than mechanistic arguments (in total 245) and especially rare under the singular condition (9 out of 36). In consequence there was a main effect of singular vs. general problems for statistical arguments, $F(1, 37) = 4.71$, $p < .05$. There was also a significant main effect of perspective, $F(6, 222) = 3.30$, $p < .01$, i.e. statistical arguments were more often formulated under the perspective of an expert (13) than under all other perspectives (0 for witnesses).

(b) Counterfactual arguments were more often formulated in singular (24) than in general problems (19) but in accordance with our first study and against the hypothesis of Sherman and McConnell (1996) this difference was not significant $F(1, 37) = .747$, $p = .39$. There was, however, a significant interaction between task type and content, $F(2, 74) = 10.894$, $p < .05$. In the car accident and allergic reaction tasks counterfactuals were more often produced under the singular condition than under the general one (14 vs. 5 respectively 5 vs. 1). In the food poisoning problem, this difference was reversed (5 vs. 13). We can offer no explanation for this interaction, but one can argue that our kinds of problems were perhaps not as general as necessary in order to gain a stable effect. Our problems involved multiple people and events but were far from universal because the described events occurred in restricted areas. The interactions show, however, again how content and context dependent causal argumentations are.

(c) Mechanistic arguments were the most common ones (245 in total) and produced by all participants alike across general (130) and singular (115) problems. We found, however, significant main effects of task content, $F(2, 74) = 19.32$, $p < .001$, and perspective, $F(6, 222) = 19.39$, $p < .001$. Nearly half (120) of all mechanistic arguments were formulated in the car accident problem. This may be due to the fact that the participants were more familiar with plausible car accident scenarios than with allergic reactions and food poisonings. In the latter two problem types the mechanisms behind the observable symptoms are less known and hidden to the unaided senses. Against the general trend of a dominance of mechanistic explanations, participants argued from the plaintiff's view equally often with observational before-after-comparisons as with mechanisms (both 20), whereas counter-arguments offering alternative explanations (28 out of 59) were especially frequent under the defendant's view. This shows a clear understanding of the addressed argumentative roles.

Table 3. Frequencies of singular (S) vs. general (G) arguments by perspective and contents

General Discussion

Not all researchers define singular and general arguments in the same way as we do. Basically, we distinguished claims about one and many cases. In the literature a related but different distinction is often drawn in respect to episodic vs. semantic or conceptual knowledge. We decided to use a deviating one-many distinction for several reasons: Firstly, our criterion shows up relatively clearly at the language surface (singular vs. plural) whereas the distinction between episodic and semantic knowledge is much more implicit. Phenomena like unemployment and crime, for instance, can be viewed as local episodic or truly universal problems alike and it often not clear from the context whether causal claims about these problems are intended as propositions about the specific circumstances in a particular economy or society or as general law-like statements. Secondly, frequently cited examples for general claims like "smoking causes cancer" sound to be common but a closer look at non-scientific text corpora shows that such unrestricted causal statements are rare. They seem to be of limited importance in non-scientific contexts.

Thus it remains an open question whether the episodic vs. law-like distinction leads to similar characteristic argument sets. Up to now, relatively few studies looked directly at the verbalization of causal arguments (Brem & Rips, 2000; Kuhn, 1991; Thagard, 1999). A reason for this may be the implicitness and vagueness of ordinary language which makes utterances difficult to analyze. But this obstacle is unavoidable if one wants to understand how causal knowledge is established and communicated in modern societies. Taxonomic and rhetoric studies are indispensable in this respect and in our opinion they should become import guides for further research. The above mentioned studies show, for instance, that statistical (Cheng, 1993) and counterfactual (Lipe, 1991) theories of causal reasoning in psychology have no foundation in a prevalence of the corresponding argument patterns in ordinary discourses. The complex distributions of argument patterns that occur in ordinary language simply cannot be explained from theories that put their focus on a single central and normative causal argument pattern.

Differences in perspectives as well as differences along the singular-general-continuum pose especially difficult problems for reductionistic theories. If the supposed reasoning patterns are the same for all persons, perspectives, and problems alike, it is hard to see how differences can emerge at all. From a rhetorical perspective, however, differences in reasoning are fundamental and in many cases irreconcilable. Our data show that argumentative competencies of humans are highly sensitive to such rhetorical demands, i.e. specific contents and contexts, argumentative roles, different backgrounds of knowledge, restrictions in knowledge, etc. We do not claim, however, that by taking a rhetorical perspective alone, these competencies are already explained. But in our view, it is a progress if such a perspective shift leads to a more adequate description of the pragmatic aspects of causal reasoning and argumentation.

Roles of Shared Relations in Induction

Hitoshi Ohnishi (ohnishi@nime.ac.jp)

Abstract

Two experiments examined the roles of shared relations between representations in induction. Lassaline (1996) found that shared attributes contribute to the inductive strength, but shared relations do not, whereas both shared attributes and shared relations contribute to similarity judgment. A structural alignment view of induction was generalized to account for these phenomena. According to the structural alignment view proposed in this paper, (1) insufficiency of the number of shared relations caused the dissociation between shared relations and inductive strength, and (2) structural alignment during similarity judgment made shared relations so salient as to increase similarity. Experiment 1 examined the first hypothesis. Participants judged inductive strength of arguments that had a crossing number of shared attributes and shared relations. The results showed that shared relations contribute to the inductive strength if a sufficient number of relations are shared. Experiment 2 examined the second hypothesis. The participants who rated similarity between categories of arguments prior to judgment of inductive strength judged arguments having a shared relation to be stronger, whereas the participants who only judged inductive strength did not judge so. The results support the proposed structural alignment view of induction.

Category-based Induction

People frequently make inferences and expand their knowledge in uncertainty. This type of inference is generally referred to as induction. One form of induction where the premises and the conclusion are of the form "All members of a category C have property P" is referred to as category-based induction.

In category-based induction, a categorical argument is said to be strong when the premises increase the degree of belief in the conclusion. Osherson, Smith, Wilkie, Lopez, and Shafir (1990) proposed that the strength of an inductive argument increases with (a) the degree to which the premise categories are similar to the conclusion category, and (b) the degree to which the premise categories are similar to members of the lowest-level category that includes both the premise and the conclusion categories. They implemented their idea as a mathematical model that is called similarity-coverage model. The similarity-coverage model provides a comprehensive explanation to a variety of phenomena in category-based induction.

As an alternative to the similarity-coverage model, Sloman (1993) proposed a connectionist, feature-based, model of induction. According to the feature-based model, an argument whose conclusion claims a relation between category C (e.g., Zebras) and property P (e.g., love onions) is judged strong to the extent that the features of C have already been associated with P in the premises.

Structural Alignment

According to the similarity-coverage model, strength of induction is based on similarities between categories. Recent studies on similarity have revealed flexible and dynamical properties of similarity (Goldstone, 1994; Goldstone, Medin, & Gentner, 1991; Markman & Gentner, 1993; Medin, Goldstone, & Gentner, 1993).

One of the most important findings is that similarity judgment involves a process of alignment of structured relational representations (Markman & Gentner, 1993). In structural alignment, the correspondences between pairs of representations are computed by seeking matches that are structurally consistent. A structurally consistent match means that each attribute or relation in one representation is placed in correspondence with, at most, one attribute or relation in the other representation.

The structural alignment view accounts for important empirical results of similarity and analogy. An important result that is relevant to induction is that attributes and relations in representations are distinguished. This result suggests the possibility that attributes and relations are also distinguished in induction.

Roles of Attributes and Relations in Induction and Similarity

Structural Alignment in Induction

Lassaline (1996) proposed a structural alignment view of induction based on structural alignment of similarity and analogy, and examined roles of attributes and relations in induction and similarity. She hypothesized that (1) shared attributes and shared relation between categories contribute to increasing similarity, whereas (2) nonshared binding relations that connect the target attribute (the attribute being mapped from one category to the other in an inductive judgment) to an attribute shared by the two categories contribute to increasing the strength of inductive arguments.

Inductive arguments related to Hypothesis 1 are illustrated in Figure 1. The four arguments have crossing numbers of shared attributes (2 and 3) and shared relations (0 and 1). In argument (a), two attributes "X and Z" are shared by two animals. Argument (c) is formed by adding a common causal relation to argument (a). Therefore arguments (a) and (c) have two shared attributes, and zero and one shared relation, respectively. Argument (b) and (d) are formed by adding a common attribute to (a) and (c), respectively. Therefore argument (b) and (d) have three shared attributes, and zero and one shared relation, respectively.

According to Hypothesis 1, animal A and B in arguments (c) and (d) are respectively judged more similar than those in arguments (a) and (b) because arguments (c) and (d) have more shared attributes. Similarly, animal A and B in arguments (b) and (d) are respectively judged more similar than those in arguments (a) and (c) because arguments (b) and (d) have a shared relation. Note that shared relations in argument (c) and (d) do not connect the target attribute "Y" and a shared attribute. Therefore these shared relations are not binding relations. Her hypotheses do not make any specific prediction about the contribution of nonbinding shared relations to inductive strength.

(a)
Animal A has X and Z.
Animal B has X, Z and Y.

Animal A also has Y?
(2A-0R)

(b)
Animal A has W, X and Z.
Animal B has W, X, Z and Y.

Animal A also has Y?
(3A-0R)

(c)
Animal A has X and Z.
Animal B has X, Z and Y.
For both animals, X causes Z.

Animal A also has Y?
(2A-1R)

(d)
Animal A has W, X and Z.
Animal B has W, X, Z and Y.
For both animals, X causes Z.

Animal A also has Y?
(3A-1R)

Figure 1: Abstract structure of stimuli used in Lassaline (1996)'s Experiment 1. xA-yR indicates that the number of shared attributes is x, and the number of shared relations is y. W, X, Z, and Y represent attributes of the stimuli.

Hypothesis 2 is relevant to induction. Inductive arguments related Hypothesis 2 are illustrated in Figure 2. The four arguments have crossing numbers of shared attributes (0 and 3) and binding relation (0 and 1). Argument (e) has a shared attribute "X." Argument (g) is formed by adding a nonshared binding causal relation to argument (e). Therefore arguments (e) and (g) have a shared attributes, and zero and one binding relation, respectively. Arguments (f) and (h) are formed by adding two common attributes to (e) and (g), respectively. Therefore argument (f) and (h) have three shared attributes, and zero and one binding relation, respectively.

(e)
Animal A has X and Z.
Animal B has X and Y.

Animal A also has Y?
(1A-0R)

(f)
Animal A has W, X and Z.
Animal B has W, X, Z and Y.

Animal A also has Y?
(3A-0R)

(g)
Animal A has X, W and Z.
Animal B has X and Y.
For animal B, X causes Y.

Animal A also has Y?
(1A-1R)

(h)
Animal A has W, X and Z.
Animal B has W, X, Z and Y.
For animal B, X causes Y.

Animal A also has Y?
(3A-1R)

Figure 2: Abstract structure of stimuli used in Lassaline (1996)'s Experiment 2. xA-yR indicates that the number of shared attributes is x, and the number of binding relations is y. W, X, Z, and Y represent attributes of the stimuli.

According to Hypothesis 2, arguments (g) and (h) are respectively judged as stronger inductive arguments than arguments (e) and (f) because argument (g) and (h) have a binding relation.

She examined roles of attributes and relations in induction and similarity. In her Experiment 1, the roles of shared attributes and shared relations in induction and in similarity were examined. One group of participants rated strength of inductive arguments that had crossing numbers of shared attributes and shared relations as illustrated in Figure 1. The other group of participants rated similarities of pairs of the animals described in each premise of those arguments. The results showed different pattern between inductive strength judgments and similarity judgments. Inductive strength ratings increased by adding a shared attribute, but did not increase by adding a shared relation. In contrast, similarity ratings increased by adding of the shared attribute and the shared relation.

In her Experiment 2, the roles of binding relations were examined. Participants did the same tasks as in Experiment 1 except that arguments included a binding relation as illustrated in Figure 2. The results showed inductive strength ratings increased by adding a binding relation as well as shared attributes. Similarity ratings also increased by adding a binding relation as well as shared attributes.

Both of her hypotheses that were derived from the structural alignment view were supported. Hypothesis 1 is consistent with previous research on similarity(Goldstone, 1994; Goldstone et al., 1991). Hypothesis 2 is consistent with structure mapping theory based on structural alignment of analogy. More specifically, Hypothesis 2 corresponds to systematicity principle in structure mapping theory of analogy (Gentner, 1983).

Roles of Shared Relations in Induction

Lassaline's structural alignment view does not make a specific prediction about roles of shared attributes and shared relations in induction. The results showed that

inductive strength increased by adding a shared attribute. This is consistent with two facts that shared attributes increase similarity and that similarity between categories increases strength of induction.

In contrast, the results about roles of shared relations are problematic. Inductive strength did not increase by adding a shared relation although similarity did increase. Lassaline concluded that a relation must bind the target attribute and a shared attribute to increase inductive strength. However her conclusion cannot explain the results that shared attributes increased inductive strength, but shared relations did not. A hypothesis that binding relations contribute to increasing induction corresponds to systematicity principle in analogy. As most researchers agree, systematicity principle is indeed a strong constraint of analogical mapping, but it is not a unique constraint. In fact, Gentner, Rattermann, and Forbus (1993) revealed that shared relations that are not connected to a common relational structure contribute to soundness ratings of analogy between stories as well as similarity ratings between stories. In addition, shared relations are treated as a constraint of analogy in some computer models (Holyoak & Thagard, 1989; Thagard, Holyoak, Nelson, & Gochfeld, 1990).

In this paper, the structural alignment view of induction is generalized to account for roles of shared relations in induction. Two experiments were conducted to reexamine the roles of shared relations in induction from the viewpoint of a generalized structural alignment. Experiment 1 examined the possibility that the shared relations affect inductive strength. Experiment 2 addressed dissociative roles of shared relations in induction and similarity.

Experiment 1

Goldstone et al. (1991) found that a shared attribute has more weight on similarity than a shared relation when shared attributes are dominant, whereas a shared relation has more weight on similarity than a shared attribute when shared relations are dominant.

The arguments used in Lassaline's Experiment 1 had only zero or one shared relation and two or three shared attributes. Therefore a shared relation might have insufficient saliency on inductive strength. If this hypothesis is correct, shared relations contribute to inductive strength when the arguments have a sufficient number of shared relations.

Method

Participants Fifty-six Keio University undergraduates participated in the experiment as part of the requirements of an introductory psychology course.

Materials and Procedure Each participant was given a booklet that described all tasks and instructions.

Each participant was given a set of 20 pairs of "genotypes of creatures of outer space" that had crossing numbers of shared attributes and shared relations. The number of shared attributes and shared relations were varied from 0 to 4 and from 0 to 3, respectively. Figure 3 shows examples of the pairs. In pair (i) genotypes A and B have a shared attribute and 2 shared relations because both A and B have "◯" in the same place and have the same relations, "on(X, X)": two symbols of the same type are stacked, at the first and third columns. In pair (j) genotypes A and B have a shared attribute and 3 shared relations. The other pairs were constructed in the same manner.

Participants were showed pairs "genotypes of creatures of outer space," referred to as Creature A and Creature B, and were told that each description was intended to refer to a different pair of creatures. They were showed the color of Creature A as a premise. Then they were asked to rate the degree of confirmation that Creature B had the same color as Creature A by selecting a number from 1 (not confirmed) to 9 (completely confirmed) to indicate their judgment.

Four arguments were printed per page. Participants were instructed to spend about 30 seconds in rating the inductive strength of each argument. The orders of the arguments were randomized.

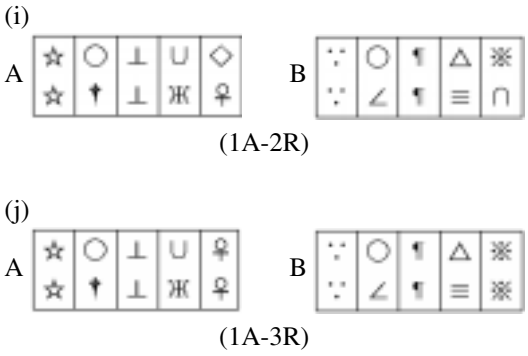

Figure 3: Example of stimuli used in Experiment 1. xA-yR indicates that the number of shared attributes is x, and the number of shared relations is y.

Results and Discussion

Since inductive strength judgments of 7 participants included missing values, they were eliminated from later analysis. As a result, 49 participants' data sets were analyzed.

Results are shown in Figure 4. Inductive strength increased with the addition of shared relations as well as the addition of shared attributes. Mean inductive strength when the arguments had 0, 1, 2, and 3 shared relations were 2.67, 2.95, 3,47, 4.06, respectively. The results showed that inductive strength increased with addition of shared relations. A two-way ANOVA was conducted on inductive strength, with number of shared attributes (0 to 4) and number of shared relations (0 to 3) as within-subject variables.

The ANOVA on inductive strength showed the main effects of number of shared attributes, $F(4,192) =$

$60.12, p <. 01$, and number of shared relations, $F(3,144) = 25.71, p <. 01$.

LSD (Least Significant Difference) post-hoc multiple comparison tests showed that inductive strength increased simply with the addition a shared attribute ($MSe = 2.77, LSD = .33, p <. 05$), and that inductive strength increased simply with the addition a shared relation ($MSe = 3.56, LSD = .34, p <. 05$). As an exceptional case, there was no significant difference between the conditions where number of shared relation were 0 and 1. There was no interaction between number of shared attributes and number of shared relations, $F(12,576) = .578, p > .1$.

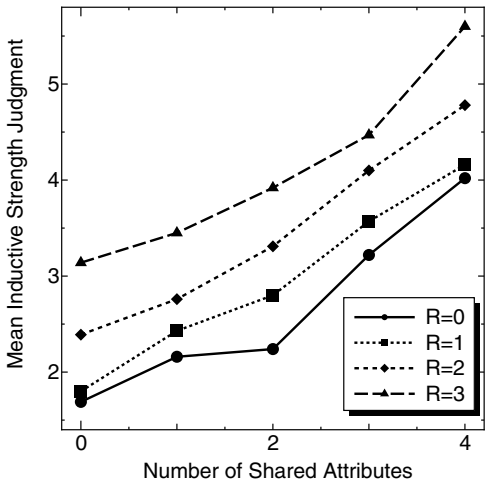

Figure 4: Mean inductive strength judgments from Experiment 1 as a function of number of shared attributes and number of shared relations. $R = 0$, 1, 2, and 3 indicate that numbers of shared relations are 0, 1, 2, and 3, respectively.

The results support the hypothesis that the shared relations contribute to increasing inductive strength judgments when a sufficient number of relations are shared. In addition, there was no significant difference between the conditions where number of shared relation were 0 and 1. This is consistent with Lassaline's results and can be accounted for by insufficiency of the number of shared relations.

A structural alignment view of induction is consistently generalized through Experiment 1. However, the results of Experiment 1 cannot explain dissociative roles of shared relations between induction and similarity because Lassaline's results showed shared relations contributed to increasing similarity but did not contribute to increasing inductive strength. Experiment 2 was conducted to explain these dissociative roles of the shared relations in inductive strength and similarity.

Experiment 2

A structural alignment view of similarity also suggests an explanation for the dissociative roles of shared relations in inductive strength and similarity. Markman and Gentner (1993) proposed that similarity judgment involves a process of structural alignment. A central prediction of structural alignment is that similarity judgments lead people to attend to the matching relational structure in a pair of items. Participants were given a pair of pictures containing cross-mappings where an attribute-based mapping and a relation-based mapping compete, and were asked to select other object in one picture that went with the cross-mapped object in the other. All of these stimuli were explicitly designed so that the participants' natural tendency was to select the similar object that shared an attribute with the other. The participants who rated the similarity of the scenes prior to performing the mapping tasks more often selected the relation-based mappings than the participants who simply performed the mapping tasks without prior similarity judgments.

These results suggest the hypothesis that the shared relations contribute to increasing inductive strength if participants rate similarities prior to inductive strength judgments even when few relations are shared. If the hypothesis is supported, the dissociative roles of shared relations in inductive strength and similarity in Lassaline's results are explained as follows. In inductive strength judgments, since only a relation was shared, a shared relation was not so salient as to contribute to increasing inductive strength. In similarity judgments, a structural alignment during similarity judgment made a shared relation so salient to contribute to increasing similarity.

Experiment 2 examined whether contribution of shared relations to inductive strength increases because of similarity judgments prior to inductive strength judgments.

Participants were assigned to one of the three inductive task conditions. Participants in the "Induction-only" condition performed inductive strength judgment in the same manner as in Experiment 1. Participants in the "Similarity-first" condition first performed similarity rating of categories in the premise and then performed inductive strength judgment. Participants in the "Nonaligning-first" condition first performed the nonaligning task and then performed inductive strength judgment. The Nonaligning-first condition was added in order to rule out the possibility that the difference of inductive strength between Induction-only and Similarity-first conditions was reduced to the difference in the time that participants looked at stimuli.

According to the hypothesis, the inductive strength judged by the participants in the Similarity-first condition is more affected by the shared relation compared with its strength judged by the participants in the two other conditions.

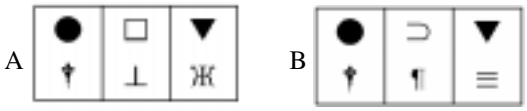
Method

Participants One hundred and sixty Keio University undergraduates participated in the experiment as part of the requirements of an introductory psychology course. They were randomly assigned to one of the three

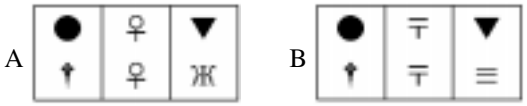
between-subject inductive task conditions.

Materials and Procedure Each participant was given a booklet that described all tasks and instructions in the same manner as in Experiment 1.

Participants in the Induction-only condition performed the same tasks as those in Experiment 1 except for the presented arguments. Each participant was given a set of 8 pairs of "genotypes of creatures of outer space." The number of shared attributes and shared relations were varied from 0 to 3 and 0 to 1, respectively. Figure 5 shows examples of the pairs.



(3A-0R)



(3A-1R)

Figure 5: Example of stimuli used in Experiment 2. xA-yR indicates that the number of shared attributes is x, and the number of shared relations is y.

Participants in the Similarity-first condition first rated similarities of "genotypes" in the arguments by selecting a number 1 (not similar at all) to 9 (very similar) to indicate their judgment. They then performed inductive strength ratings in the same manner as the participants in the Induction-only condition.

Participants in the Nonaligning-first condition first judged whether each creature was an animal or a plant. They then performed inductive strength ratings in the same manner as the participants in the Induction-only condition.

Participants were instructed to spend about 30 seconds in each judgment task.

Results and Discussion

Since judgments of 8 participants included missing values, they were eliminated from later analysis. As result, 51, 51, and 50 participants' data sets in the Induction-only, the Similarity-first, and the Nonaligning-first conditions were analyzed, respectively.

Results are shown in Figure 6. Inductive strength ratings increased by 1.13 points with the addition of a shared relation in the Similarity-first condition whereas inductive strength ratings increased by 0.43 and 0.30 points with the addition of a shared relation in the Induction-only and Nonaligning-first conditions, respectively.

A three-way ANOVA was conducted on inductive strength with inductive task conditions (Induction-only, Similarity-first, Nonaligning-first) as a between-subject

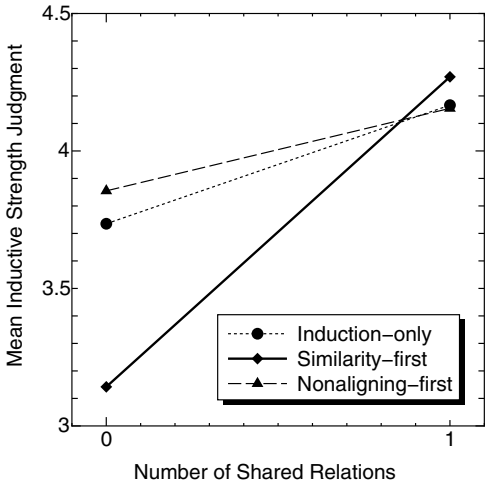


Figure 6: Mean inductive strength judgments from Experiment 2 as a function of number of shared relations.

variable, and with number of shared attributes (0 to 3) and number of shared relation (0, 1) as within-subject variables.

The ANOVA on inductive strength showed the main effects of number of shared relations, $F(1,149) = 38.46, p <. 01$, and number of shared attributes, $F(3,447) = 242.91, p <. 01$. There was no effect of inductive task condition, $F(2,149) = .69, p > .1$.

There was a significant interaction between inductive task conditions and number of shared relation, $F(2,149) = 6.60, p <. 01$. There was also a significant interaction between number of shared attributes and number of shared relation, $F(3,447) = 2.84, p <. 05$. There was no interaction between inductive task conditions and number of shared attributes, nor a three-way interaction ($F(6,447) = 1.49, p > .1$ and $F(6,447) = .51, p > .1$, respectively).

A significant interaction between inductive task condition and number of shared relation supports the hypothesis that similarity judgments prior to inductive strength increase contribution of shared relation to inductive strength. The results cannot be reduced to the difference of the time that participants looked at stimuli because nonaligning tasks did not increased contribution of shared relation to inductive strength judgments.

There were simple main effects of shared relation in the Induction-only and the Nonaligning-first conditions as well as in the Similarity-first condition ($F(1,149) = 6.21, p <. 05$, $F(1,149) = 3.01, p <. 1$, and $F(1,149) = 42.45, p <. 01$, respectively). The most likely explanation for these effects is that pictorial representations of stimuli made participants sensitive to shared relation.

The mean ratings of inductive strength in the Similarity-first condition was lower than two other conditions although there was no effect of inductive task condition. A possible interpretation is that maximal inductive strength was restrained because no pair of stimuli

was not so similar, and the absence of a shared relation decreased inductive strength.

A significant interaction between number of shared attributes and number of shared relation does not have specific interpretation. This interaction was caused by that effects of shared relation were smaller when the shared attribute was zero. The ANOVA was conducted again, this time eliminating the conditions where number of share attributes was zero. The results showed no interaction between number of shared attributes and number of shared relation. The other interactions and main effects did not change.

The results support the hypothesis that the shared relations contribute to increasing inductive strength if participants rate similarities prior to inductive strength judgments even when few shared relations are shared. The results also confirm the explanation for the dissociative roles of shared relations in inductive strength and similarity in Lassaline's results. In her results, a shared relation did not contribute to increasing inductive strength because the shared relation was not salient in this case, whereas a shared relation contributed to increasing similarity because structural alignment during similarity judgment made the shared relation salient.

General Discussion

The structural alignment view proposed by Lassaline (1996) can be consistently generalized as follows. First, attributes and relations are distinguished in induction as well as in similarity judgment. Second, a relation binding the target attribute and shared attributes is a strong constraint in induction. Third, in addition, shared attributes and shared relations are also constraints in induction if they are sufficiently salient. If shared relations are salient, participants easily align relations as well as attributes.

According to the structural alignment view proposed here, shared relations contribute to increasing inductive strength if they are sufficiently salient. In Experiment 1, a sufficient number of shared relations increased to make relations salient. The results showed that shared relations contributed to increasing inductive strength when a sufficient number of relations were shared.

In Experiment 2, participants rated similarity prior to inductive strength judgment to make a shared relation salient. According to the structural alignment view of similarity, similarity judgment involves a structural alignment that leads participants to attend to the matching relational structure. Therefore participants who rated similarity prior to inductive strength judgment were expected to be able to easily align a shared relation. The results showed that a shared relation contributes to increasing inductive strength if participants rated similarity prior to inductive strength judgment.

The results of Experiment 1 and 2 are consistent with the proposed structural alignment view, and are also consistent with the fact that shared relations contribute to soundness ratings of analogy. The proposed structural alignment view of induction more consistently corresponds to a structural alignment view of similarity and analogy than does Lassaline's.

Abstract

In this paper, we propose a model of embodied communications focusing on body movements. Moreover, we explore the validity of the model through psychological experiments on human-human and human-robot communications involving giving/receiving route directions. The proposed model emphasizes that, in order to achieve smooth communications, it is important for a *relationship* to emerge from a mutually entrained gesture and for a *joint viewpoint* to be obtained by this relationship. The experiments investigated the correlations between body movements and utterance understanding in order to confirm the importance of the two points described above. We use robots so that we can control parameters in experiments and discuss the issues related to the interaction between humans and artifacts. Results supported the validity of the proposed model: in the case of human-human communications, subjects could communicate smoothly when the relationship emerged from the mutually entrained gesture and the joint viewpoint was obtained; in the case of human-robot communications, subjects could understand the robot's utterances under the same conditions but not when the robot's gestures were restricted.

Introduction

Why do people use gestures when communicating? A common scene on a street involving giving/receiving route directions is some person and a stranger making gestures together as if dancing synchronously and rhythmically (see Figure 2). These gestures appear not only when the person describes turns at visible locations, but also at invisible ones. Moreover, it has been shown that people are unable to achieve smooth communications if they are restricted from using spontaneous gestures (Ono et al., 2001). Consequently, gestures play an important role in human-human communications.

In this paper, however, we do not discuss *emblem gestures* such as the OK sign; these gestures have arbitrarily defined meanings and figures in social conventions. The target of our research is *mutually entrained gestures*, where a speaker and a hearer spontaneously and synchronously move their bodies according to the entrainment resulting from mutual actions and utterances. We focus on such gestures because smooth communications between humans can be expected when these gestures are used, as illustrated by the above example involving giving/receiving route directions.

In order to investigate the mechanism of the mutually entrained gestures described above, we conduct experiments on human-robot communications as well as human-human communications. The reason why we use a robot is that we can unrestrictedly design experiments by using a programmable robot's gestures. Moreover, an investigation of human-robot communications can contribute to research on the methodology of robot design and the interaction between humans and artifacts.

The purpose of this paper is to propose a model of embodied communications that can give an explanation for the mechanism of communications described above and, moreover, provide evidence for the validity of the model through psychological experiments. The main characteristic of our model is to focus on the *relationship* emerging from a mutually entrained gesture and the *joint viewpoint* obtained by the relationship. The experiments concretely investigate the correlations between body movements and utterance understanding in human-human and human-robot communications involving giving/receiving route directions. In such a task, it is hard for a person and a stranger to communicate with each other if they do not share the same viewpoint. Here, in order to obtain a joint viewpoint, both sides need to construct a relationship emerging from mutually entrained body movements. We investigate the process of communications in the experiments by using our implemented robot.

Embodied Communications

Previous Research on Gestures

Research on gestures conducted to investigate the mechanism of communications emerged around 1980. In this field, McNeil was the first to carry out cutting-edge research. He pointed out that gestures are synchronized with speech in communications, and thus both are closely connected in the cognitive system (McNeil, 1987). McNeil's research provided findings leading to the development of research on the functions of gestures.

However, previous research has mainly analyzed the speaker's gestures in communications. In other words, many researchers have analytically investigated the correlations between speech and the speaker's body movements. Consequently, their aim has been to explain an internal mechanism of an individual speaker. However,

these research works have not looked into the dynamical mutual interaction between a speaker and a hearer.

In contrast, we focus on the *dynamical mutual interaction* in human-human and human-robot communications involving giving/receiving route directions. Especially, the reason why we come to adopt this route directions is that spontaneous gestures such as pointing easily appear in this context. Kita (2000) analyzed a speaker's gestures for this task but did not deal with the dynamical mutual interaction between them. In this research, we are able to give evidence for a hypothesis in detail because we can control the parameters in experiments by using a robot.

Model of Embodied Communications

In this paper, we propose a model of embodied communications focusing on entrained body movements. Our model is basically described by the following formula:

$$(S, U) \quad I$$

Here, is a viewpoint for understanding an utterance in a situation, S is the situation around a speaker and a hearer, U is an utterance from the speaker, and I is information obtained by having understood utterance U.

For example, let us suppose that in a situation S involving giving/receiving route directions, a person A utters "Go right" to a stranger B while both are facing each other. Let us further suppose that B understands from his/her viewpoint of A that the utterance means the "right" of A. In this case, the relation among the viewpoint, situation, utterance, and information is expressed as $_A(S, U_A) \quad I_B$. However, B may instead understand from his/her viewpoint of himself/herself that the utterance means the "right" of him/her. In this case, the relation is expressed as $_B(S, U_A) \quad I_B$.

The above ambiguity can be effectively solved by using an absolute coordinate system. For example, a person can clearly direct a stranger to a destination when both sides can use a visible landmark or object, or when both sides can construct a similar cognitive map (this assumes the stranger has previously visited the area). In this case, the viewpoint is determined definitely.

However, a person cannot use an absolute coordinate system when landmarks and turns to the destination are invisible, or when a stranger has not visited the area before. In this case, it is difficult to maintain a joint viewpoint in communications because the stranger is unable to imagine the route map of the person; the person's memory access also becomes overloaded.

As described in the Introduction, people seem to solve the problem of deciding a viewpoint by mutually entrained body movements. In other words, people first construct a relationship that emerges from a mutually entrained gesture. This relationship allows people to obtain a joint viewpoint. Finally, they can communicate with each other smoothly because of the utterance understanding achieved as a result of this joint viewpoint.

In our proposed model, the characteristic of communications discussed above is expressed as follows:

$$(\emptyset, U) \quad I \tag{1}$$

$$O({}_iR_j) \tag{2}$$

$$E(torso, arms, eyes) \quad {}_iR_j \tag{3}$$

Here, $\emptyset$ indicates the situation where there is nothing to point out, ${}_iR_j$ is the relationship between persons i and j, and O is a function for obtaining the viewpoint from the relationship. Moreover, *torso* and *arms* are expressions for entrained movements of the torso and arms, while *eyes* expresses the eye contact in communications. E is a function of the relationship emerging from the entrained movements.

These formulae express the process of communications involving giving/receiving route directions as follows. People cannot adopt an absolute coordinate system when they do not have a landmark or object to point out. Consequently, it is hard for them to achieve utterance understanding because of the difficulty of obtaining a joint viewpoint (Formula 1). To overcome this problem, they try to construct a relationship to obtain the joint viewpoint (Formula 2). This relationship emerges from mutual entrained body movements (Formula 3). Smooth communications can be achieved through these processes because the joint viewpoint makes both the speaker's utterance and the hearer's understanding easier.

In our model, we formalize the process of communications described above. We carry out psychological experiments to explore the validity of the model in the following two chapters.

Human-Human Communications

Experiments

Experiments on human-human communications were conducted by the following method.

Outline of experiments We focused on the interaction between a subject and a person involving giving/receiving route directions as an informant just happened to be passing by. Here, we investigated the appearance of their gestures, gestural arrangements, utterances, and the level of utterance understanding.

Subjects Ten undergraduate and graduate students (male and female). The subjects had not previously visited the experimental environment, and thus did not know the route to any destination at all.

Environment Figure 1 shows an outline of the experimental setup. These experiments were done in the hallways of a laboratory. Point A denotes the place where the route directions were given, and B and C denote the goals, i.e., a cafeteria and an information desk, respectively. Point T1 denotes a turn in the route from A to B, and Points T2-T4 denote turns from A to C. Only the corner of T1 is visible from A.

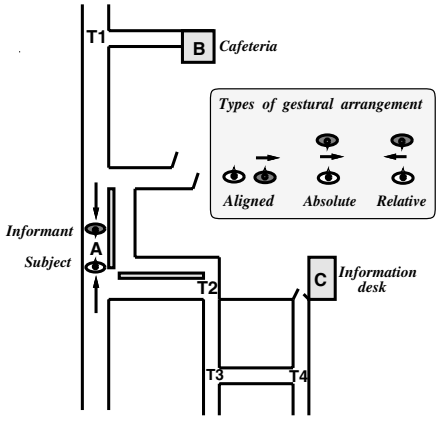

Figure 1: Experimental setup: arrangement of subject, informant, destinations, and turns.

Procedure The subjects received the following instructions from the experimenter (position A): "Ask a passerby the way to the cafeteria and the information desk and go to each place by yourself." The behaviors and utterances of the subjects and the persons were recorded with a camera and a microphone.

Evaluation The results of the experiments were evaluated from the record of the subjects' and the persons' behaviors, i.e., gestural arrangements, arm and elbow movements, and eye contact. In addition, we evaluated the time needed to communicate and the accuracy of the communicated information.

We classified the gestural expressions and arrangements into three categories, i.e., *aligned*, *absolute*, and *relative* gestures, following the literature (Kita, 2000) (see the upper right-hand side of Figure 1). To illustrate, let us assume that, at position A in Figure 1, an informant directs a subject to destination B by telling him/her to turn right at corner T1. In *aligned gesture*, an informant makes gestures to indicate his/her right aligning his/her torso orientation with that of the subject. In *absolute gesture*, an informant makes gestures to indicate the subject's right while facing the subject. In *relative gesture*, an informant makes gestures to indicate his/her right while facing the subject.

Results

First, the gestural expressions and arrangements that the subjects and the persons took were *aligned gesture* in nine out of ten cases and *relative gesture* in the remaining one case. These results were the same for both destinations. Next, Table 1 shows the analyzed results of synchronized gestures between the subjects and the persons. Synchronized arm gestures were observed in six out of ten cases in the route directions to destination B and eight out of ten cases to destination C. Here, synchronized arm gestures mean that the subject synchronously makes similar movements to the person's spontaneous arm movements (see Figure 2). In this experiment, all of the persons made arm movements. In addition, all of those who made synchronized gestures moved their extended arm right and left. Moreover, in all cases, they made eye contact. In particular, in the more complicated route to C, eye contact was made with high frequency.

Table 1: Results of entrained actions of arms and eyes in human-human interaction.

	Arm synchronized	Elbow extended	Eye contact (total)
Cafeteria	6/ 10	6/ 6	12 times/ 123 sec
Information	8/ 10	8/ 8	25 times/ 216 sec

Figure 2: Photo of mutually entrained gesture in human-human communications in the route direction.

Furthermore, the time needed to communicate was 17.2 seconds in the case of destination B but 32.2 seconds in the case of destination C. That is, the more complicated route direction statistically needed much more time ($t_{(18)} = 2.122,\ p < .05$). However, there was not much difference in the kinds of expressions used in the utterances between the two destinations. Eventually, all of the subjects could arrive at the two destinations. In other words, information was accurately communicated from the person to the subjects.

A summary of the experimental results is as follows. First, the persons acting as informants made spontaneous gestures not only when they described turns at visible locations but also at invisible ones. The subjects involuntarily made entrained and synchronized gestures to the persons.

We can assume the following relation between the experimental results and our proposed model. The subjects had not previously visited the experimental environment. Therefore, it was hard for the subjects to understand the persons' utterances because of the difficulty of obtaining a joint viewpoint (Formula 1). To overcome this problem, they tried to construct a relationship to obtain the joint viewpoint (Formula 2). This relationship emerged from mutually entrained body movements (Formula 3).

In the next chapter, we describe experiments on human-robot communications in order to investigate these mechanisms in detail. We can unrestrictedly design the experiments by using a programmable robot's gestures. Moreover, the investigation of human-robot communications can contribute to research on robot design and the interaction between humans and artifacts.

Human-Robot Communications

Experiments

Experiments on human-robot communications were conducted by the following method.

Outline of experiments We focused on the interaction between a subject and a robot as an informant involving giving/receiving route directions. Here, we investigated the appearance of the subject's gesture and the level of utterance understanding while changing the robot's gesture.

Subjects Thirty undergraduate and graduate students (male and female). The subjects were randomly divided into six groups. The subjects had not previously visited this experimental environment, as in the human-human experiments.

Robot Our robot system can make gestures by using the upper part of its body in the same way as a human (see Figure 3). The robot has two arms, two eyes, a mobile platform, and various actuators and sensors. With this equipment, the robot can generate almost all of the behaviors needed for communications with humans.

Environment Figure 4 shows an outline of the experimental setup. These experiments were done in the hallways and lobby of a laboratory. Points S and R denote the initial positions of the subject and robot, respectively. Point A denotes the place where the route directions were given, and B denotes the goal, i.e., the lobby. Points T1-T4 denote turns in the route from A to B, directed by the robot. Only the corner of T1 is visible from A.

Procedure The experiments consisted of the following six phases.

1. The subjects received the following instructions from the experimenter (position S): "Ask the robot the way to a lobby and go there by yourself." The question to the robot was specified as follows: "Tell me the way to the lobby."

2. The subjects moved from S to A, and the robot from R to A.

3. At position A, the subjects asked the question, and the robot answered. The robot could make its utterance with synthesized speech sounds. The content of the utterance was "Go forward, turn right, turn left, turn right, turn left, and then you'll be at the destination." The robot could make gestures while uttering this. In these experiments, we prepared six conditions under which the robot's gesture was changed.

4. The subjects tried to go to the lobby after receiving the robot's directions.

5. The experiments finished whether the subjects arrived at the lobby or gave up after losing their way. The subjects psychologically evaluated the robot through a questionnaire after the experiments finished.

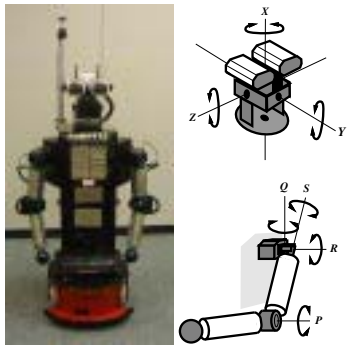

Figure 3: Outline of robot called "Robovie" (left), and robot's head and arm motion mechanisms (right).

Conditions We prepared the following six conditions from C-1 to C-6, which differed in terms of the robot's body movements (see Figure 5). The content of the utterance was the same under every condition.

C-1 (No gesture): The robot did not move.

C-2 (Absolute gesture): The robot raised its left arm leftward when telling the subject that he/she should go right, while it raised its right arm rightward when telling the subject that he/she should go left.

C-3 (Absolute gesture with gaze): In addition to C-2, the robot turned its eyes to the subject while making the utterance.

C-4 (Only aligned torso): The robot rotated so that it aligned its torso with the subject.

C-5 (Aligned gesture): In addition to C-4, the robot raised an arm forward telling the subject when he/she should go forward, rightward when the subject should go rightward, and leftward when the subject should go leftward.

C-6 (Aligned gesture with gaze): In addition to C-5, the robot turned its eyes to the subject while making the utterance.

Evaluations The results of the experiments were evaluated from the record of the subjects' behaviors and the answers of the questionnaire. In the questionnaire, the subjects were asked whether they understood the robot's utterance and to give a psychological evaluation of the robot on a seven-point scale for six items: *Familiarity*, *Sincerity*, *Reliability*, *Intelligence*, *Extroversion*, and *Kindness*.

Predictions

In the experiments, we gave evidence for the following three predictions derived from the proposed model. The more the robot's gestures increase systematically rather than randomly, i.e., the more the conditions shift in order from C-1 to C-6,

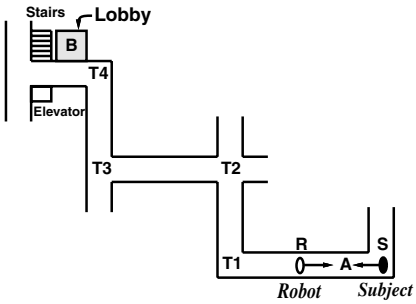

Figure 4: Experimental setup: arrangement of subject, robot, destination, and turns.

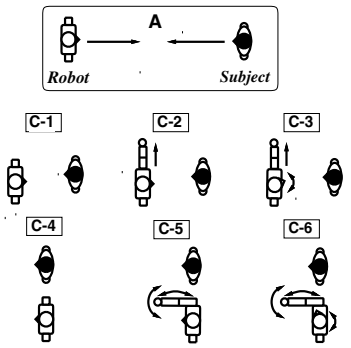

Figure 5: Outline of experimental conditions under changing robot gestures.

Prediction 1: the more the subjects' gestures will increase by entrainment and synchronization with the robot's, and consequently, a relationship will emerge from the mutual gestures.

Prediction 2: the easier the joint viewpoint will be obtained by the relationship.

Prediction 3: the easier the subjects will understand the utterance of the robot and arrive at the destination by using the obtained viewpoint.

Here, Predictions 1, 2, and 3 correspond to Formulae (3), (2), and (1) in the model of embodied communications, respectively.

Results

We give evidence for the three predictions in the order of Predictions 1, 3, and 2 to make the point of our argument clearer.

Verification of Prediction 1 From the observation results on the subjects' behaviors, we analyzed the subjects' gestures. First, the gestural arrangements that the subjects took were as we had expected (see Figure 5). Next, Figure 6 shows the ratio of appearances of the subjects' body movements under each condition. In this analysis, we classified the subjects into three categories: subjects who did not practice body movements at all (*Nothing*), subjects who only moved their hands (*Hand*), and subjects who moved and raised their hands

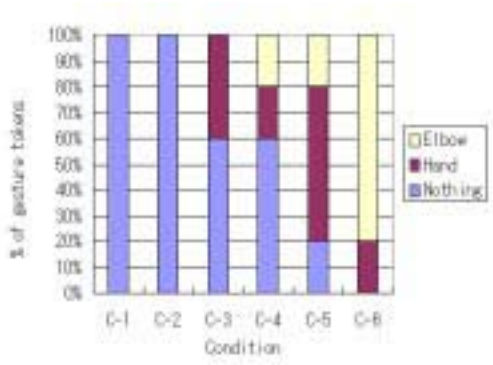

Figure 6: Results of subjects' body movements in human-robot interaction.

Figure 7: Photos of a subject under Condition C-1 (left) and two subjects under C-6 (center and right).

up to the elbow level (*Elbow*). In the analysis, a significant difference was found between the ratio of appearances of the subjects' body movements and the conditions ($\chi^2 = 25.210$, $p < 01$). In other words, the more the conditions shifted from 1 to 6 (i.e., the more the robot's gestures increased systematically), the more the subjects' gestures increased in sync. Moreover, the average scores for the numbers of times the subjects turned their eyes to the robot were higher when the robot turned to meet the eyes of the subjects (C-3 and C6).

We show appearances of the experiments in Figure 7. First, the left-hand side of Figure 7 shows the appearance of a subject not making any body movement and not turning his eyes to the robot at all (C-1). In contrast, the center of Figure 7 shows the appearance of a subject making an entrained body movement and turning his eyes to the robot (C-6). The right-hand side of Figure 7 also shows the appearance of a subject making an entrained body movement and turning her eyes in the same direction as the robot (C-6).

As a result of the observations described above, we could confirm that relationships emerged between the subjects and the robot from mutually entrained gestures. Consequently, Prediction 1 was supported.

Verification of Prediction 3 We recorded the time the subjects spent moving from A to B in Figure 4. Table 2 shows the average time and the number of subjects not arriving at B under each condition. Regarding the average time, no significant difference was found between the conditions. However, the average time in C-6 was the shortest.

Table 2: Average time until subjects' arrival at destination, and number of subjects not arriving at destination.

	C-1	C-2	C-3	C-4	C-5	C-6
Time to destination	69.5	71.3	67.7	70.2	66.8	65.4
Number of subjects not arriving	1	2	2	0	0	0

A noteworthy point is that a considerable number of subjects did not arrive at the goal in C-1, C-2, and C-3. The results of the questionnaire clearly showed that the subjects who did not arrive were unable to correctly understand the robot's utterance. One of the comments often heard was that they could not understand whether the robot's utterance including "left" and "right" meant the robot's or the subjects'. In other words, the reason why the subjects did not understand the utterance was that they could not obtain a joint viewpoint with the robot.

Consequently, the subjects who did manage to obtain a joint viewpoint could understand the robot's utterance and arrive at the goal, whereas the subjects who did not were unable to understand and arrive at the goal. Therefore, Prediction 3 was supported.

Verification of Prediction 2 First, we discuss obtaining a joint viewpoint from the aspect of body arrangement. Under the verification of Prediction 3, it was clear that all of the subjects could obtain a joint viewpoint when the robot aligned its body arrangement with the subject's to the destination (C-4, C-5, and C-6). In contrast, approximately one-third of the subjects could not obtain a joint viewpoint when the robot did not align its body arrangement (C-1, C-2, and C-3). Consequently, it is hard for subjects to obtain a joint viewpoint when no relationship emerges from the use of body arrangement.

Next, we discuss obtaining a joint viewpoint from the aspect of mutually entrained gestures such as synchronized arm movements and eye contact. As discussed in the verification of Prediction 1, from the results of the observed data, the more the robot's gestures increased systematically, the more the subjects' gestures did so. Moreover, from the results of the questionnaire, the more the conditions shifted from C-1 to C-6, the higher the average scores became (see Figure 8). In other words, the more the conditions shifted, the smoother the communications became. Based on this consideration, the relationship that emerged from the entrained gesture made it easier to obtain the joint viewpoint.

As a result of the above observations, Prediction 2 was supported. Consequently, the validity of our proposed model was given evidence by the three supported predictions.

Discussion and Conclusions

In this paper, we proposed a model of embodied communications focusing on body movements. Moreover, we explored the validity of the model through experiments on human-human communications involving giving/receiving route directions. The results of the experiments roughly supported our research direction. However, we could not investigate the details of the model because we were unable to manipulate the parameters in the experiments. Therefore, we carried out similar experiments using our implemented robot system. From the results of these experiments, we could give evidence for the validity of the model more appropriately.

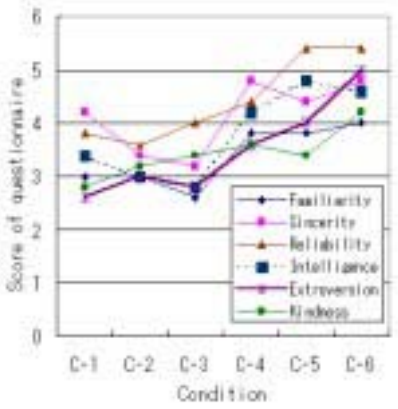

Figure 8: Results of subjects' psychological evaluations to a robot.

The contributions of our research should be viewed from two perspectives. First, our model of embodied communications suggests a new direction in research on communications. The target of previous research had mainly been the mechanism of verbal communications based on informatics approaches, e.g., Shannon's model. After that, McNeil's school pointed out that gestures are synchronized with speech. However, they have not yet modeled a whole conception of interactive communications that includes the function of embodiment. Our model gives a clue toward better understanding of such communications.

Moreover, the results of this research can be applied to interactive technologies between humans and artifacts. In other words, artifacts that can draw out human physical movements can make humans feel familiar with them. These cognitive engineering technologies enable us to develop an interface system and a robot system in the work's next generation.

Abstract

Given the importance attached to memory in everyday life, the inability to recall items on demand can be problematic. An apparently ironic phenomenon has been identified, however, which suggests that in addition to retrieving desired memories, the act of remembering inhibits or suppresses related memories. We show here that a competitive model, designed to investigate the development of the cortical visual system, provides an explanation for the suppression of some memories as a consequence of remembering others. We confirm a number of specific predictions based on our model as to when retrieval-induced forgetting effects should or should not occur. The model suggests that the mechanisms by which memories are formed and adapted may also underlie retrieval-induced forgetting effects. In addition to having important practical implications, the model provides a theoretical base for the transfer of theories and ideas between two separate levels (cortical processing and memory formation and adaptation) of understanding brain function.

Introduction

Recent evidence suggests that far from being a detrimental process, forgetting has an adaptive role (Anderson & McCulloch 1999; Bjork 1989; Macrae & MacLeod 1999). When trying to remember a specific memory, available retrieval cues are often insufficiently specified to the extent that related but unwanted information is also accessed. This unwanted information can interfere with our ability to retrieve the information we wish to recall. A potential solution to this problem is through the temporary suppression or inhibition of related material (Anderson & McCulloch 1999; Anderson & Spellman 1995; Anderson et al 1994; Anderson, Bjork & Bjork 2000; Bjork et al 1998; Ciranni & Shimamura 1999; MacLeod & Macrae 2001; Macrae & MacLeod 1999). Importantly, this temporary suppression of related memories – retrieval-induced forgetting – occurs without the need for explicit cues to forget and can therefore be considered an intrinsic part of the act of remembering (Anderson & Spellman 1995; Anderson et al 1994; Macrae & MacLeod 1999). Other explanations, such as output interference (where items recalled early in a list can interfere with the retrieval of subsequent items) have been eliminated as potential explanations for this phenomenon using a variety of methods. Direct evaluation using statistical techniques have shown that there is no tendency for the retrieval-induced forgetting effect to be larger for those participants who recalled practised items first (MacLeod in press; MacLeod & Macrae 2001; Macrae & MacLeod 1999). More direct evidence that an inhibitory process is involved comes from the demonstration that temporary suppression is observed in all items that are related (whether by initial set or other semantic links) to the suppressed items (i.e. second order inhibition, Anderson & Spellman 1995).

Retrieval-induced Forgetting

In an experiment showing retrieval-induced forgetting, participants are typically given two sets of information to remember regarding two separate categories (*A_1, A_2,…,A_10, B_i, B_ii, B_iii,…,B_x, e.g, 'John_cheerful, John_tolerant,…; Bill_vigorous, Bill_sensible,…)* followed by a retrieval practice session on a subset of items from one of the lists (the retrieval practice or RP set, *A_1, A_2,…A_5,* e.g. complete the following: *'John_ch____').* Following a distracter task (name as many capital cities as you can), participants are asked to recall as many of the items as possible.

Figure 1 shows the pattern of results from such an experiment (see Methods). A greater proportion of the practised items (RP+, left bar) were recalled than unpractised items in either the same set (RP-, middle bar) or in the unpractised set (NRP, right bar). This enhancement (RP+ versus NRP) shows the facilitatory effect of practice on subsequent recall. Retrieval-induced forgetting is evidenced by the fact that recall performance of the non-practised items in the practised set (RP-) was worse than the recall of non-practised items in the non-practised set (NRP). Thus, retrieval-induced forgetting is a selective suppression of related items and not a general suppression of all memories (Anderson & McCulloch 1999; Anderson & Spellman 1995; Anderson et al 1994, 2001; Bjork et al 1998; Ciranni & Shimamura 1999; MacLeod & Macrae 2001; Macrae & MacLeod 1999). An output interference explanation would predict that retrieval-induced forgetting effects would be higher where there was a tendency to recall RP+ items early in the list. As noted in the introduction, retrieval-induced forgetting is not due to items from the practiced subset (RP+ items)

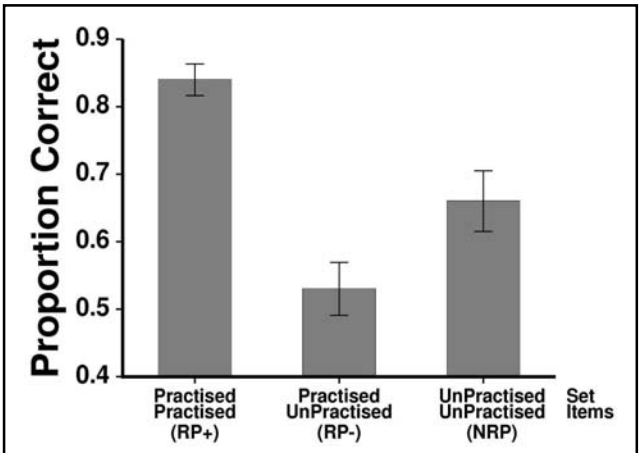

Figure 1: Retrieval-induced forgetting. Mean (±SEM, n=20) of the proportion of items remembered in each of each item type (RP+, RP- or NRP). The recall of unpractised items in the practised set (RP-) was less ($p < 0.05$) than the recall of the unpractised items in the unpractised set (NRP). Overall effect of conditions $F_{[2,38]}=28.3$, $p < 0.0005$.

being recalled first during the free recall task. (Anderson & Spellman 1995; MacLeod in press; MacLeod & Macrae 2001; Macrae & MacLeod 1999).

As the act of remembering during practice can selectively suppress memories for related but unpractised items, retrieval-induced forgetting must be influenced by the relationships between the items established during memory formation (Anderson & McCulloch 1999; Anderson & Spellman 1995). We were therefore interested in whether or not the mechanisms underlying retrieval-induced forgetting were different from the mechanisms that established the memories. We begin by considering, in broad terms, the required properties of a model consistent with the experimental data on retrieval-induced forgetting. As retrieval-induced forgetting is undirected (Anderson & McCulloch 1999; Anderson & Spellman 1995; Anderson et al 1994; Macrae & MacLeod 1999), learning should be unsupervised. Also, as retrieval-induced forgetting occurs with both semantic (Macrae & MacLeod 1999) and episodic memories (Ciranni & Shimamura 1999), the model should show unsupervised learning of both semantic and episodic-like memories. Finally, as inhibitory mechanisms are implicated, the model should contain inhibitory or competitive processes. We first show that a model consistent with this broad outline shows retrieval-induced forgetting. We then use the model to formulate three predictions of when retrieval-induced forgetting will not be observed. These predictions are verified experimentally.

Methods

We employed a computational approach to aid understanding of the role of inhibitory mechanisms in mental life. Computational testing of psychological theories can provide a powerful conceptual framework from which principled sets of research questions can be derived. However, using computational models in this way is not straightforward. The high number of degrees of freedom can lead to over-fitting the data and hence offer neither explanatory power nor generalisation to other scenarios. Hence, the observation that a model can fit experimental data is insufficient to validate the underlying processes within the model. In addition, results from a model developed around underlying psychological processes will be restricted in interpretation to the assumed underlying psychological processes: such a model can determine whether the assumed processes could underlie observed phenomena, but is weak at determining whether the assumed processes are actually in operation and important.

We address the caveats of using computational models to investigate psychological processing in two ways. First, selection of the category of model is made in broad terms without specific implementation to match observed psychological phenomena. If such a model is observed to produce the phenomena of interest, predictions from changing parameters in the model can then be validated with experimental data. The experimental validation of predictions overcomes, at least partially, the difficulties associated with many degrees of freedom that, in turn, gives rise to over-fitting the experimental data. Second, we assume that if the model reflects the psychological processes in a meaningful way, the parameters of the model will relate to psychological processes. This is not simply that the output of the model relates to the phenomena of interest, but that the parameters relate to underlying psychological processes. If the parameters of a model can be related to psychological processes, then the model may provide insight into how these processes interact.

Simulation methods

Damage to cortical tissue appears necessary for retrograde amnesia, implying that the neural representation in cortex correlates with the long-term memory. As inhibitory mechanisms are implicated in both the formation and functioning of neural representation (Oram and Perrett, 1994; Desimone and Duncan, 1995) and cognitive interactions between those representations (Anderson et al., 1994; Anderson and Spellman, 1995; Ciranni and Shimamura, 1999), we chose to investigate whether inhibitory processes involved in the formation of representations/memories could also underlie the interactions between representations/memories revealed by retrieval-induced forgetting.

The model consisted of two sets of 10 input nodes representing the individual items and two input nodes representing the set identifiers. The 22 input nodes were fully connected to the 10 output memory nodes, initially with random weights (0..1). Each node had an associated trace activity, Tr, which was dependent on the node's Tr at the previous time step and the node's current activity, Act: $Tr_{(time+1)} = (1-\delta)Tr_{time}+\delta Act$. The trace activity time constant δ was set at 0.5, with similar results obtained for δ=0.2 to δ=0.8. Weights between input i and memory node j were set randomly (0…1) with updating (learning) based on the trace activity, $\Delta Wt_{[i,j]} = \alpha(Act_i - Wt_{[i,j]})Trace_j$. The weight change rate, α, was 0.01 (similar results were obtained for α=0.001 to α=0.2). The $(Act_i - Wt_{[i,j]})$ ensures that the weights are bounded (-1..1). Initial training consisted of setting the activities of the input node corresponding to one of the input items to 1, calculating the activity of the memory nodes, updating the weights, then resetting the activity of the input node to 0, then "presenting" another input item. The activity of the set node associated with each input item was set to 1 while items within the set were presented. Retrieval practice was run in an analogous way for one half of the items in set 1, except that activity of the item nodes was set at 0.5 representing the partial cueing in the experimental paradigm. The representational strength was calculated as the activity in the item nodes following activation of 1.0 of the set node. Weight change was calculated as the change in the representational strength from after training to after retrieval practice. The change was normalised by dividing by the representational strength after training.

Experimental methods

Following Anderson et al (1994), the study comprised four phases: study, practice, distracter and final test. Participants were presented with ten items of information presented individually for 5s about two witness statements (one concerning a personal theft and the other a bank robbery). The practice phase followed immediately after the study phase. Participants were presented with five questions about a subset of items concerning one of the witness statements (RP+ items). Each question was presented three times. Counterbalancing and randomisation of question order ensured that each of the items appeared equally often in the RP+, RP-, and NRP conditions. Participants were then given a 5-min distracter task (write down as many capital cities as you can). Finally, participants were given a surprise free recall task in which they were required to recall as much of the information contained in the two statements. The number of correctly recalled items was noted for each group (RP+, RP- and NRP) and converted to proportion correct by dividing by the number of items in each group (RP+=5, RP-=5, NRP=10 and Figure 1).

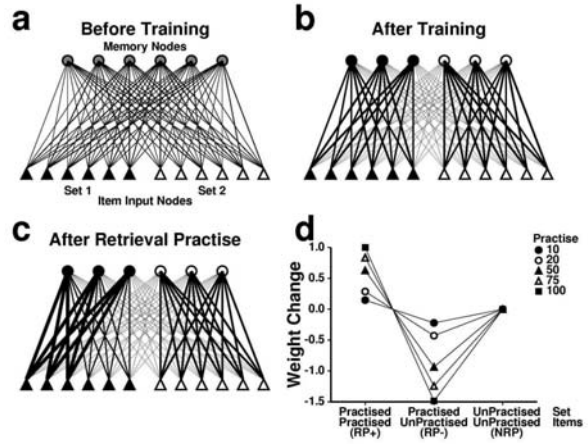

Figure 2: Modelling retrieval-induced forgetting. The weights between item nodes and memory nodes (representing the strength of the memory) are depicted by the thickness of the connecting line. The grey scale of the memory nodes indicates the strength of connection between the set node (not shown) and the memory nodes. A: Before training, the weights between input and memory nodes were random. B: Weights after the training. C: Retrieval practice re-distributed the weights linking the set 1 items with the memory nodes while leaving the weights on set 2 unaltered. D: Change in the weights representing the memories of the items and their set membership. As practice increases from 10 to 100 iterations, the strength of the memory inhibition also increases.

Results

We adapted a fully connected single layer unsupervised competitive model that forms both semantic and episodic like memories by learning from both past and present activity (Foldiak 1990, 1991; Oram & Foldiak 1996). The model consists of two sets of input items, each containing 10 items. Two additional inputs were used to indicate the training set. Initial weights from the input to output nodes were set randomly. Competitive interactions were modelled using a winner-take-all implementation (Foldiak 1991; Oram & Foldiak 1996) between the 10 nodes in the output layer. The network we adapted loads each output node with equal share of the input variance (Foldiak 1990; Oram & Foldiak 1996). The trace activity (Tr) imparts a structure to the inputs in the form of temporal co-variance between items. This co-variance results in the equally distributed input variance being parceled into equal variances associated with the different input sets and, within each set, an equal representation of the individual items. Thus, each output node learns part of the co-variation between a "set" node and the "item nodes". The resulting representation is best described as sparse, being neither fully distributed nor local. Sparse

representations have the benefits of both distributed and local representations and seem to describe accurately cortical representations. The greater the number of output nodes, the sparser the representation. Qualitatively similar results are obtained when the number of output nodes varies from 4-30 output nodes.

There were two phases to training: in the 1st phase, the model was sequentially presented with each of the items with the items set membership also activated. This is analogous to the initial learning phase of retrieval-induced forgetting paradigms. In the 2nd phase, the model is sequentially presented with half the items from one set partially activated (the retrieval practice phase). The changes in the strength of the model's representations of items at different stages during simulated retrieval-induced forgetting are shown schematically in Figure 2a-d (thick lines indicate a strong link, thin lines indicate a weak link). Before training (Figure 2a) the weights are random and small. Learning rules based on recent as well as current activity, such as those employed here, learn temporal relationships between inputs (episodic-like memories) as well as relationships between nodes with concurrent activity (semantic-like memories). This allows the individual set-item relationships and the relationships between the different items within the same set to be learned. The inhibitory competition between nodes keeps the set-item representations of different sets of inputs separate (Foldiak 1991; Oram & Foldiak 1996). After training (Figure 2b) the representation of the

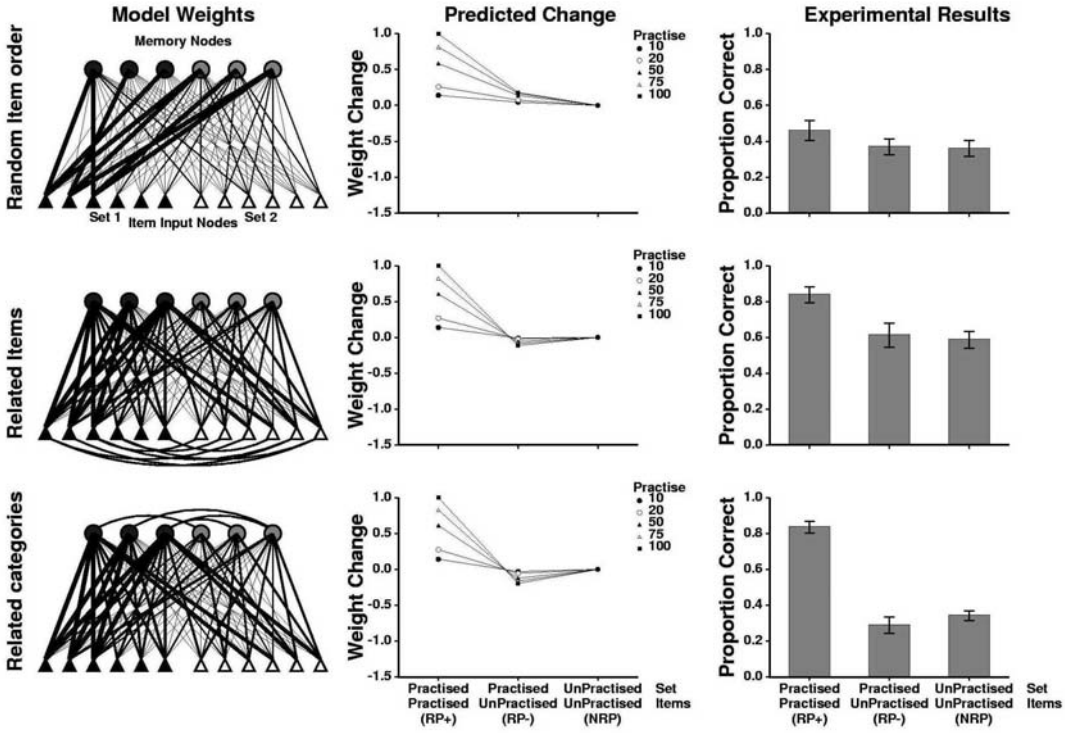

Figure 3: Predicting the disruption of retrieval-induced forgetting. The three rows show different conditions under which the model predicts that retrieval-induced forgetting will not occur and the results of experimental studies. The change in the representational strengths of the RP+, RP- and NRP items in the model following retrieval practice are shown in the middle column. The results of the experimental studies (mean proportion correct ±SEM in free recall for the RP+, RP- and NRP item types) are shown in the right column. Upper Row: Lack of coherence between items (random presentation of items). The model was run with trace activity time constant δ=1 (otherwise experiment as in Figure 1) producing overlapping representations of set 1 and set 2 (left). Accuracy of predicted recall was reduced compared with items which were temporally coherent. The absence of retrieval-induced forgetting (compare top middle with Figure 2D)was confirmed experimentally ($p > 0.5$, right). Middle Row: Effect of semantic links between items. Direct connections (strength = 0.5) between input items in set 1 and set 2 produces overlapping representations of set 1 and set 2 (left). Retrieval-induced forgetting was so attenuated that it was predicted to be undetectable experimentally (middle). This was confirmed experimentally ($p > 0.2$). Lower Row: Effect of confounding by category. When connections between memory nodes (25% chance) were included (strength = 0.5), item-set memories showed overlap between sets (left), which again predicts greatly attenuated effects of retrieval-induced forgetting (middle). This was also confirmed experimentally ($p > 0.05$).

items in the memory nodes is divided into two sets, with little or no overlap. Following retrieval-practice (Figure 2c), the strength of the representation of practised items (RP+) is increased (without the simulated retrieval practice, the representation of the RP- and RP+ items is equivalent). The strength of the representation of unpractised RP- items is reduced because of repeated occurrences of high activity in the memory nodes with no activity in the input nodes representing the RP- items. As the retrieval-practice did not activate the memory nodes associated with the NRP items, the strength of representation items in the non-practised set is not influenced by retrieval-practice. Figure 2d shows that the network predicts the phenomena associated with retrieval-induced forgetting: the expected recall of RP+ items is enhanced compared to the recall of the NRP items and, as with retrieval-induced forgetting, the recall of the RP- items is lower than the recall of the NRP items. Thus, a competitive model can show retrieval-induced forgetting effects. The model does not provide a direct prediction of any effect of the order in which items will be recalled: we use the strength of representation as our metric. Note, however, that although the representational strength would suggest free recall beginning with RP+ items, the retrieval-induced forgetting effect in the model is not due to any form of output interference, only the strength of representation.

Given the variable success experimenters have had in producing retrieval-induced forgetting effects, we were particularly interested in examining the conditions under which retrieval-induced forgetting would not occur. We wished therefore to evaluate the model by changing those model parameters which suggest a strong influence on retrieval-induced forgetting and experimentally testing the predicted effects. We chose to manipulate those model parameters that have readily identifiable psychological counterparts. If the model parameter that represents the degree of continuity between the items (trace activity) is reduced, the items in each of the different sets to be remembered do not form a coherent pattern after the initial training, and the clarity of the relationships between items and their sets is reduced (Figure 3, top left). The overlap between the representations of items in different sets predicts reduced levels of recall performance compared with the situation where the continuity between items is easily established. Following simulated retrieval-practice, the strength of both the RP- and the NRP item representations is reduced while the strength of the RP+ representations is increased, i.e., an absence of retrieval-induced forgetting (Figure 3, top middle). When items used in the initial experiment (Figure 1) were presented in random order such that no coherence between the items was evident, retrieval-induced forgetting did not occur. In addition, absolute performance levels were reduced compared to when the same items were presented in a coherent fashion (compare Figure 3, top right and Figure 1).

Links between individual input items of the different sets can be thought of as exemplar-exemplar links based on semantic relationships between item inputs. Activation of one item will lead to (partial) activation of those related items in the second set. The concurrent activation leads to item representations that do not map perfectly with the input set (Figure 3, center left), so that retrieval practice reduces the strength of representation of both the RP- and NRP items whilst increasing the RP+ representation (Figure 3, center). Semantic relationships between input items were obtained experimentally by using appearance descriptors concerning two individuals (e.g. *Bill_Nike trainers, Bill_Slim build…, John_Adidas trainers, John_Medium build*) as the input items (*trainers*, *build* etc forming explicit links). As predicted, retrieval-induced forgetting did not occur (Figure 3, center right). Finally, links between the representations of the item groups (the memory nodes) models the existence of pre-existing groupings involving the items. This can be thought of as the existence of indirect or implicit semantic links (exemplar-category-exemplar). The overlap of pre-existing groupings of the items of the different sets leads to the representation of single items being associated with both sets (Figure 3, lower left). The effect of confounding relationships between the memory nodes was examined by asking participants to learn representations of employees in different companies that were confounded by gender. Again, the prediction from the model was met: retrieval-induced forgetting did not occur (Figure 3, lower right).

Discussion

The results of these studies highlight two important aspects of memory formation and maintenance. First, we have shown a mechanism by which practice and revision (consolidation) of selected memories can lead to suppression of related memories but leave unrelated and unpractised memories unaffected (Figure 1). While others have noted the restricted occurrence of retrieval-induced forgetting (Anderson & McCulloch 1999), our model allows specific predictions to be made about both performance levels and the strength of retrieval-induced forgetting effects. The four predictions about performance in a cognitive memory task (Figure 3, middle column) were all tested and verified experimentally (Figure 3, right column). This suggests competitive models with learning based on past as well as present activity can help predict how, why and when these types of memory interactions occur. Second, the model suggests that the effects of practice and revision of selected memories are due to the same processes by which memories are first established and hence need not be regarded as separate cognitive processes. Support for retrieval-induced forgetting as an intrinsic

property of memory formation comes not simply from the demonstration that a model can produce retrieval-induced forgetting effects without explicitly coding the effect, but also that the same model predicts the absence of retrieval-induced forgetting effects (Figure 3).

In day-to-day function, retrieval-induced forgetting is important because it allows the updating or alteration of memory without interference of or disruption to other memories. For example, remembering where you parked your car today rather than where you had parked it yesterday should not interfere with your memory of the shopping you need to do. This type of selective adjustment of memories has practical implications: police interview techniques could be adjusted to minimise the potential loss of pertinent information from witnesses; teaching the establishment of conceptual links between aspects of the curriculum should be emphasised with revision of all the related material; students who revise only part of their course may well be placing themselves at a disadvantage because of the active suppression of related memories. If, as our model suggests, retrieval-induced forgetting effects are intrinsic to memory formation, then a simple way of reducing susceptibility to this kind of forgetting is to create many links during initial learning – perhaps the reason why the development of complex schemata provides resistance to such forgetting (Anderson & McCulloch 1999).

We have shown that a competitive model reveals a potential mechanism allowing prediction of experimental data concerning the cognitive processes of memory formation and adaptation. Our model shares similarities with that of Bauml (1997). However, our model suggest the suppression normally attributed to retrieval processes could itself be part of the mechanism by which memories interact and are updated. The choice of model provides not only a potential explanation of memory formation and adaptation but also demonstrates that a mechanism proposed to describe the selectivity of single cells within extra-striate visual cortex (Foldiak 1991; Oram & Foldiak 1996; Oram & Perrett 1996; Wallis & Rolls 1997) can operate at the much coarser scale associated with episodic and semantic memories and their interactions. The existence of a single model that operates at both fine (single cell) and coarse (episodic and semantic memory) scales is appealing because it provides a medium for the transfer of theories and ideas between two different levels of approach to brain function and their subsequent testing.

The Origins Of Syllable Systems : An Operational Model

Pierre-yves Oudeyer
Sony Computer Science Lab, Paris, France
e-mail : py@csl.sony.fr

Abstract

Many models, computational or not, exist that describe the acquisition of speech: they all rely on the pre-existence of some sort of linguistic structure in the input, i.e. speech itself. Very few address the question of how this coherence and structure appeared. We try here to give a solution concerning syllable systems. We propose an operational model that shows how a society of robotic agents, endowed with a set of non-linguistically specific motor, perceptual, cognitive and social constraints (some of them are obstacles whereas others are opportunities), can collectively build a coherent and structured syllable system from scratch. As opposed to many existing abstract models of the origins of language, as few shortcuts as possible were taken in the way the constraints are implemented. The structural properties of the produced sound systems are extensively studied under the light of phonetics and phonology and more broadly language theory. The model brings more plausibility in favor of theories of language that defend the idea that there needs no innate linguistic specific abilities to explain observed regularities in world languages.

Introduction

There are many studies about the acquisition of speech sounds, and of language in general: a lot of data is available and a lot of theories as well as operational models have been developed (Altman, 1995). Although there is great disagreement for these questions, one assumption is logically done by these models: a pre-existing language already exists, with all its associated structure and redundancies. Depending on the theoretical position, either the acquisition of a particular language consists in adjusting a number of parameters of an innate language acquisition device that already knows most of the structure of languages (Chomsky and Halle, 1968), or it relies on statistical learning techniques able to infer regularities from the data. On the contrary, very little is known about how this structure and these regularities originated, from a situation where there was no sound system at all (and no language in general) ?. In brief, how did speech emerge and why does it have the shape it has ? This ignorance is due partly because the question of the origins of language has been an actively researched question only for slightly more than a decade (Hurford et al. 1998), partly because no meaningful data of sound systems of the first speaking humans exists (by nature, speech leaves no physical trace in its environment), and partly because the questions are simply very difficult. Because the mechanisms involved are bound to be complex and involve the interaction of many environmental, physical, neuro-cognitive and genetic entities, and because data are scarce, computational models have been increasingly used in the past 10 years in the field (Hurford and al., 1998). Indeed, their nature allows on the one hand to test the operational plausibility and feasibility of otherwise highly speculative theories, and on the other hand to gain new insights about how certain aspects can be explained by the intricate dynamics of the complex systems involved.

The research presented here concerns a computational model of the origins of syllable systems, which are thought to be a fundamental unit of the complex sound system of nowadays human languages. It aims at being a plausible implementation, and hence a proof of feasibility, of the theory that claims that sound systems originated and have properties explained by the self-organization of motor, perceptual, cognitive, social and functional constraints that are not linguistically specific, and this in a cultural manner (Steels, 1998). In brief, this theory states that speech is a complex cultural adaptive system. Among the forces at stake are articulatory ease, perceptual distinctiveness, time and memory limitations, lexicon pressure, efficiency of communication, noise in the environment and conformance to the group. The word constraint is used in its most general meaning: it can be obstacle or opportunity as we will see.

A number of computational models concerning the origins of sound systems have already been developed, mainly for phonemes, and more precisely at the vowel level. Two of them are representative: the first one was developed by Lindblom (1992), and consisted in showing that the numerical optimization of a number of motor and perceptual constraints defined analytically allowed to predict the most frequent vowel systems in the human languages (in particular the high occurrence of the 5 vowel system /e i a u o/). Whereas it gave an idea of why vowel systems have the properties observed by phoneticians, it did not give any idea of what process could have achieved this optimization. Indeed, it is not plausible that primitive humans may have willingly computed all possible vowel systems and took an optimal one (and still if this was the case, this does not tell us how they agreed on which of the many solutions that exist). This shortcoming was corrected by the model of de Boer (1999)

, who places itself in a broader class of models consisting in setting up a society of agents endowed with realistic capabilities and physical constraints (whose action on the sound system is not explicit) and have them interact in order to build culturally an efficient communication system (Steels, 1998; Steels and Oudeyer 2000). More specifically, in his model no explicit optimization was performed, but rather near-optimal systems were obtained only as a side effect of adaptation to the task of building a communication system. Coherence did not come from a genetically pre-specified plan, but from the self-organization arising from positive feedback loops.

Much fewer existing models tackle the question of the origins of complex sounds, in particular syllables. Lindblom (1992) and then Redford (1998) have developed models resembling the Lindblom model for vowels: they consist in defining explicitly with analytical formulas a number of constraints, then running an optimization algorithm and showing that near-optimal systems have regularities characteristic of the most common syllable systems in the human languages. An example of regularity is the sonority hierarchy principle, which states that the sonority of syllables tends to increase until their nucleus, and then decrease. The present model aims at applying the multi-agent based modeling paradigm mentioned earlier to the question of the origins and properties of syllable systems: like de Boer's model, it should not only try to explain why syllables tend to be the way they are, but also what actual process built them. An additional requirement needed by this model is the fact that agents should be as realistic as possible, and should operate in the real world. One of the reasons for the need of realism is that previous models have shown that constraints are important to the shape of sound systems: when dealing with too abstract constraints, there is a danger to find wrong explanations. Furthermore, Redford showed that certain phenomena can be understood only by considering the interactions between constraints, so models should try to incorporate most of them.

The next section presents an overview of the model with its different modules. A more comprehensive description can be found in a companion paper (Oudeyer 2001) dedicated to the technical details of the setup. Then we present results about the behavior of the system, and discuss implications for phonetics and phonology, and more generally language epigenesis.

The model

The imitation game

Central to the model is the way agents interact. We use here the concept of game, recently operationalized in a number of computational models of the origins of language (Steels, 1998). A game is a sort of protocol that describes the outline of a conversation, allowing agents to coordinate by knowing who should try to say what kind of things at a particular moment. Here we use the "imitation game" developed by de Boer for his experiments on the emergence of vowel systems.

A round of a game involves two agents, one being called the speaker, and the other the hearer. Here we just note that each possess a repertoire of items/syllables/prototypes, with a score associated to each of them (this is the categorical memory described below). The speaker initiates the conversation by picking up one item in its repertoire and utters it. Then the hearer tries to imitate this sound by producing the item in its repertoire that matches best with what he heard. Then the speaker evaluates whether the imitation was good or not by checking whether the best match to this imitation in its repertoire corresponds to the item uttered initially. Then he gives a feedback signal to the hearer in a non-linguistic manner (see Steels, 1998). Finally, each agent updates its repertoire. If the imitation succeeded, the scores of involved items increase. Otherwise, the score of the item used by the speaker decreases and there are 2 possibilities for the hearer: either the score of the prototype used was below a certain threshold, and this item is modified by the agent who tries to find a better one ; or the score was above this threshold, which means that it may not be a good idea to change this item, and a new item is created, as close to the utterance of the speaker as the agent can do given its constraints and knowledge at this time of its life. Regularly the repertoire is cleant by removing the items that have a score too low. Initially, the repertoires of agents are empty. New items are added either by invention, which takes place regularly in response to the need of growing the repertoire, or by learning from others.

The production module

Vocal tract A physical model of the vocal tract is used, based on an implementation of Cook's model (Cook 1989). It consists in modeling the vocal tract together with the nasal tract as a set of tubes that act as filters, into which are sent acoustic waves produced by a model of the glottis and a noise source. There are 8 control parameters for the shape of the vocal tract, used for the production of syllables. Finally, articulators have a certain stiffness and inertia.

Control system The control system is responsible for driving the vocal tract shape parameters given an articulatory program, which is the articulatory specification of the syllable. Here we consider the syllable from the point of view of the frame-content theory (MacNeilage 1998) which defines it as an oscillation of the jaw (the frame) modulated by intermediary specific articulatory configurations, which represent a segmental content (the content) corresponding to what one may call phonemes. A very important aspect of syllables is that they are not a mere sequencing of segments by juxtaposition: co-articulation takes place, which means that each segment is influenced by its neighbors. This is crucial because it determines which syllables are difficult to pronounce and imitate. We model here co-articulation in a way very similar to what is described in (Massaro 1998), where segments are targets in a number of articulatory dimen-

sions. [1] The constraint of jaw oscillation is modeled by a force pulling in the direction of the position the articulators would have if the syllable was a pure frame, which means an oscillation without intermediary targets. This can be viewed as an elastic whose rest position at each time step is the pure frame configuration at this time step. It is motivated by important neuro-scientific evidence whose synthesis can be found in (MacNeilage, 1998). Finally, and crucially, we introduce a notion of articulatory cost, which consists in measuring on the one hand the effort necessary to achieve an articulatory program and on the other hand the difficulty of this articulatory program (how well targets are reached given all the constraints). This cost is used to model the principle of least effort explained in (Lindblom 1992) : easy articulatory programs/syllables tend to be remembered more easily than others. Agents are initially given a set of pre-defined targets that can be thought to come from an imitation game on simple sounds (which means they do not involve movements of the articulators) as described in (de Boer 2000, Steels and Oudeyer 2000). Although the degrees of freedom that we can control here do not correspond exactly to the degrees that are used to define human phonemes, we chose values (see Oudeyer 2001) that allow them to be good metaphors of vowels (V), liquids (C1) and plosives (C2), which mean respectively sonorant, less sonorant, and even less sonorant phonemes (sonority is directly related to the degree of obstruction of the air flow, which means the more articulators are opened, the more they contribute to a high sonority of the phoneme).

The perception module

The ear of agents consists of a model of the cochlea, and in particular the basilar membrane, as described in (Lyon 1997). It provides the successive excitation of this membrane over time. Each excitation trajectory is discretized both over time and frequency: 20 frequency bins are used and a sample is extracted every 10 ms. Next the trajectory is time normalized so as to be of length 25. As a measure of similarity between two perceptual trajectories, we used a technique well-known in the field of speech recognition, dynamic time warping (Sakoe and Chiba 1980). Agents use this measure to compute which item in their memory is the closest. No segmentation into "phonemes" is done in the recognition process: the recognition is done over the complete unsegmented sound. Agents discover which phonemes compose the syllable only after recognition of the syllable and by looking at the articulatory program associated to the matched perceptual trajectory in the exemplar (see below). In brief, phonemes are not relevant for perception, but only for production. This follows a view defended by a number of researchers (Seguy, Dupoux et Mehler 1995) who showed with psychological experiments that the syllable was the primary unit of recognition, and that phoneme recognition came only after.

[1] The difference is that, as described in the companion paper (Oudeyer 2001), we provide a biologically plausible implementation inspired from a number of neuroscientific findings (Bizzi and Mussa-Ivaldi 1991) and that uses techniques developed in the field of behavior-based robotics (Arkin 1999).

The brain module

The knowledge management module of our agents consists of 2 memories of exemplars and a mechanism to shape and use them. A first memory (the inverse mapping memory) consists of a set, limited in size, of exemplars that serve in the imitation process: they represent the skills of agents for this task. Exemplars are associations between articulatory programs and corresponding perceptual trajectories. The second memory (the categorical memory) is in fact a subset of the inverse-mapping memory, to which a score is added to each exemplar. Categorical memory is used to represent the particular sounds that count as categories in the sound system being collectively built by agents (corresponding exemplars are prototypes for categories). It corresponds to the memory of prototypes classically used in the imitation game (de Boer 1999).

Initially, the inverse mapping memory is built through babbling. Agents generate random articulatory programs, execute them with the control module and perceive the produced sound. They store each trial with a probability inverse to the articulatory cost involved (prob=1-cost). The number of exemplars that can be stored in this memory is typically quite limited (in the experiments presented below, there are 100 exemplars whereas the total number of possible syllables is slightly above 12000). So initially the inverse mapping memory is composed of exemplars which tend to be more numerous in zones where the cost is low than in zones where the cost is higher. As far as the categorical memory is concerned, it is initially empty, and will grow through learning and invention.

When an agent hears a sound and wants to imitate it, he first looks up in its categorical memory (if it is not empty) and find the item whose perceptual trajectory is most similar to the one he just heard. Then he executes the associated articulatory program (noise is always added to target values). Now, when the interaction is finished, in any case (either it succeeded or failed), it will try to improve its imitation. To do that, it finds in its inverse mapping memory the item (it) whose perceptual trajectory matches best (it may not be the same as the categorical item). Then it tries through babbling a small number of articulatory variations of this item that do not belong to the memory: each articulatory trial item is a mutated version of it, i.e. one target has been changed or added or deleted. This can be thought of the agent hearing at a point "ble", and having in its memory the closest item being "fle". Then it may try "vle", "fli", or even "ble" if the chance decides so (indeed, not all possible mutations are tried, which models time constraints: here they typically try 10 mutations). The important point is that these mutation trials are not forgotten for the future (some of them may be useless now, but very useful in the future): each of them is remembered with a probabil-

ity inverse to its articulatory cost. Of course, as we have memory limitation, when new items are added to the inverse mapping memory, some others have to be pruned. The strategy chosen here is the least biased: for each new item, a randomly chosen item is also deleted (only the items that belong to categorical memory can not be deleted).

The evolution of inverse mapping memory implied by this mechanism is as follows. Whereas at the beginning items are spread uniformly across "iso-cost" regions, which means skills are both general and imprecise (they have some capacity of imitation of many kinds of sounds, but not very precise), at the end examplars are clustered in certain zones corresponding to the particular sound system of the society of agents, which means skills are both specialized and precise. This is due to the fact that exemplars closest to sounds produced by other agents are differentiated and lead to an increase of exemplars in their local region at the cost of a decrease elsewhere.

Behavior of the model

Efficiency

The first thing one wants to know is simply whether populations of agents manage to develop a sound system of reasonable size and that allows them to communicate (imitations are successful). Figure 1 and 2 show an example of experiment involving 15 agents, with a memory limit on inverse-mapping memory of 100 exemplars, with vocalizations comprising between 2 and 4 targets included among 10 possible ones (which means that at a given moment, one agent never knows more than about 0.8 percent of the syllable space). In figure 1, each point represents the average success in the last 100 games, and on figure 2, each point represents the average size of categorical memory in the population (i.e. the mean number of syllables in agents' repertoires). We see that of course the success is very high right from the start: this is normal since at the beginning agents have basically one or two syllables in their repertoire, which implies that even if an imitation is quite bad in the absolute, it will still get well matched. The challenge is actually to remain at a high success rate while increasing the size of the repertoires. The 2 graphs shows that it is the case. To make these results convincing, the experiments was repeated 20 times (doing it more is rather infeasible since each experiment basically lasts about 2 days), and the average number of syllables and success was measured in the last 1000 games (over a total of 20000 games): 96.9 percent is the mean success and 79.1 is the mean number of categories/syllables.

The fact that the success remains high as the size of repertoire increases can be explained. At the beginning, agents have very few items in their repertoires, so even if their imitations are bad in the absolute, they will be successfully recognized since recognition is done by nearest-neighbours (for example, when 2 agents have only 1 item, no confusion is possible since their is only

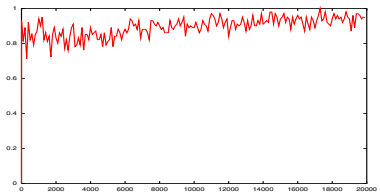

Figure 1: Example of the evolution of success in interactions for a society of agents who build a sound system from scratch

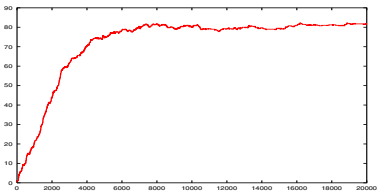

Figure 2: Corresponding evolution of mean number of items/categories in repertoires of agents along with time

1 category !). As time goes on, while their repertoires become larger, their imitation skills are also increasing : indeed, agents explore the articulatory/acoustic mapping locally in areas where they hear other utter sounds, and the new sounds they create are hence also in these areas. The consequence is a positive feed-back loop which makes that agents who knew very different parts of the mapping initially tend to synchronize their knowledge and become expert in the same (small) area (whereas at the beginning they have skills to imitate very different kinds of sounds, but are poor when it becomes to make subtle distinctions in small areas).

This result is relevant to all theories of speech (and more generally, theories of language), innatist or not. Indeed, whereas the literature is rich of reasons explaining why having complex sound systems was an advantage for the first speaking humans is, no precise account of how it could have been built was described. For instance, even Pinker and Bloom (1990), who defend the idea that nowadays humans have a lot of linguistic knowledge already encoded in the genes, acknowledge that it certainly got there through the Baldwin effect and so was initially certainly the result of a cultural process. They give cues about how acquired skills and sound systems could have been transferred into the genes, but not how they got to be acquired from a situation where there was nothing !

Structural properties

Now that we have seen that a communication system was effectively built, one has to look whether the structural properties of the produced repertoires of syllables resemble human syllable systems. Indeed, human syllable systems are far from random: only very few combinations of types of phonemes occur in human languages compared to the high number of mathematically possible ones, and some occur significantly more often than others (Vennemann 1988) . For instance, all languages have CV sylla-

Table 1: % of syllable types in produced and random systems

CV	CVC	CC
25.3/0.2	20.1/1.3	16.1/0.5
CCV	CVVC/CCVC/CVCC	other
14.4/1.3	14.1/22.5	10/74.2

Table 2: % of syllables respecting the sonority hierarchy

full model	jaw constraint removed	chance
70.9 per	21.5 per	5.3 per

bles, but CVCC is rare. The difference in frequencies exist both across and within languages. A first study about the syllable types of the produced systems was achieved. Statistics about the set of all the syllables produced by 20 runs were computed (for each run, measures were done after 20000 games). Table 1 sums up the result by giving the relative frequency in use of a number of syllable types (C means "C1 or C2"). "Relative frequency in use" means that each syllable counts as the number of times it has been used by the agents in the games it played in its life. This is a better measure than simply counting the frequency of occurrence in a syllable system, because it takes into account the fact that certain syllables tend to be adopted earlier than others, which implies that they are used more times than others, and models the relative frequency effects observed within languages. The second percentage measures the proportion of the particular type of syllable in the space of all combinatorially possible ones in the experiment. This can be viewed as a measure of syllable frequencies for randomly generated repertoires.

The first observation we can do is that there is a strong difference between the relative frequencies of syllables in actual systems and in randomly generated systems. Moreover, we find that the ordering between syllables types along their frequency is very similar to the one observed in human languages (Venemann 1988), except for the presence of CC in third position (which we think is due to too low acoustic noise, unlike in the real world). These results are rather consistent with those found by Redford, and conform to what she calls the "iterative principle of syllable structure": "simpler syllables types are expected to occur more frequently than complex ones in a systematic fashion", where the notion of "simplicity" is constructed over the most simple syllable CV: increase in complexity comes by adding C or V iteratively at the end or beginning or CV, and then after by replacing some C by V or the contrary.

A second important tendency of human languages is the "sonority hierarchy principle" [2] Whereas the measures in table 1 indicate that this seems to be the case in our experiment, they are too loose to conclude, especially because they blended C1 and C2. So we made measures over 20 runs about which proportion of syllables belonging to the repertoire of agents did obey the sonority hierarchy principle, using the fact that sonority of V is higher than sonority of C1, which is higher than sonority of C2 (due to the way they obstrue the air flow). Additionally, we made an experiment in which the oscillation of the jaw constraint was removed, in order to evaluate the hypothesis of Peter McNeilage that says that it is the main explanation for the sonority hierarchy principle. Table 1 sums up the results, with a column showing what is the proportion of syllable in the set of combinatorially possible syllables that respect this hierarchy.

We see that the sonority hierarchy is respected by most of the syllables of the emergent repertoires in the standard model. Yet, not all of them respect it, which is not that surprising since syllables like C1C1V do not imply an important deformation of the pure frame and so have a low cost, and do not respect the principle (there are 2 adjacent segments with the same sonority). Anyway, the actual percentage as compared to chance is much higher. When we remove the jaw constraint, we observe that the percentage of syllables respecting this hierarchy drops to around 20 percent, but is still substantially above chance. It indicates that the jaw constraint is crucial, but not the only responsible. In fact, when we remove the jaw constraint, we still start every syllable with the rest position corresponding to the closed jaw. So for instance syllables beginning with a vowel will still have a high articulatory cost. Of course for example C2C2 syllables will have a much lower cost in this case that in the case with jaw oscillation, but these syllables are very sensible to noise and do not have a high perceptual discriminability, which makes agents prune them quite often. As a result, a reasonable proportion of syllables that respect the hierarchy remain.

Until now, we have only looked at how the model produced syllable systems that reflect universal tendencies of human languages. We also have to look how well it matches with the diversity that exists across languages (Vennemann, 1988). Indeed, tendencies are just tendencies and there are cases of languages whose syllable systems properties significantly differ from the mean (for example, in Berber, there are many syllables with long consonant sequences, and more strikingly, there are syllables that do not contain any vowel). Additionally, two languages that have for instance the same relative ratios of syllable types may implement these in very different manners. The first kind of diversity was difficult to observe in a statistically significant manner, since the relative frequencies of syllable types most often are very close to the mean above mentioned, and since not enough experiments were conducted to study rare outliers. Nevertheless, they were observed in a number of particular cases: for example, one of the obtained population

[2] in a syllable, the sonority or loudness first increases to a peak and then may decrease again. It is very rare that for instance it first decreases and then increases or that more than 1 change in sonority direction occurs in one syllable. For instance, "ble" is preferred to "lbe". Sonority/loudness is directly linked to the degree of obstruction of the air, and in particular to the degree of opening of the jaw.

had 55 percent of CVC/CCV syllables against only 20 percent of CV syllables. Some categorical differences were also observed: several populations did not have any CVVC or CVCC syllables for instance. The second kind of diversity was easier to observe in the system: you never get the same repertoires in 2 different runs of the experiment. In the 20 runs used for the experiments above, the mean number of common syllables was 20.2 (repertoires had sizes varying between 70 and 88), among which mainly 2-phonemes syllables due to their small number. Of course this result is not directly transposable to real languages since we always gave here the same set of phonemes in the beginning, whereas in reality these phonemes are not pre-given but should co-evolve with syllables, and so may lead to repertoire of syllables composed of very different phonemes [3]. Nonetheless, we get a good idea of how universal tendencies come from the fact that there are non-linguistically specific constraints/biases in the problem that agents are solving, whereas diversity comes from both the fact that these constraints are soft and that there exist many satisfying solutions to the problem. Operationally speaking, variety emerges because there is stochasticity locally in time and space, which makes that different societies may engage different pathways due to historical events: indeed, historicity is fundamental to the explanation of diversity. This view contrasts in different aspects with a number of innatist theories, especially optimality theory (Archangeli and Lagendoen 1997). Of course, there is a common point with optimality theory at a very general level: constraints are crucial to the explanation of language universals and diversity. Yet, a fundamental difference is the nature of constraints: in the case of optimality theory, they are linguistically specific, whereas here they are generic constraints of the motor, perceptual and cognitive apparati (we also have social constraints that are far from any concept in OT) [4]. Now, the second important difference is the way these constraints are used to explain diversity: in OT, a particular syllable system corresponds to a particular ordering of constraints (some are stronger than others, which means that a low ranked constraint may be over-ridden if one has to satisfy a higher ranked constraint), which means a different constraint satisfaction problem. Conversely, in OT, one ordering of constraint implies a fixed syllable system (in terms of syllables types). On the contrary, here we do not require a different set of constraints to obtain different kinds of systems, because there are many syllables systems that can be developed and allow efficient communication given only one set of constraints. Our model thus avoids a number of theoretical problems that OT is faced with: Where do the linguistic constraints come from ? If they are in the genes, how did they get there ? Why are there different orderings of constraints ? How one can pass from a set of constraints to another (which must happen since language evolves and syllable systems change) ?

[3] This is a limit of the model (that the model of Redford has also), but we think this limitation was necessary as a first step so that the resulting dynamics would not get too complicated to analyse.

[4] An example of constraint in OT is the *COMPLEX constraint which states that syllables can have at most one consonant at an edge or the NOCODA constraint which says that syllables must end with vowels.

Conclusion

We have presented an operational model of the origins of syllable systems whose particularity is the stress on embodiment and situatedness constraints/opportunities, which implies the avoidance of many shortcuts usually taken in the literature. It illustrates in details (and brings more plausibility) the theory which states that speech originated in a cultural self-organized manner, taking as a starting point a set of generic non-linguistically specific learning, motor and perceptual capabilities. In addition to the demonstration of how an efficient communication system could be built with this parsimonious starting point, some specific properties that are known about human sound systems can be explained by our model : on the one hand, universal tendencies like the preference for CV and CVC syllable types and the sonority hierarchy principle ; on the other hand, diversity. A forthcoming paper will present other properties of human sound systems predicted by this model, among which the critical period phenomenon, the difficulty to learn a second language and the difficulty to learn artificial random sound systems as compared to “natural ones”.

Abstract

Do people learn categories by abstracting prototypes, forming simple rules, remembering specific exemplars, or by some combination of these? Although some consensus seems to be emerging for a combination of rule formation and exemplar memorization, recent work has revived interest in prototype abstraction (e.g., Smith et al., 1997; Smith & Minda, 1998). We reexamined this recent evidence with an eye toward an alternative simple strategy subjects could use within those particular studies. A very simple strategy, available in some categorization tasks in which corrective feedback is supplied, is to classify the current stimulus in the same category as the previous stimulus if the two are sufficiently similar to one another. This simple strategy makes no recourse to stored category representations of any kind. And this strategy will be useful only under certain circumstances. Reexamining the work by Smith and colleagues, we found that those category structures that produced evidence for prototype abstraction could be "learned," at least to some degree, using this simple strategy. Moreover, simulated data sets created using this simple strategy were better fitted by a prototype model than an exemplar model. We argue that evidence for prototype abstraction from the studies by Smith and colleagues may be weaker than they originally claimed.

Introduction

Do people learn categories by abstracting prototypes, forming rules, remembering exemplars, or some combination of these? In the domain of learning novel perceptual categories, we can trace an evolving dominance of various theoretical accounts from rule formation via hypothesis testing in the early years of categorization research (e.g., Bruner et al., 1956; Trabasso & Bower, 1968), to prototype abstraction (e.g., Homa, 1984; Posner & Keele, 1968; Reed, 1972), to exemplar storage and retrieval (e.g., Hintzman, 1986; Medin & Schaffer, 1978; Nosofsky, 1986). More recently, there has been a reemerging interest in the importance of rule learning in categorization (e.g., Allen & Brooks, 1991; Nosofsky et al., 1994; Nosofsky & Palmeri, 1998). This has led to a variety of hybrid accounts proposing a combination of rule learning and exemplar memorization (e.g., Erickson & Kruschke, 1998; Johansen & Palmeri, 2001; Palmeri, 1997; Palmeri & Johansen, 1999; see also Ashby et al., 1998). Arguably, there seems to be an emerging consensus for some kind of combination of rule formation and exemplar memorization in category learning. However, there has also been reemerging interest in the potential role of prototype abstraction in category learning as well, at least under certain conditions (e.g., Smith et al., 1997; Smith & Minda, 1998). The goal of the present article was to critically reexamine this evidence for prototype abstraction that has been provided by Smith and colleagues.

Evidence for Prototype Abstraction

According to prototype models, people learn categories by averaging their experiences with specific exemplars to derive an abstract prototype and classify new objects according to similarity to stored prototypes. By contrast, according to exemplar models, people remember information about specific exemplars, with no abstraction of prototypes or other summary representations, and classify new objects according to their similarity to the stored category exemplars. Numerous studies have compared and contrasted the ability of exemplar models and prototype models to account for observed categorization data – the majority of studies found that exemplar models provided a far superior account, both qualitatively and quantitatively (e.g., Buse-

Table 1: An example category structure from Smith and Minda (1998), Experiments 1 and 2.

111101	wysezo	000100	gafezi

meyer et al., 1984; Medin & Schaffer, 1978; Palmeri & Nosofsky, 2001; Shin & Nosofsky, 1992).

Challenging this previous work, there have been some recent studies that have reexamined the potential explanatory power of prototype models compared to exemplar models under a variety of conditions. In this work, prototype models have been found to provide superior fits to some data (Smith et al, 1997), especially early in category learning (Smith & Minda, 1998).

Smith et al. (1997) conducted a series of category learning experiments using structures and stimuli quite similar to those shown in Table 1. Stimuli were six-letter (6D) pronounceable nonsense words composed of alternating consonants and vowels. At each position in the word, one of two possible letters could appear (e.g., the first letter could be either g or w). The two categories were generally formed around a prototype (e.g., *gafuzi* versus *wysero*) with most category members differing from their category prototype along one or two dimensions (e.g., *gasuzi*). Category structures were either linearly separable (LS) or nonlinearly separable (NLS). Linearly separable categories are those that can be partitioned on the basis of some weighted additive combination of information along the individual dimensions (Medin & Schwanenflugel, 1981). As shown in Table 1, the nonlinearly separable categories have an exception item that is similar to the prototype of the contrasting category (e.g., *wysezo* in the *gafuzi* category). In the first experiment of Smith et al. (1997), one set of category structures was relatively easy (ELS and ENLS) and another set of category structures was relatively difficult (DLS and DNLS).

Each subject learned one of the four possible category structures. On each trial of the experiment, the subject was presented with one of the items randomly selected from one of the two categories to be learned. The subject classified the item as a member of category A or category B and then received corrective feedback.

Smith et al. (1997) tested the ability of prototype and exemplar models to account for the probabilities of classifying each stimulus as a member of category A or B on an individual subject basis. Across all four conditions of Experiment 1, they found that the prototype model provided a better account of the observed data than the exemplar model for half of their subjects. Their evidence for a prototype model advantage is summarized in Table 2. A YES in the second column signifies that at least some proportion of the individual subjects were displaying categorization behavior that a prototype model was better able to account for.

To illustrate, focusing on the ENLS category, the subgroup of subjects that a prototype model better accounted for averaged 92%, 78%, and 23% correct on the prototypes, normal items, and exception items, respectively. Consistent with the predictions of the prototype model, these subjects erroneously classified the exception items as being members of the category of the prototype they were most similar to. By contrast, the subgroup of subjects that an exemplar model better accounted for averaged 81%, 79%, and 51% correct on the prototypes, normal items, and exceptions.

Smith et al. (1997) and Smith and Minda (1998) provided further evidence for a prototype model advantage across a series of experiments. One manipulation they performed varied the number of dimensions present in the stimuli. With six dimensions (6D) it is possible to create well-differentiated categories (those with high within-category similarity and low between-category similarity) with many members. However, with only four stimulus dimensions (4D), categories tend to be much less differentiated and tend to be much smaller. Smith and colleagues have argued that prototype models show their advantage where prototype abstraction is most likely to succeed, under those conditions where categories are composed of stimuli with many dimensions, where categories are large in size, and where categories are well differentiated. (As a further manipulation, in some experiments nonsense words were used, while in other experiments cartoon animals were used.) As summarized in Table 2, Smith et al. (1997) documented a series of conditions under which some proportion of subjects used prototype abstraction. In Smith and Minda (1998), evidence for prototype abstraction, if present, was observed in the early stages of category learning; exemplar models generally fared better than prototype models in later stages of learning. For experiments from that article, a YES in the second column of Table 2 signifies that a prototype model provided a superior account of early stages of category learning. As shown in Table 2, for some of the category structures Smith and colleagues tested, no evidence for prototype abstraction was observed.

A Simple Categorization Strategy

In all of the experiments cited in Table 2, prototype and exemplar models were tested on their ability to account for category learning data. This data was obtained from trials in which subjects were presented a stimulus, made a response, received feedback, were presented the next stimulus, made a response, received feedback, and so on. Our goal was to investigate whether some subjects could be using some form of the following very simple strategy to provide the correct answer without relying on abstracted prototypes or learned exemplars.

We will use the category structure shown in Table 1 as an example. Suppose on some trial, a subject is shown the following stimulus

gafuzi

and is then asked to classify it as a member of category A or category B. The subject responds *category A* and the computer provides the following feedback

CORRECT, *gafuzi* is a member of *category A*

Suppose the subject is next presented this stimulus

gafuri

and is asked to classify it. The subject could rely on abstracted prototypes, or remembered exemplars, or

formed rules. But perhaps a far simpler strategy is to classify it in the same category as gafuzi since they are so similar to one another. The computer just verified that gafuzi is a member of *category A* so it is reasonable to guess that gafuri might also be a member of *category A* as well. The subject responds *category A* and the computer provides the following feedback

CORRECT, gafuri is a member of *category A*

Suppose the subject is next presented this stimulus

wasero

and is asked to classify it. Well, this stimulus looks quite different from the previous stimulus, gafuri, so it might make sense to classify it in the opposite category as gafuri. The subjects responds *category B* and the computer provides the following feedback

CORRECT, wasero is a member of *category B*

Finally, suppose the subject is presented this stimulus

gafezi

Well, this stimulus looks very different from the previous one, wasero, so it might make sense to classify it in the opposite category. The subject responds *category A* and the computer provides the following feedback

WRONG, gafezi is a member of *category B*

Examining Table 1, we see that this stimulus is the exception to category B. Using this very simple strategy, our subject would seem to perform quite well at classifying everything but the exceptions. Recall that Smith et al. (1997) reported that their subjects whose data was best fit by a prototype model consistently classified the exceptions in the wrong category as well.

Table 2: Evidence for Prototype Abstraction from Smith et al. (1997) and Smith & Minda (1998). See text for a key to the experiment notation.

Experiment	Prototypes?	Strategy?
Smith et al. (1997)		
Experiment 1 6D ELS	YES	YES
Experiment 1 6D DLS	YES	YES
Experiment 1 6D ENLS	YES	YES
Experiment 1 6D DNLS	YES	YES
Experiment 2 4D NLS	NO	NO
Experiment 2 6D NLS	YES	YES
Smith & Minda (1998)		
Experiment 1 6D LS	YES	YES
Experiment 1 6D NLS	YES	YES
Experiment 2 6D LS	YES	YES
Experiment 2 6D NLS	YES	YES
Experiment 3 4D LS	NO	NO
Experiment 3 4D NLS	NO	NO
Experiment 4 4D NLS	NO	NO
Experiment 4 6D NLS	YES	YES

Note. The second column (Prototypes) indicates whether evidence for prototype abstraction was observed. The third column (Strategy) indicates whether the simple strategy yields above chance performance.

Does the Simple Strategy Work?

This is certainly a strategy that subjects could use to classify stimuli in an experiment. But, does it really work? In many cases, no. For example, let us consider the experiments reported by Medin and Schwanenflugel (1981). Different groups of subjects learned linearly separable and nonlinearly separable categories. Their results were important because they found that NLS categories could be easier to learn than LS categories, a result inconsistent with additive prototype models. By contrast, this result was an a priori prediction of multiplicative exemplar models. Let us first examine the category structure from the third experiment from Medin and Schwanenflugel (1981) in some detail. Using an abstract notation, for the LS structure, stimuli in category A were 0111, 1110, and 1001 and stimuli in category B were 1000, 0001, and 0110. For the NLS structure, stimuli in category A were 1100, 0011, and 1111, and stimuli in category B were 0000, 0101, 1010. We performed a Monte Carlo simulation of the simple strategy using these two category structures. For each of 1000 simulated subjects for each structure, we generated a random sequence of stimulus trials. On each simulated trial, if the current stimulus matched the previous one on more than two dimensions, then the same category response as the previous stimulus was used. If the current stimulus matched the previous one on fewer than two dimensions, then the other category response was used. If the current stimulus matched the previous one on exactly two dimensions, then a random response

Table 3: Best fitting model (exemplar or prototype) to data simulated using the simple strategy. See text for a key to the experiment notation.

Experiment	Prototypes?	Model
Smith et al. (1997)		
Experiment 1 6D ELS	YES	Prototype
Experiment 1 6D DLS	YES	Prototype
Experiment 1 6D ENLS	YES	Prototype
Experiment 1 6D DNLS	YES	Prototype
Experiment 2 4D NLS	NO	–
Experiment 2 6D NLS	YES	Prototype
Smith & Minda (1998)		
Experiment 1 6D LS	YES	Prototype
Experiment 1 6D NLS	YES	Prototype
Experiment 2 6D LS	YES	Prototype
Experiment 2 6D NLS	YES	Prototype
Experiment 3 4D LS	NO	–
Experiment 3 4D NLS	NO	–
Experiment 4 4D NLS	NO	–
Experiment 4 6D NLS	YES	Prototype

Note. The second column (Prototypes) indicates whether evidence for prototype abstraction was observed. The third column (Model) indicates whether the Prototype or Exemplar model provided a better fit to the simulated data.

was generated. Averaging across 1000 simulated subjects, this strategy produced just 34.1% accuracy on the LS structure and 33.7% accuracy on the NLS structure. To see why this simple strategy produced accuracy far worse than just guessing, let us examine the NLS structure. Both NLS categories contain stimuli that mismatch each other on every dimension (1100 and 0011 in category A, 0101 and 1010 in category B). When these mismatching stimuli follow one another, they always produce the wrong response (e.g., erroneously categorizing 0011 as a member of category B because it is preceded by 1100 which was labeled a member of category A). Moreover, on other pairs of sequential trials, stimuli that follow one another match on exactly half the dimensions, producing a random response.

This simple strategy fails at other category structures as well. For the second experiment of Medin and Schwanenflugel (1981), the simple strategy produced 46.6% accuracy for their LS structure. For the category structure from Experiment 4 of Medin and Schaffer (1978), the simple strategy produced 44.6% accuracy. Applying the simple strategy to the classic category structures from Shepard, Hovland, and Jenkins (1961), we obtain predicted accuracies for their problem Types I-IV as following: Type I: 70.8%, Type II: 42.7%, Type III: 57.3%, Type IV: 57.0%, Type V: 43.1%, Type VI: 15.2%. In addition to underpredicting the overall level of accuracy observed when subjects learn these various categories, this simple strategy mispredicts the order of difficulty of the various problem types. For separable-dimension stimuli, the difficulty of the problems is ordered I < II < III,IV,V < VI (Nosofsky et al., 1994; see also Nosofsky & Palmeri, 1996). Clearly, this simple strategy is not what subjects can use in many categorization experiments.

But, the simple strategy does work well when "learning" other category structures. Let us turn now to the category structures shown in Table 1, which were used in Experiments 1 and 2 of Smith and Minda (1998). Following the procedure described above, we used a Monte Carlo simulation procedure to generate categorization responses for the LS and NLS categories using the simple strategy. For each of 1000 simulated subjects, we generated a random sequence of stimuli, with each stimulus presented once per block. On each trial, if the current stimulus matched the previous one on more than three dimensions, then the category of the previous stimulus was used. If the current stimulus matched the previous one on fewer than three dimensions, then the other category was used. If the current stimulus matched the previous one on exactly three dimensions, then a random response was generated.

Using this simple strategy, accuracy of approximately 73% correct was possible for both the LS and NLS category structures (excluding the two exceptions in the NLS structure, which the strategy erroneously classified, the overall accuracy for the remaining items was over 84%). The overall performance is less than the accuracies achieved by subjects in Smith and Minda (1998) by the end of learning, which was slightly over 80% correct for both structures. However, in their experiment, evidence for the use of prototypes was only observed during the early blocks of learning. Smith and Minda fitted the prototype and exemplar models to blocks of 56 trials and found that the prototype model fitted better than the exemplar model during the early blocks of learning. It seems quite possible that subjects might start out using the simple strategy during the early blocks of learning, especially since the strategy correctly classifies nearly three out of four items. As subjects acquire more experience with the categories, they may begin to shift to using stored exemplar information to improve performance.

We next tested the ability of this simple strategy to correctly categorize stimuli from the other category structures used by Smith and colleagues. As summarized in Table 2, the simple strategy produced above chance categorization in just those category structures that Smith and colleagues found evidence for prototype abstraction. For notation, those category structures for which the simple strategy works are indicated by a YES in the third column of Table 2. Could the apparent use of prototypes actually be a signature for the use of this very simple strategy instead?

Which Model Fits Better?

Suppose that subjects are engaging in this simple strategy of comparing the current stimulus with the previous one and selecting the category label accordingly. Let us further assume that they are not abstracting prototypes, are not learning rules, and are not remembering exemplars. Smith and colleagues obtained data from their subjects and compared how well a prototype model and an exemplar model accounted for categorization judgments. If subjects are using the simple strategy, would a prototype model or an exemplar model provide a better account of the categorization judgments produced using this simple strategy?

We will focus on just those structures for which the simple strategy actually yields above chance categorization, as indicated by a YES in the third column of Table 2. Using the simple strategy, we employed the Monte Carlo simulation techniques discussed earlier to generate data from a large number of simulated subjects for each of the indicated category structures. We then examined how well a prototype model or an exemplar model accounted for this simulated data. Clearly one possibility is that the prototype model accounted for some of the simulated data and an exemplar model accounted for the rest of the simulated data. A far more interesting possibility is that either an exemplar model or a prototype model provided a better account for the entire set of simulated data. This would pose an interesting problem of identifiability. The data were generated using a simple strategy of local stimulus comparisons without storing long-term category representations of

any kind. Yet by comparing just a prototype model and an exemplar model, we may erroneously conclude on the basis of model fits that subjects were actually abstracting prototypes or remembering exemplars.

To be specific, we fitted a prototype model and an exemplar model to the simulated data generated using the simple strategy. For the exemplar model, an item to be classified is compared with the stored exemplars of category A and category B. The probability of classifying the item into one of those categories is given by the relative summed similarity of the item to the stored exemplars of the two categories. For the prototype model, the probability of classifying the item is given by the relative similarity to the prototypes of the two categories. Similarity between an item i and a stored exemplar j (or an abstracted prototype j) is given by

$$S_{ij} = \prod_m s_m^{\delta(i,j)}$$

where the $0<s_m<1$ are free parameters along all m dimensions. The $\delta(i,j)$ is a function that returns a 0 if i and j match along dimension m and returns a 1 if i and j mismatch. A small value of s_m indicates that dimension m is particularly diagnostic. Because of the multiplicative similarity rule, mismatches along that dimension will have a large effect on decreasing similarity.

For the exemplar model, evidence for category A, E_A, is found by summing the similarities of an item to all exemplars in category A, and evidence for category B, E_B, is found by summing the similarities to all exemplars in category B. For the prototype model, evidence for category A, E_A, is the similarity to the category A prototype, and the evidence for category B, E_B, is the similarity to the category B prototype. The probability of classifying i into category A is then given by

$$P(A \mid i) = \frac{b_A E_A}{b_A E_A + b_B E_B}$$

where b_A is the category A bias (as might be expected, the bias terms did not contribute to any significantly improved fits to the simulated data). The prototype model and the exemplar model were fitted to the simulated data using a hill-climbing procedure that located parameters that minimized the sum of squared error between simulated observations and model predictions.

The summary of this modeling was straightforward. The prototype model provided a better account of the data that was simulated using the simple strategy than did the exemplar model. This finding is summarized in Table 3. As shown in the third column, for every structure which could be "learned" using the simple strategy, and for which Smith and colleagues found evidence for prototype abstraction, the prototype model provided a superior account of the simulated data. Although the data was generated using a strategy that made no recourse to abstract prototypes, the prototype model fitted that simulated data better than the exemplar model. If subjects were indeed using this simple strategy, one might erroneously conclude that they were abstracting prototypes when in fact they were relying on local stimulus information to make a categorization decision.

Summary and Conclusions

Smith and colleagues (Smith et al., 1997; Smith & Minda, 1998) have provided evidence for prototype abstraction in category learning. We noted that in their experiments, they examined data from learning trials in which feedback was always provided. We investigated the possibility that subjects could use this corrective feedback to classify the subsequent item in the category learning task without making recourse to long-term category representations of any kind. According to this simple strategy, subjects must only compare the current item with the previous one. The previous item had been labeled explicitly by the experimenter in the form of corrective category feedback. The current item is classified in the same category as the previous one if they are sufficiently similar to one another, otherwise the current item is classified in the other category.

First, we observed that those structures that Smith and colleagues found evidence for prototype abstraction were those category structures which could be "learned" using this simple strategy. In other words, engaging in these local stimulus comparisons could produce categorization accuracy greater than chance. For comparison, we documented a number of other category structures for which this simple strategy would be unsuccessful.

Second, we simulated data using this simple strategy for those structures for which the simple strategy would work. We then fitted a prototype and an exemplar model to this simulated data. In every case, the prototype model fitted the simulated data better. If subjects were to use this simple strategy, without relying on stored category representations, we might erroneously conclude from these model fits that subjects were abstracting prototypes when they were not.

In a recent paper, Stewart, Brown, and Chater (in press) documented evidence for the use of sequential information in categorization similar to what we are proposing. Using what they called a memory and contrast (MAC) strategy, they tested whether subjects would respond with the same category as on the previous trial if there was a small difference between the two stimuli, and a different label if the difference was large, just like the simple strategy we investigated. Not only did they demonstrate that the MAC strategy could achieve well over 80% accuracy on the category structures they tested, but they also reported highly systematic sequence effects in the experiments they reported, which were consistent with the use of a MAC strategy. The sequence effects they observed were inconsistent with exemplar models and other models they investigated.

So, the conclusion of our work along with that of Stewart and colleagues is perhaps best described as a cautionary tale. When we engage subjects in category learning experiments, our goal is typically to understand something about the long-term category representations

that subjects may have formed about those categories. Yet, subjects will use whatever information they have available to them to make a correct response, perhaps without even using any long-term category knowledge. They can clearly use feedback from previous trials to categorize on a current trial, at least under some circumstances. Or they can learn something about categories during testing in ways that may be entirely unanticipated by the investigator.

Abstract

Two experiments are described that examine the role of speed in the categorisation of affective biological motion displays. For the first experiment movements were recorded for 10 affects and the point-light animations of them were shown to participants in a recognition task. The resultant confusion matrices were analysed using the ALSCAL multi-dimensional scaling procedure and produced a 2-dimensional psychological space. The psychological space for discrimination was similar to that from recent models of experienced affect in that the first dimension corresponded to the activation dimension from these models. A strong correlation between the movement speed and the activation dimension confirmed the finding. From these results it would appear that the mapping between stimulus properties and representation of activation in affect is a fairly direct one. For the second experiment more sad, angry and neutral movements were collected. New movements of different duration, but identical spatial displacement were made using an interpolation algorithm. Observers viewed the movements as point light displays and heir task was to rate intensity of affect. Results from this experiment indicate speed plays a major role in modulating the intensity of activation in perceived affect.

Introduction

Humans can easily tell each other apart and interpret subtle differences in behaviour that communicates intentions, identity and emotions easily. Cues from facial features are used for much of this recognition, however, highly impoverished stimuli - such as point-light displays - convey sufficient information for the recognition of such person properties (Barclay, Cutting & Kozlowski, 1978, Cutting & Kozlowski, 1977; Dittrich, Troscianko, Lea & Morgan, 1986; Hill & Pollick, 2000; Kozlowski & Cutting, 1978; Mather & Murdoch, 1994; Runeson & Frykholm, 1981; Runeson & Frykholm, 1983; Walk & Homan, 1984). The cues that convey this information in biological motion are of primary interest to us and using point light displays of human arm movements, we have concentrated on the recognition of emotion from biological motion.

In exploring the way in which humans recognise affect, it is possible not only to look at the accuracy with which an affect is recognised, but also at the structure of the representation of affect. A number of models for the structure of experienced affect have been suggested that resemble each other in a number of factors (Russell, 1980; Watson and Tellegen, 1985; Thayer, 1989, Larsen and Diener; 1992; Feldman, Barrett and Russell, 1999). The similarities between these models are that the structure of affect is a two-dimensional and continuous structure. This structure is referred to as a circumplex model (Feldman, Barrett and Russell, 1999). The two dimensions of the circumplex models are bipolar and independent. One dimension represents valence (for instance hedonic tone, pleasant – unpleasant) and the other, arousal or activation (arousal – sleep/ activated – deactivated). The models are also continuous, with affects falling on a circle, centred on the origin of the psychological space defined by the two dimensions.

Although these models were established as representing one's own experience of affect, there is recent evident to suggest that experience and perception interact when observing another person's actions (Decety and Grezes, 1999; Rizzolatti, Fadiga, Gallese and Foggassi, 1996). Additionally biological motion relies on both specialised bottom-up processes of motion detection (Mather, Radford and West, 1992; Neri, Morrone and Burr, 1998) and interactions between these and top-down processes (Shiffrar and Freyd, 1990, 1993; Thornton, Pinto and Shiffrar, 1998). In the case of affect perception such a top-down process may well originate from the influence of an internal structure of affect.

It seems reasonable, therefore, to further explore the possible relationship between perception and structure of affect. There is also, currently, little research that concentrates specifically at the recognition of emotion

from biological motion. The special case of interpreting stylised dance movements from point-light displays, has received some attention (Dittrich, Troscianko, Lea & Morgan, 1986, Walk & Homan, 1984). Dittrich et al found good evidence that these movements can be expressive, however, they did not address more typical movements.

Two experiments are reported that highlight the relationship between the structure of experienced affect and perception of other's affect from simple arm movements. We also report the importance of the role that the speed of such movements, play in affect discrimination.

Experiments

General Methods

Movement Collection Arm movement data was obtained using a three-dimensional position measurement system (Optotrak, Northern Digital). Actors read the emotional scene setting story and then performed drinking and knocking actions. While they made the movements, the position of their head, right shoulder, elbow, wrist, and the first and fourth metacarpal joints were recorded using infra red emitting diodes.

Each movement record was processed to obtain the start and end of the movement as well as other kinematic properties such as tangential velocity, acceleration and jerk of the wrist. The start of the movement was defined as the point 116 msec before the tangential velocity of the wrist rose above a criterion value, and the end by the point 116 msec after the velocity passed below the criterion. This start/end velocity criterion was defined as 5% of the peak tangential velocity of the wrist. To measure kinematics, instantaneous measures of the wrist kinematics (velocity, acceleration and jerk) were taken and kinematic markers of duration, average velocity, peak velocity, peak acceleration, peak deceleration and jerk index were identified. Jerk index was defined as the magnitude of the jerk averaged over the entire movement and relates to the smoothness of a movement (Flash & Hogan, 1985).

Stimuli In all experiments each recorded point of the arm movement was presented as a point light on a graphics computer (Octane, SGI) from a sagittal view.

Experiment 1

We presented knocking and drinking movements with 10 different affects and measured the ability of participants to categorise affect. We examined the perception of affect within the framework of a psychological space and related aspects of this psychological space to physical properties of the movements.

Methods

Movement Collection Knocking and drinking movements were recorded with affect. Two actors read a brief story that set the emotional scene for each movement. Measurements of the 10 affects (afraid, angry, excited, happy, neutral, relaxed, sad, strong, tired and weak) were obtained. This yielded a total of 120 movements (10 affects X 2 actors X 2 actions X 3 repetitions), however, due to recording difficulties data was lost for 2 movements of one actor.

Stimuli and Participants All 118 movements were displayed as above to fourteen Glasgow University student volunteers. Participants were naïve to the purpose of the study and were paid for their participation.

Design and Procedure Displays were blocked by the possible combinations of actor and action (2 actors x 2 actions). There were 4 trial blocks and a practice session of four trials. The order of blocks was randomised and participants were told that they would see a knocking or drinking arm movement. For each trial, participants viewed a computer display of the movement and were then presented with a dialog box that contained the names of the ten possible affects. Their task was to identify the affect by selecting one of the 10 choices.

Results

Over all the trials participants answered correctly 30% of the time; ranging from 15% (strong) to 50% (afraid) correct, this was significantly better than the chance value of 10% [t (13) = 20.3, $p < .005$, two-tailed]. Although the overall recognition rate was not high this

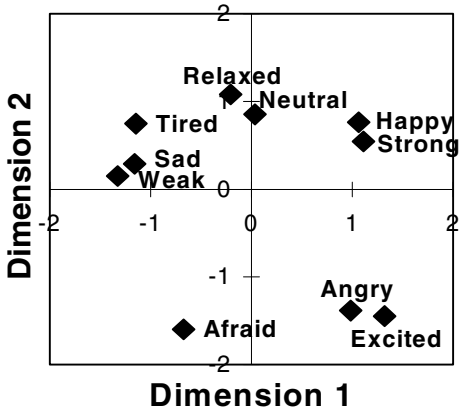

Figure 1. The psychological space obtained for Experiment 1

could be partially accounted for by some consistent misidentifications. For example, weak movements were identified as weak, sad or tired with equal frequency.

To better understand the structure of the results, a psychological space of the affects was constructed using the INDSCAL multidimensional scaling procedure (Kruskal and Wish, 1978). The 10x10 confusion matrix for each of the 4 block conditions was converted to measures of dissimilarity and input to the INDSCAL algorithm. The resultant solution was a unique 2-dimensional psychological space (see Figure 1) with r^2 = .87 and stress = .15. The first dimension accounted for approximately 70% of the variance and the second dimension for 17% of the variance. The two-dimensional structure of the psychological space is similar to that which would be predicted from a circumplex model of affect (see introduction) with the first dimension representing activation and the second dimension representing pleasantness.

Comparison of Psychological Space to Movement Kinematics.

We examined the movement kinematics to see whether any physical properties of the movement were related to either of the two dimensions defining the psychological space.

One of the striking things in the movement data is that the kinematic markers we measured consistently and smoothly differed between affects. For instance, sad movements were always slower than neutral movements and both these were slower than angry movement. This seems to correspond to the activation dimension from the models of affect. To test this, the kinematic markers were correlated to Dimension 1 and Dimension 2 co-ordinates of the 10 affects in the psychological space. Results of all these correlations are presented in Table 1, and Figure 2 shows an example of this relationship.

From Table 1 we can see the Dimension 1 (activation) co-ordinate of an affect correlated with the kinematic markers in such a way that energetic movements were positively correlated with shorter duration and greater magnitudes of average velocity, peak velocity, acceleration, deceleration and jerk. For Dimension 2 we found that, to a lesser extent there was a tendency of longer duration and smaller magnitude of the other kinematic markers to be correlated with positive affect. We examined this further by rotating the psychological space to find the orientation that maximised the r-squared values of the correlation with the six kinematic markers. It was found that a 27° counter-clockwise rotation resulted in the highest correlation with the kinematic markers with a r^2 value of 0.88 for Dimension 1 and 0.03 for Dimension 2. From these results it can be seen that while the original psychological space is roughly oriented so that energy in Dimension 1 is correlated with the speed of the movement, rotation of the space can improve the correlation.

Experiment 2

The aim of this experiment was to further investigate the role of speed in the recognition of affect from human movements. New sad, neutral and angry lifting and knocking movements were recorded from 3 women and 3 men. Through time warping (Bruderlin and Williams, 1995) the duration of movements were manipulated to change their speed. The original and morphed movements were displayed as point light stimuli to 10 participants who judged the intensity of affect.

Methods

Movement Collection Movements from 6 actors were recorded as they performed lifting and knocking actions with the three affects - angry, neutral and sad. As before, there were differences between kinematic markers for the movements. Angry movements had the

Table 1. Correlation of Movement Kinematics with Dimension 1 & 2 of psychological space. All values are Pearson's r and are significan at p<.oo5

Kinematic Properties	Dimension 1	Dimension 2
Duration	-0.85	0.65
Average Velocity	0.92	-0.49
Peak Velocity	0.91	-0.53
Peak Acceleration	0.83	-0.68
Peak Deceleration	-0.79	0.57
Jerk Index	0.83	-0.59

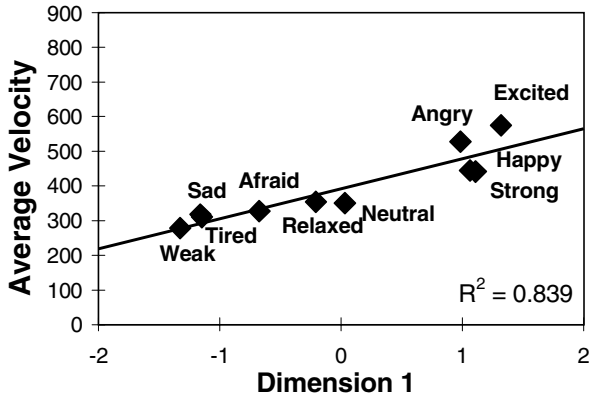

Figure 2. Plot of the average velocity of an affective movement versus the Dimension 1 coordinate obtained in the psychological space. Similar results are obtained for plots of the other kinematic markers versus Dimension 1.

shortest duration and highest velocities and sad the longest duration and lowest velocities.

For each movement the start and end points were defined using their velocity profile. Movement duration was defined as:

Duration = End point - Start point

For each actor a temporal step-size was calculated:

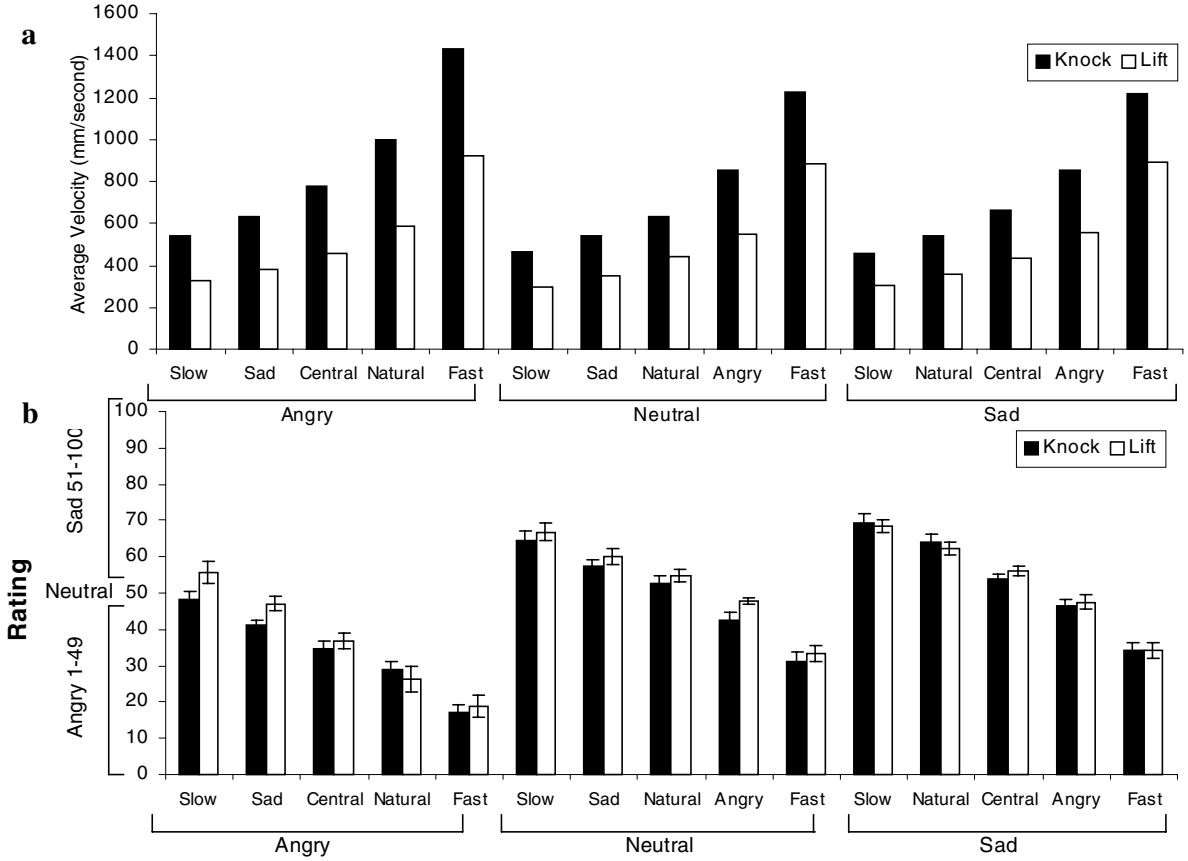
Step-size = (Sad Duration - Angry Duration)/2

The natural movements and the step-size calculation, were used in an interpolation algorithm (Hill and Pollick, 2000) to obtain 5 movements of differing duration for each affect. This yielded 15 movements for each actor, 3 of which were the natural movements. The interpolation preserved spatial properties of the movements such as the distance travelled by points between frames, but caused changes in spatio-tempotal properties, such as the average and peak velocities (see figure 3 and 4a). Movements had the following duration. A slow duration that was slower than the natural sad duration by one step-size; a natural sad duration; a central duration between angry and sad, this was very similar to the natural neutral movement duration; a natural angry duration; a fast duration, faster than the angry duration by 1 step-size. The central duration for neutral movements was the natural duration.

Participants Ten Glasgow University paid student volunteers participated in the experiment. All were naïve to the purpose of the study.

Design and Procedure Displays were blocked by action (2 actions). There were two blocks of trials, randomly ordered between participants. Participants were told that they would see human knocking and lifting movements. For each trial, participants viewed a computer display of the movement and were then presented with a dialog box that contained a 100-point scale for them to manipulate. First participants had to categorise the movement, then to rate its intensity.

A score between 1 and 49 indicates that the movement was perceived as angry, 1 being intense anger and 49, mild anger. A score of 51-100 indicates that the movement was perceived as sad, 51 being mildly sad and 100, intense sadness. A score of 50 indicates that the movement was neutral.



Frigure 3 a) The velocity of movements averaged across 6 actors and b) the rating participants gave to each movement, averaged across 6 actors and 10 participants. The x-axes illustrate the affect and duration used in the interpolation procedure. In b the rating scale is illustrated on the y-axis.

Results

For each affect there was a clear change in the classification and intensity ratings of affect as movement duration increased (figure 4b). This was the case for all three emotions, however, angry movements were seldom categorised as sad or neutral. These results are better illustrated when the rating data is correlated with kinematic markers, table 2 summarises these results.

Table 2. Correlation of kinematic markers with rating data, all values are Pearson's r and are significant at $p < .001$

Affect	Duration	Peak Velocity	Average Velocity
Angry	0.81	-0.67	-0.62
Neutral	0.91	-0.79	-0.79
Sad	0.96	-0.79	-0.82

Discussion

In this experiment the speeds of affective human arm movements were manipulated by changing movement duration. When new and original angry movements were viewed, they generally retained their identity as angry affect, but the intensity of perceived affect was modulated by velocity changes. Sad and neutral movements were similarly affected by changes in velocity, but faster movements were categorised as angry. These results further emphasise the role of velocity in affect, however, it is clear that there are other properties of the movements that were not controlled by velocity, but that play a role in the discrimination of affect. Currently it is only possible to speculate about what these properties are, but they may include spatial relationships, such as posture, between points of the displays; phase relations between the points or more dynamic properties, such as perceived force. It is clear, however, that velocity plays a major role in the recognition of affect from biological motion displays, particularly in modulating the intensity of perceived affect.

General Discussion

The results of Experiment 1 showed that the perceived affect of arm movements conformed well to models of experienced affect (Russell, 1980; Watson and Tellegen, 1985; Thayer, 1989, Larsen and Diener; 1992; Feldman Barrett and Russell, 1999). Moreover, the activation axis of these models was correlated to physical characteristics of the movement in a consistent manner such that greater activation was related to greater magnitudes of velocity, acceleration and jerk of the movement.

The finding of a circumplex structure for perceived affect is consistent both with duality between the perception and production of movement as well as a role for high-level information in the interpretation of motion derived from human movement. In addition, the continuous structure of the circumplex model parallels the smoothly varying range of speeds with which a movement can be performed. Thus, it would appear that the mapping between stimulus properties and representation of affect is a fairly direct one for the activation axis. However, such a direct connection between stimulus and representation has proven elusive for the second dimension of pleasantness. Other research has suggested that subtle phase relations between the joints (Amaya, Bruderlin and Calvert, 1996) might possibly carry information about affect.

The results from Experiment 2 further showed the way in which speed modulates interpretation of affective movements. However, factors controlling dimension 2 of the psychological space, could not be entirely discounted. For sad and neutral movements it was possible to change the percept to be angry, but angry movements remained discriminable as angry at most speeds. This suggests that angry movements are distinct form the other movements in some other way and that humans are sensitive to this difference. Indeed, angry, afraid and excited movements fell at a different location on the second dimension in Experiment 1, than the other movements. So perhaps whatever properties in the movements control this dimension also act as "danger indicators". From an evolutionary point of view such indicators makes good sense and it could be argued that this would enhance the models of experienced affect, since pleasantness may be just another way of discriminating emotions that a person seek out, from those they avoid.

Graph-based Reasoning: From Task Analysis to Cognitive Explanation

David Peebles (djp@psychology.nottingham.ac.uk)
Peter C.-H. Cheng (pcc@psychology.nottingham.ac.uk)

Department of Psychology, University of Nottingham, Nottingham, NG7 2RD, U.K.

Abstract

Models of graph-based reasoning have typically accounted for the variation in problem solving performance with different graph types in terms of a task analysis of the problem relative to the particular visual properties of each graph type (e.g. Lohse, 1993; Peebles, Cheng & Shadbolt 1999, submitted). This approach has been used to explain response time and accuracy differences in experimental situations where data are averaged over experimental conditions. A recent experiment is reported in which participants' eye movements were recorded while they were solving various problems with different graph types. The eye movement data revealed fine grained scanning and fixation patterns that are not predicted by standard task analytic models. From these eye-movement studies it is argued that there is a missing level of detail in current task analytic models of graph-based reasoning.

Introduction

The ability to retrieve and reason about information in graphs and diagrams is a skill which requires the complex interaction of three primary elements: the cognitive abilities of the user, the graphical properties of the external representation, and the requirements of the task. Several frameworks have been proposed to understand interactive behaviour of this sort. In the area of graph-based reasoning, Peebles, Cheng & Shadbolt (1999, submitted) have proposed the GBR model incorporating these three factors. Gray (2000; Gray & Altmann, 2000) has proposed the *Cognition-Task-Artifact triad* within which to characterise interactive behaviour in the related context of human-computer interaction. This latter framework has recently been further developed by Byrne (in press) to encompass the perceptual and motor capabilities of the user, termed *Embodied Cognition*.

The main aim of these models and frameworks is to aid the development of detailed cognitive models of the cognitive, perceptual and motor processes involved in the tasks under study. Constructing cognitive process models that are grounded in cognitive theory allows the incorporation and testing of relevant cognitive factors such as the required declarative and procedural knowledge, the strategies adopted, and the limitations of working memory. This approach contrasts with that of *cognitive task analysis* which simply specifies the cognitive steps required to perform the task.

In the area of graph-based reasoning, Lohse (1993) developed the GOMS class of task analysis techniques (Card, Moran, & Newell, 1983; Olson & Olson, 1990; John & Kieras, 1994) by including additional cognitive parameters to produce a cognitive model which simulates how people answer certain questions using line graphs, bar graphs and tables. Lohse's model was based on the assumption that graph knowledge is represented as graph schemas (Pinker, 1990) which allow the recognition and interpretation of different classes of graph. Included in a graph schema are task-specific rules that define sequences of procedures for retrieving information from the graph given a particular information-retrieval task. Lohse's model predicted the time to answer a given question by assuming that people scanned the graphical representation in a manner which produced an optimal sequence of eye movements that minimized the number of saccades and fixations to reach the target location.

In the *Graph Based Reasoning* (GBR) model (Peebles et al., 1999, submitted), a similar set of assumptions was employed to explain several results of experiments investigating the factors affecting reasoning with *informationally equivalent* (Larkin & Simon, 1987) graphs of different types from the same general class; Cartesian coordinate (x–y) graphs. Figure 1 shows the types of graph used in our experiments. The graphs are informationally equivalent as the both encode the same two functions between time and the variables A and B. The *Function* graph in Figure 1a represents time on the *x* axis and the A and B variables on the *y* axis whereas the *Parametric* graph in Figure 1b represents the A and B variables on the *x* and *y* axes respectively while time is plotted as a parameterizing variable along the curve.

Although the two graphs assign different variables to their axes, they would be considered similar in several important ways identified in the literature. Firstly, both are *Cartesian* graphs using a two dimensional coordinate system to relate quantities and represent magnitudes. It is likely, therefore, that both graphs invoke similar general schemas and interpretive processes (Pinker, 1990; Kosslyn, 1989). Secondly, both are simple line graphs and consequently share many of the same general interpretive rules. Furthermore, it is likely that inferences from both graphs are influenced by the same set of biases (Carpenter & Shah, 1998; Gattis & Holyoak, 1996; Shah & Carpenter, 1995). Finally, the graphs are infor-

mationally equivalent as they have been generated from the same data set.

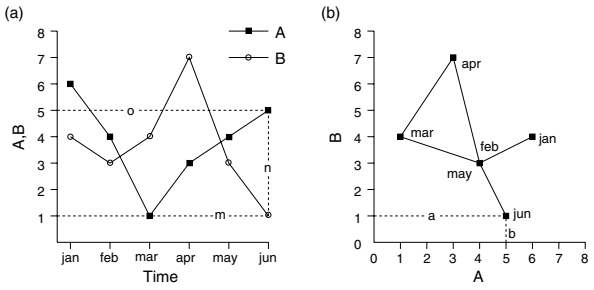

Figure 1: Informationally equivalent function and parametric graphs

Despite these similarities, however, in previous experiments we have demonstrated that for a wide range of questions, parametric and function graph users differ substantially in both the time it takes to respond and in their rates and patterns of errors (Peebles et al., 1999, submitted). The GBR model has been successful in explaining why such differences occur with these graph types despite their many common properties. Using the graphs in Figure 1 as an example, we found in our experiments that when participants were asked to retrieve the value of A when the value of B is 1, responses from parametric graph users were significantly more rapid and accurate than those from the function graph users. The GBR model explains these differences in terms of the optimal visual scan path the users follow through the graph. The variability in responses is apparent from the sequence of hypothesised saccades in the two graphs. In Figure 1a, the sequence of saccades is *m*, *n*, *o*, whereas in Figure 1b the process requires just two saccades, as shown by the line sequence *a*, *b*. The higher probability of an erroneous response using the function graph was explained by the additional number of possible incorrect saccades that the function graph users may make.

Although these optimality assumptions are useful in that they provide an account of differences in mean RT and error data for the different graph conditions, it remains an open question, however, whether they gloss over important cognitive and strategic factors at an individual level. For example, graph users may be required to re-encode items of information that have been lost from working memory during the course of processing. In addition, given that graph users are aware that information is available for re-scanning at all times, it is possible that they may make a strategic decision to trade off additional saccades for a reduction in working memory load. If this is the case, then the current analyses may miss out an important level of detail which sheds light on the cognitive load that these tasks are imposing and the strategies by which graph users optimise their retrieval procedures. Furthermore, information at this level of detail will provide valuable constraints on cognitive models of these reasoning processes.

To address these issues, we devised an experiment in which participants were asked to solve some simple tasks using different graph types of the same general class which, based on the optimality assumptions above, would be predicted to produce different response patterns. These predictions can be elaborated in terms of an optimal sequence of fixations required to solve the given task. To test these optimality assumptions and predictions, therefore, some of the participants' eye movements would be recorded as they solved the problems.

One of the most common tasks carried out when using a graph is to elicit the value of one variable corresponding to a given value of another. This task was chosen for the experiment as it is so widely performed and because the procedures involved are relatively simple. The knowledge required to carry out these tasks is primarily the sequence of fixations required to reach the *given location* in the graph representing the given value of the given variable and then from there to the *target location* representing the corresponding value of the required variable. In previous research, however, we have discovered that the effectiveness of a particular graphical representation for retrieving the required information depends on the details of the task, i.e. which variable is given and which is sought (Peebles et al., 1999, submitted).

Experiment

Method

Participants and materials Forty-four undergraduate and postgraduate psychology students from the University of Nottingham were paid £3 to take part in the experiment. The experiment was carried out using two PC computers with 17 in displays. A further four participants from the same population were paid £5 to participate in the eye-movement study. The eye tracker employed in the experiment was an SMI iView system using a RED II desktop pupil/corneal reflectance tracker with a sampling rate of 50 Hz. This system records eye movements at 20 ms intervals remotely from a position in front of the experimental computer display. Although the system contains an automatic head movement compensation mechanism, to further reduce recording error due to head movement, participant's heads were restrained in a frame fixed to the table.

The stimuli used in the experiment were four graphs, shown in Figure 2, depicting the amount (in millions of units) of UK offshore oil and gas production between two decades, 1970–1979 and 1980–1989. The graphs and data sets were designed so that the independent variable (IV—year) and the two dependent variables (DVs—oil and gas) all had ten values ranging from 0 to 9 and that the full range of these values was represented by the data points for oil and gas in both decades.

Participants were seated approximately 80 cm from the 72 ppi computer display. The graphs were 15.5 cm square (including axis labels), corresponding to approximately 11.1° of visual angle. The characters representing variable values were 0.4 cm high (approximately .21° of

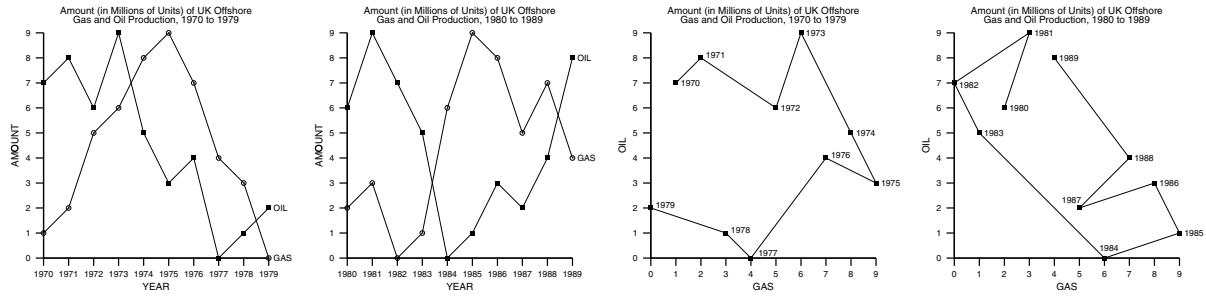

Figure 2: Function and Parametric Graphs Used in the Experiment

visual angle) while those for the axis labels and questions were 0.4 cm and 0.5 cm high (approximately .29° and .36° of visual angle) respectively. Axis ticks were spaced 1.5 cm (approximately 1.1° of visual angle) apart.

The full range of values for each of the variables was used to produce 120 questions. These questions all had the same basic structure and were of three types; DV–DV and DV–IV questions gave the value of one of the dependent variables and required the corresponding value of the second DV or the IV respectively, while IV–DV questions gave a value of the independent variable and required the corresponding DV value to be produced. There were 20 of each of question type and participants were required to answer all 60 for both decade graphs, producing a total of 120 questions.

Design and Procedure The experiment was a mixed design with one between-subjects variable, (graph type) and two within-subjects variables (question type and graph number). Participants were randomly allocated to one of the two graph type conditions producing a total of 22 participants per condition in the main experiment and two participants per condition in the eye movement study. During the experiment, the two graphs were presented alternately with the first graph being selected at random. On each trial, a graph would be presented with a question above it. The questions were presented in a form so that the minimum amount of text was shown. For example, the question GAS = 2, OIL = ? requires the value of oil when gas is equal to 2 to be found. When a year value was required, the final items of text in the question would be YEAR = 197? or YEAR = 198? depending on the current graph being presented and participants were instructed beforehand to enter only the final number of the target year. Each element of the question was centered on a co-ordinate point which remained invariant throughout the experiment with approximately 3.5 cm (approximately 2.5° of visual angle) between the centres of adjacent text items. Together with the graph and question, a button labelled *Answer* appeared in the top right corner of the window. Participants were instructed to click on this answer button as soon as they had obtained the answer to the question. Response times were recorded from the onset of a question to the mouse click on the answer button. When this button was clicked upon, the button, graph and question were removed from the screen and a circle of buttons labelled clockwise from 0 to 9 appeared centered on the answer button. Participants entered their answers by clicking the appropriate number button. When the number button was clicked, the next graph, question, and answer button appeared on the screen. This method was devised so that participants in the eye movement study would not have to take their eyes away from the screen to enter answers, as would be the case if using the keyboard.

Before starting the experiment, participants were given as much time as necessary to become familiar with the two graphs in their condition and were also provided with an opportunity to practice entering numbers using the circle of number buttons and the mouse. Participants were asked to answer the questions as rapidly and as accurately as possible

Results

Response accuracy and latency data The proportions of correct responses and mean response times (RTs) for each of the question types for the two graphs in each condition are presented in Figure 3. Confirming the relative simplicity of the experimental tasks, the data reveal high levels of accuracy for all three question types in both graph conditions. An ANOVA on the response accuracy data, however, revealed a significant effect of question type $F(2, 239) = 28.187$, $p < 0.01$, $MSE = 0.123$ indicating that some types of question were generally more demanding than others. The nature of this effect can be clearly seen in Figure 3. In both graph conditions, more errors were made carrying out the DV–DV task than the other two while the IV–DV task was the most accurately responded to.

While there is little variability in the accuracy of responses between conditions, the time taken by participants in the two groups to make these responses varies significantly both between conditions and within each condition according to the type of question being attempted. An ANOVA on the RT data revealed significant effects of question type $F(2, 239) = 18.447$, $p < 0.01$, $MSE = 4974038$, and graph number $F(1, 239) = 5.76$, $p < 0.05$, $MSE = 1223302$ and significant interactions be-

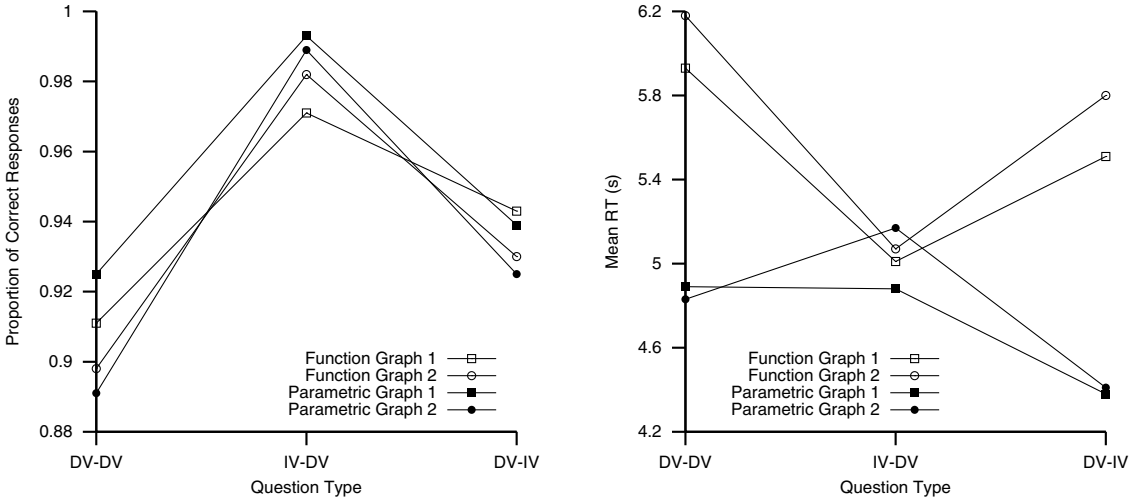

Figure 3: Plots of mean correct responses and RTs for function and parametric graph conditions for each question type

tween graph type and question type $F(2, 239) = 36.314$, $p < 0.01$, $MSE = 9791754$ and between graph type, question type and graph number $F(2, 239) = 3.913$, $p < 0.05$, $MSE = 466423$. The nature of these effects and complex interactions is apparent in Figure 3. In both conditions, it takes approximately 5 s to read the question and retrieve the required DV value for a given year. However, to carry out the reverse task and find the year corresponding to a given DV value takes, on average, over 1 s longer when using the function graph than when using the parametric graph. A similar disparity in RT is found when the task is to retrieve a DV value corresponding to a given DV value.

In both conditions, errors are evenly distributed over experiment trials. The mean proportion of correct responses over the first 10 trials for function and parametric graphs is .91 and .94 respectively. Over the course of the experiment, the mean RT for both conditions reduced by approximately 2 s, the rates of these reductions being described by power functions with similar slopes.

To analyse the results of the experiment, the display was divided into five regions in a manner similar to that employed by Carpenter and Shah (1998). The regions, shown in Figure 4, were the same for all four graphs and define the relevant units of the display for the fixation analysis: *question, graph pattern, x-axis, y-axis*, and *answer* buttons.

The pattern of RT data from the experiment can be explained by the GBR model using the optimality assumptions and fixation predictions outlined above. The significant increase in time to answer DV–IV questions using the function graphs is due to the fact that in the parametric graphs, the target values are positioned next to the given location so that the additional cognitive and perceptual processes required to fixate on the target location are not required. In this case the optimal sequence of fixations is predicted to be: *question, axis, graph, answer* whereas that for the function graphs is: *question, axis, graph, axis, answer*.

The DV–DV questions are of the same type as the example question given in the introduction and so the smaller mean RT in the parametric condition can be accounted for in terms of the previous explanation, namely, that to reach the target location in the function graphs requires an additional saccade and fixation and the associated cognitive operation to retrieve a further step in the process. So, the optimal sequence of fixations for parametric graphs is predicted to be: *question, axis, graph, axis, answer*, whereas that for the function graphs is: *question, axis, graph, graph, axis, answer*.

For the IV–DV questions, the relative rapidity with which function graph users are able to answer these questions compared to others is due to the fact that they are able to rapidly identify the given year on the x axis and then carry out the two step process of identifying the target point on the correct line and retrieving its value from the y axis. The optimal sequence of fixations for this procedure is: *question, axis, graph, axis, answer*. The data show that this procedure takes approximately the same time as the corresponding procedure for the parametric graphs which requires the search of the given year in the graph and the retrieval of its value from the target axis, the optimal fixation sequence of this procedure being: *question, graph, axis, answer*.

The results of the main experiment show that, despite the numerous similarities that exist between function and parametric graphs, the type of graph used can significantly affect the time it takes to retrieve the required information and that this effect is dependent on the nature of task. The experiment also showed that the probability of retrieving incorrect information depends on specific details of the task, i.e. which variable is given in the ques-

tion and which variable value is being sought. The GBR model explains these differences in terms of a detailed task analysis and the assumption of an optimal scan path through the graph to the target location.

Eye movement data To analyse the eye movement data, the raw x and y co-ordinate data from the eye tracker were aggregated into *gazes*—sequences of consecutive fixations on a display region unbroken by fixations in other regions (Carpenter and Shah, 1998). The minimum duration of a gaze was defined as 100 ms as this value was sufficiently large to eliminate most saccades, short fixations and noise in the data while still capturing all the relevant fixations. The data from each participant were analysed so that gazes of 100 ms or more in each region were recorded and a scan path consisting of the sequence of gazes for each question was produced.

Several interesting patterns emerge from the analysis of these gaze sequences. Firstly, the average number of transitions between regions for all questions types, shown in Table 1, is consistently greater than the optimal number predicted by the GBR model. For all of the question types, and irrespective of the type of graph being used, participants made, on average, between three and four additional transitions in order to reach the solution. In the majority of cases, these additional transitions were between the axes and the graph and the question and the graph as participants rarely fixated upon the answer region until entering an answer. In 31% of all trials, participants made at least one additional gaze on an axis after having previously fixated upon that axis and then the graph. A detailed visual analysis of the raw eye movement data for these trials revealed that in most cases, participants had fixated upon a given axis value and then proceeded to the plot point in the graph corresponding to that value. Upon reaching this point, an additional saccade was then made to the axis to check that the value was in line with the point.

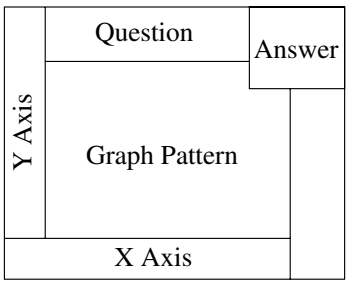

Figure 4: Five regions of the display defined for the fixation analysis

From the eye movement data analysis, it is clear that, although the participants did, in general, solve the various problems by following the optimal gaze paths characterised by the GBR model, they made considerably more gazes than is predicted by the model. Although it is likely that many of these additional transitions are due to checking procedures of the sort outlined above, it is possible that common patterns in the gaze sequences indicate limitations of working memory or problem solving strategies adopted by graph users. For example, in 62.7% of all trials and irrespective of the question type being attempted, participants made at least one additional gaze on the question after having initially gazed upon the question and subsequently the graph. This pattern suggests two possible explanations. The first is that participants have initially encoded the three elements of the question but are required to re-encode certain parts of it that are unable to be retrieved from working memory due to the cognitive load involved in carrying out the problem solving procedures. The second explanation is that participants have adopted a strategy by which only the initial part of the question is encoded and the second part is encoded only when required. According to this explanation, in the majority of trials, participants effectively break the problem into two sections, the first to get to the given location in the graph, the second to move from the given location to the target location corresponding to the solution. It is also possible that the observed gaze patterns may result from a combination of these factors if, during the course of the experiment, participants adopt the above strategy in order to minimise the number of question element retrieval failures.

Table 1: Mean number of gaze transitions between display regions for Function and Parametric graphs observed (Obs) for each question type, and the optimal (Opt) number predicted by the GBR model

Question	Function		Parametric	
Type	Obs	Opt	Obs	Opt
DV–DV	7.66	5.0	8.21	5.0
IV–DV	7.86	5.0	8.90	4.0
DV–IV	8.05	5.0	8.05	4.0

Discussion

Reasoning with Cartesian graphs involves a complex interaction between the perceptual and cognitive abilities of the reasoner, the visual properties of the graph, and the specific task requirements. Models of graph-based reasoning (e.g. Lohse, 1993; Peebles et al., 1999, submitted) have largely focussed on providing a detailed analysis of the task in relation to the the visual properties of the graph and explaining differences in performance in terms of the interaction of these two elements. These models have been successful in accounting for variations in aggregate RT data between users of different graph types by characterising an optimal sequence of fixations based on the task analysis that will achieve the goal. Error data is also explained by hypothesising sets of plausible deviations from these optimal sequences.

To produce detailed cognitive models of graph use grounded in cognitive theory, however, then the third,

cognitive element of the triad must be fully incorporated into these accounts. The explanatory and predictive power of cognitive models in complex interactive domains compared to cognitive task analyses has been demonstrated (e.g. Gray, John, & Atwood, 1993). By incorporating such cognitive factors as the user's knowledge, strategies and working memory capacity into graph-based reasoning models, the explanatory and predictive power of these models can be increased and greater insights into the processes and factors affecting these complex interactions can be obtained.

Although the standard experimental variables of RT and error rates provide some information upon which to formulate and test cognitive hypotheses, much richer data is obtained when eye movements are recorded during the experiment. In such a visual domain as graph-based reasoning, eye movements are an important source of information regarding how people acquire and process graphical information and the strategies they adopt when interpreting and working with graphs. This has been demonstrated by Carpenter and Shah (1998) in their analysis of eye movements in graph comprehension tasks which revealed the cyclic nature of the pattern recognition and cognitive processes involved in graph comprehension.

In contrast, the present experiment provides an example of how eye movement data can be used in the analysis of more goal directed graph-based reasoning tasks in which the aim of the interaction is not to simply understand the graph but to retrieve specific information from it. The results of the main experiment showed that the ability of people to retrieve the same information from computationally inequivalent but visually similar Cartesian graphs can be significantly affected by the type of graph used. A plausible explanation of these differences can be provided by the GBR model in terms of an analysis of the task and an assumption of the optimal scan path through the graph to the target location representing the problem solution. These results support and extend the findings of previous experiments (Peebles et al., 1999, submitted) and provide further evidence that the GBR model can account for data that cannot be explained solely in terms of the visual properties of the graphs.

The actual scan paths revealed by the eye movement study show, however, that these optimality assumptions serve as an approximation that can be applied to data aggregated over experimental conditions but which tend to obscure the detailed sequences of saccades made by individuals. It is clear that further research is required to investigate the cognitive factors underlying these saccade patterns in greater detail. It is also clear, however, that cognitive models of graph-based reasoning must incorporate more sophisticated cognitive mechanisms in order to account for these findings.

Abstract

The notion of feedback activation from semantics to both orthography and phonology has recently been used to explain certain semantic effects in visual word recognition, including polysemy effects (Hino & Lupker, 1996; Pexman & Lupker, 1999) and synonym effects (Pecher, in press). In the present research we tested an account based on feedback activation by investigating a new semantic effect: number of features (NOF). Words with high NOF (e.g., LION) should activate richer semantic representations than words with low NOF (e.g., LIME). Richer semantic representations should facilitate lexical decision task (LDT) and naming task performance via feedback activation to orthographic and phonological representations. The predicted facilitory NOF effects were observed in both LDT and naming.

Introduction

Although the average speaker or reader of English seldom notices it, the English language is actually quite ambiguous in its usage. For example, many English words are "polysemous", in that they have multiple meanings (e.g., BANK). Thus, deriving the intended meaning requires the use of context. These polysemous words have been a useful tool in psycholinguistic research since they allow researchers the opportunity to study the impact of semantic ambiguity on word recognition and reading.

There is now considerable evidence that semantic ambiguity produces a processing advantage in lexical decision tasks (LDT) and naming tasks. That is, responding in those tasks is usually faster to polysemous than nonpolysemous words (Borowsky & Masson, 1996; Gottlob, Goldinger, Stone, & Van Orden, 1999; Hino & Lupker, 1996; Hino, Lupker, Sears, & Ogawa, 1998; Jastrzembski, 1981; Jastrzembski & Stanners, 1975; Kellas, Ferraro, & Simpson, 1988; Lichacz, Herdman, LeFevre, & Baird, 1999; Millis & Button, 1989; Pexman & Lupker, 1999; Rubenstein, Garfield, & Millikan, 1970). This effect has proven difficult to explain for current models of word recognition. For example, Joordens and Besner (1994) attempted to simulate polysemy effects using two PDP models but found that neither model was successful. The problem is that polysemy involves a one-to-many mapping between orthography and semantics and, thus, polysemous words should create competition in the semantic units. Because Joordens and Besner assumed that lexical decision performance depends on the settling time in the semantic units, the inevitable result was that this competition hindered, rather than facilitated, performance. That is, according to this and similar models, polysemy should produce a processing disadvantage in LDTs (for related discussions see Besner & Joordens, 1995; Kawamoto, Farrar, & Kello, 1994; Borowsky & Masson, 1996; Piercey & Joordens, 2000; Rueckl, 1995).

As Hino and Lupker (1996) argued, however, it is possible to explain polysemy effects within a PDP framework if slightly different assumptions are made. Following Balota, Ferraro, and Connor's (1991) basic argument, Hino and Lupker assumed that semantic activation feeds back to the orthographic units. That is, when a target word is presented, there is initially activation of an orthographic representation for that word. Very quickly, there is also activation of a semantic representation for the target word (and also activation of a phonological representation). The semantic representation then increases the activation of the orthographic (and phonological) representation via feedback connections. Because polysemous words (e.g., BANK) have a more extensive semantic representation than nonpolysemous words, polysemous words would produce more semantic activation than nonpolysemous words. Hence, the feedback activation from semantics to orthography should be stronger for polysemous words than for nonpolysemous words. As a result, the activation in the orthographic units for polysemous words should increase more rapidly than that for nonpolysemous words. Assuming that lexical decision responses are mainly based on orthographic activation, the expectation is that LDT responses should be faster for

polysemous than for nonpolysemous words, as is typically observed.

The explanation for polysemy effects in naming tasks is similar. For polysemous words, there would be considerable semantic activation, which would then help activate the phonological (as well as the orthographic) units. This semantic activation of phonological units could happen two ways: via feedforward connections for orthography-semantics-phonology linkages, and also via feedback connections for orthography-phonology-semantics-phonology linkages. In a naming task, it is assumed that responses are based on activation in the phonological units. Polysemous words would receive more phonological activation (via semantics), which would lead to a processing advantage in the naming task. Thus, according to Hino and Lupker (1996), polysemy effects in both tasks can be readily explained within a fully-interactive, PDP-type model of word recognition if feedback activation is assumed to play an important role in the process.

Note that certain models of word recognition do assume an important role for feedback connections. For example, Van Orden and Goldinger (1994; see also Stone, Vanhoy & Van Orden, 1997) argued for a system that incorporated both feedforward and feedback activation between sets of processing units. Additionally, in Seidenberg and McClelland's (1989) PDP model, feedback connections were proposed, although they were never implemented. Feedback connections from semantic to orthographic units were also included in some of Plaut and Shallice's (1993) simulations. Thus, models of this sort would be quite consistent with the existence of polysemy effects.

What should also be noted is that polysemy effects are not the only effects in the word recognition literature consistent with Hino and Lupker's (1996) feedback activation account. For example, Pexman, Lupker, and Jared (2001) argued that a feedback activation explanation, involving feedback from the phonological to the orthographic units, was required in order to explain homophone effects. Homophones are words like MAID and MADE for which multiple spellings (and meanings) correspond to a single phonological representation. As had been typically reported (e.g., Rubenstein, Lewis, & Rubenstein, 1971), homophones produced longer lexical decision response latencies than control words in Pexman et al.'s experiments. These homophone effects were most apparent for low frequency homophones with high frequency homophone mates, and were larger in LDT when pseudohomophones (e.g., BRANE) were used as foils (as compared to pseudoword foils, e.g., PRANE).

In terms of the feedback activation account, homophone effects are assumed to be caused by a single phonological representation activating two orthographic representations (Pexman et al., 2001) while polysemy effects are presumed to be caused by multiple semantic representations activating a single orthographic representation (Hino & Lupker, 1996). That is, in spite of the fact that these two effects go in opposite directions, they are both presumed to be due to the basic architecture of the word recognition system (rather than being due to specific strategies). Pexman and Lupker (1999) argued that, if this account is correct, the two effects should occur simultaneously (i.e., in the same trial block) and both effects should be larger whenever there is increased opportunity for feedback to affect processing (i.e., when pseudohomophone foils are used). As predicted, Pexman and Lupker found that polysemy and homophone effects co-occurred and both were significantly larger with pseudohomophone foils than with pseudoword foils, supporting the feedback activation account.

One additional result that is consistent with Hino and Lupker's (1996) account comes from Pecher's (in press) examination of a different semantic factor: number of synonyms. Whereas polysemous words involve a many-to-one feedback mapping from the semantic units to the orthographic units (which helps increase the activation of the appropriate orthographic units), words with synonyms involve a one-to-many feedback mapping from the semantic units to the orthographic units. Thus, the feedback activation for a word with synonyms would tend to be dispersed to different orthographic representations, which should produce competition at the orthographic level. As a result, in contrast to the processing advantage created by polysemy, words with synonyms should be at a processing disadvantage. Pecher reported that responses were slower for words with synonyms (e.g., JAIL) than for words without synonyms (e.g., MILK) in both LDT and naming, and explained these results in terms of feedback processes.

The purpose of present paper was to provide a new examination of the feedback activation account. Polysemous words, like BANK, have a number of different, relatively distinct, meanings. Thus, according to the feedback activation account, these words create considerable semantic activation and, hence, more feedback activation for the orthographic and phonological units, producing faster responding. A similar situation should arise with any words that create relatively more semantic activation, regardless of whether that activation corresponds to several distinct meanings. In order to examine this prediction, we investigated the effect of number of features in LDTs and naming tasks.

Semantic features are attributes or characteristics that describe the meaning of a word. For instance, for the word LAMP, its semantic features might include such things as "is bright", "has light bulbs", "produces heat", "has a shade", etc. The notion that word meanings can be represented by semantic features has been controversial (e.g., Keil, 1989; Medin, 1989; Rips, 1989). That is, concept representations seem to involve much more than feature information; including such things as general world knowledge about relations between features, and heuristics like essentialism (the notion that things like lamps have "essences"). McRae, de Sa, and Seidenberg (1997; see also McRae, Cree, Westmacott, & de Sa, 1999) suggested, however, that featural representations do play an important role in at least the initial computation of word meaning. Based on the feedback activation account, it would be predicted that words with many features would produce

more semantic activation and, hence, more feedback to the orthographic and phonological units than words with few features. Thus, in LDTs and naming tasks, faster responding should be observed for words with a large number of features than for words with a small number of features.

The suggestion that word recognition may be faster for words with more semantic activation, or "richer" semantic representations, is not a new one. In previous research, effects of concreteness and/or imageability have been examined (e.g., Cortese, Simpson, & Woolsey, 1997; de Groot, 1989; James, 1975; Strain & Herdman, 1999; Strain, Patterson, & Seidenberg, 1995; Zevin & Balota, 2000), with results tending to show faster responding in LDTs and naming tasks for concrete or imageable words than for abstract words. It has been argued, in fact, that highly imageable or concrete words have richer semantic representations because they activate more semantic features than abstract words (Jones, 1985; Plaut & Shallice, 1993). According to the feedback activation account, however, activation of a larger number of semantic features should facilitate word recognition even when all of the stimuli are highly imageable. That is, even if all of the target words are concrete nouns, if some words activate more semantic features than others do, they should produce more rapid responding in word recognition tasks. Thus, there should be number of features (NOF) effects when concreteness and imageability have been controlled.

In this research we tested these predictions. Experiments 1A and 1B were LDTs, and 1C was a naming task.

Method

Participants

The participants in these experiments were undergraduate students at the University of Calgary. There were 40 participants in Experiment 1A, 38 in Experiment 1B, and 35 in Experiment 1C.

Stimuli

Words The word stimuli for Experiments 1A, 1B, and 1C, were selected from norms provided by Ken McRae (see McRae & Cree, in press). The McRae norms were collected by asking participants to list features for a large number of concrete nouns. Two sets of words were created: one set consisted of 25 words with low NOF and the other set consisted of 25 words with high NOF. These sets were matched on several dimensions. The mean values on these dimensions, for the selected sets of words, are listed in Table 1.

Foils There were 60 pseudowords presented in Experiment 1A and 60 pseudohomophones presented in Experiment 1B.

Procedure

On each trial, a letter string was presented in the centre of a 17-inch Sony Trinitron monitor controlled by a MacIntosh G3 and presented using PsyScope (Cohen, MacWhinney, Flatt, & Provost, 1993). In Experiments 1A and 1B, lexical-decision responses were made by pressing either the left button (labeled NONWORD) or the right button (labeled WORD) on a PsyScope response box. In Experiment 1C, naming responses were made into a microphone attached to a PsyScope response box.

Table 1: Mean Characteristics for Word Stimuli

Word characteristic	Low NOF words	High NOF words	Difference test $t(48)$
Number of features	12.00	20.40	-18.05**
Kucera & Francis (1967) frequency	10.80	14.32	<1
Subjective familiarity	3.84	3.97	<1
Number of meanings	1.08	1.07	<1
Word length	6.28	5.52	1.65
Number of syllables	1.80	1.56	1.25
Orthographic neighborhood size	3.00	3.64	<1

** $p < .001$

Experiment 1A – Results and Discussion

For this experiment, mean response latencies and mean error percentages are presented in Table 2. In all experiments, data were analyzed with subjects ($F1$ or $t1$) and, separately, items ($F2$ or $t2$) treated as random factors.

For high NOF words, response latencies were faster and there were fewer response errors (compared to responses for low NOF words) and, thus, there were significant NOF effects in both the latency analysis ($t1(39) = 2.95$, $p < .005$, $SE = 5.13$; $t2(48) = 1.40$, $p = .16$, $SE = 15.30$), and in the error analysis ($t1(39) = 2.66$, $p < .01$, $SE = 0.79$; $t2(48) = 1.17$, $p = .25$, $SE = 1.88$).

The results of Experiment 1A demonstrated that participants could more easily make word/nonword decisions for high NOF words than for low NOF words. According to the feedback activation account, this advantage was due to the additional semantic activation created by high NOF words. This additional semantic activation provided stronger feedback to the orthographic representation for the word presented, enhancing the activation of its orthographic units and speeding responding. In order to examine this NOF effect further, we used pseudohomophones as foils in Experiment 1B. According to the feedback activation account, these foils make lexical decisions more difficult because they require participants to set a higher criterion for orthographic activation. This leads to longer response times for both words and foils and increases the opportunity for feedback activation to affect responding. Thus, if the NOF effect is due to feedback activation from semantics to orthography, the effect should be larger in Experiment 1B.

Table 2: Mean Lexical Decision Latencies and Mean Error Percentages for Experiments 1A and 1B

	Experiment 1A (pseudoword foils)				Experiment 1B (pseudohomophone foils)			
Stimulus type	RT	Error %	RT effect	Error effect	RT	Error %	RT effect	Error effect
High NOF word	525	2.9			555	3.0		
Low NOF word	541	5.0	-16**	-2.1**	590	5.3	-35**	-2.3**
Foil	602	4.0			650	6.2		

**$\underline{p} < .01$

Experiment 1B – Results and Discussion

For this experiment, mean response latencies and mean error percentages are presented in Table 2.

As in Experiment 1A, response latencies were faster and there were fewer response errors for high NOF words, and so there was a significant NOF effect in the latency analyses ($\underline{t}1(37) = 5.01$, $\underline{p} < .001$, $\underline{SE} = 7.28$; $\underline{t}2(48) = 2.01$, $\underline{p} = .05$, $\underline{SE} = 21.30$), and in the error analysis ($\underline{t}1(37) = 2.98$, $\underline{p} < .005$, $\underline{SE} = 0.78$; $\underline{t}2(48) = 1.18$, $\underline{p} = .24$, $\underline{SE} = 1.95$).

In Experiment 1C we tested an additional prediction of the feedback activation account: because semantic activation also facilitates the activation of phonological units, high NOF words should also produce faster naming latencies.

Experiment 1C – Results and Discussion

For this experiment, mean naming latencies and mean error percentages are presented in Table 3.

Table 3: Mean Naming Latencies and Mean Error Percentages for Experiment 1C

Stimulus type	RT	Error %	RT effect	Error effect
High NOF word	525	0.3		
Low NOF word	555	1.4	-30**	-1.1*

*$\underline{p} < .05$, **$\underline{p} < .01$

For high NOF words, naming latencies were faster and there were fewer response errors, so there was a significant NOF effect in the latency analyses ($\underline{t}1(34) = 10.36$, $\underline{p} < .001$, $\underline{SE} = 2.96$; $\underline{t}2(48) = 2.09$, $\underline{p} < .05$, $\underline{SE} = 16.38$), and in the error analysis ($\underline{t}1(34) = 2.33$, $\underline{p} < .05$, $\underline{SE} = 0.45$; $\underline{t}2(48) = 1.41$, $\underline{p} = .16$, $\underline{SE} = 0.83$).

Again, responses were faster for words with high NOF. This suggests that semantic activation also provides strong feedback to the phonological units, facilitating naming responses.

Our 2 sets of words were not perfectly matched; there were slight differences between sets on several dimensions. To ensure that these differences were not the source of the observed effects, we conducted regression analyses. These analyses showed significant, unique effects of NOF for response latencies and response errors in Experiment 1A, response latencies (but not errors) in Experiment 1B, and naming latencies (but not naming errors) in Experiment 1C.

General Discussion

The present results demonstrate the influence of a previously unexamined semantic variable on visual word recognition. In the past, effects have been reported for concreteness and imageability (e.g., Cortese, Simpson, & Woolsey, 1997; de Groot, 1989; James, 1975; Strain & Herdman, 1999; Strain, Patterson, & Seidenberg, 1995; Zevin & Balota, 2000), and for polysemy (e.g., Borowsky & Masson, 1996; Gottlob et al., 1999; Hino & Lupker, 1996; Hino et al., 1998; Jastrzembski, 1981; Jastrzembski & Stanners, 1975; Kellas et al., 1988; Lichacz et al., 1999; Millis & Button, 1989; Pexman & Lupker, 1999; Rubenstein et al., 1970). The number of features effects reported here are independent of these effects. Our word stimuli were all concrete nouns, and were all nonpolysemous, differing only in terms of how many features participants ascribed to those words. Thus, our results provide support for the claim that it is the "richness" of a semantic representation that facilitates word recognition regardless of how that richness is created.

We have argued here that the NOF effects observed in our LDT and naming experiments (as well as a number of other semantic effects) support Hino and Lupker's (1996) feedback activation account. A key issue to address is to what extent other models of semantic effects, in particular, polysemy effects, could explain our NOF effects.

Alternative Explanations

Kawamoto et al. (1994) reported a successful simulation of polysemy effects in LDT using a model in which it was assumed that: (a) lexical decision performance is mainly based on activation of the orthographic units and (b) as a result of learning with their particular error-correction algorithm, weights for connections between orthographic units were enacted differently for polysemous and nonpolysemous words. Polysemy was captured in the model by having two different semantic patterns linked to a

single orthographic pattern. This inconsistent orthographic-to-semantic mapping created weaker connections between orthography and semantics. As a result, connections among orthographic units became more important in producing the appropriate orthographic activation for polysemous targets. In contrast, for nonpolysemous targets, semantic activation played a major role in producing the appropriate level of orthographic activation.

With respect to NOF effects, however, there would seem to be no reason why the number of features would affect the strength of either orthographic-to-semantic mappings or the connections among orthographic units. Neither our low nor high NOF words involved any orthographic-to-semantic inconsistencies. Thus, the model would have no obvious way to explain a NOF effect.

Borowsky and Masson (1996) successfully simulated their polysemy effects with a model in which it was assumed that lexical decisions are made on the basis of the "familiarity for a letter string's orthography and meaning" (p. 76). The model was a Hopfield network, and familiarity was assumed to be represented by the summed energy within the orthographic and meaning modules, with this energy reflecting the extent to which the network had settled into a basin of attraction. Energy was higher for polysemous words than for nonpolysemous words, due to proximity. That is, in the model, all the meaning-level units were initially set to +1 or –1 in a random fashion. Each unit was then updated until the network moved into a correct pattern. The distance (or the number of units to be changed) from the initial pattern to the correct pattern was probabilistically smaller when there were two correct patterns of activation (i.e., for polysemous words) than when there was only one correct pattern (i.e., for nonpolysemous words). Thus, the network moved into a basin of attraction more quickly for polysemous words than for nonpolysemous words, explaining the polysemy effect observed in LDT.

With respect to NOF effects, regardless of how many features a word has, it has only a single correct pattern of semantic activation. Thus, words with many features would not benefit from proximity like polysemous words do. Therefore, as with Kawamoto et al.'s (1994) model, this model would have no obvious way of explaining NOF effects.

It is possible that either of these models could be modified in a way that would allow them to explain NOF effects in LDT. In neither case, however, would the models provide as parsimonious an account as that provided by the feedback activation account. Further, in both cases, new assumptions would be needed to explain NOF effects in naming.

The results of the present experiments provide evidence that LDT and naming performance is faster for words with rich semantic representations, where richness is defined in terms of the number of semantic features activated. These effects suggest that word recognition performance will be best explained by fully-interactive models involving both feedforward and feedback activation.

Acknowledgments

This research was supported in part by grants to Penny M. Pexman and Stephen J. Lupker from the Natural Sciences and Engineering Research Council of Canada (NSERC). The authors thank Ken McRae for providing us with the feature norms, and Lorraine Reggin and Jodi Edwards for programming the experiments and testing participants.

Abstract

In an extensive research tradition in categorization, researchers have looked at how participants will classify new objects into existing categories; or the factors affecting learning to associate category labels with a set of objects. In this work, we examine a complementary aspect of categorization, that of the spontaneous classification of items into categories. In such cases, there is no "correct" category structure that the participants must infer. We argue that the this second type of categorization, unsupervised categorization, can be seen as some form of perceptual organization. Thus, we take advantage of theoretical work in perceptual organization to use simplicity as a principle suitable for a model of unsupervised categorization. The model applied directly to similarity ratings about the objects to be categorized successfully predicted participants' spontaneous classifications. Moreover, we report evidence whereby perceived similarity is affected by spontaneous classification; this supplements the already substantial literature on such effects, but in categorization situation where the objects' classification is not pre-determined.

There are several situations in real life where novel objects can be spontaneously organized into groups. Consider a set of pebbles taken from a beach, or cloud patterns on a particular day, or just meaningless shapes shown onto a computer screen. This spontaneous classification can be appropriately labeled "unsupervised" because there are no "correct" categories the observer need to infer. By contrast, in supervised categorization, the learner (e.g., a child or someone learning a new language), has to infer what a category is by observing exemplars of the category and guessing their category membership (e.g., a child could be corrected for calling an apple an orange; through a process of corrective feedback, she would eventually learn to associate the appropriate objects with the category label "orange").

Supervised vs. unsupervised categorization

While there has been very little theoretical work on unsupervised categorization, this has not been the case for supervised categorization. Several models have been put forward, covering different intuitions about the cognitive mechanisms of supervised categorization. For example, in definitional accounts of concepts (e.g., Katz & Fodor, 1963), categories are characterized by necessary and sufficient conditions for an item to be a category member (see Pothos & Hahn, 2000, for a recent evaluation). In exemplar theories (e.g., Nosofsky, 1989), a concept is represented by a set of known instances of that concept; new instances are therefore assigned to different categories in terms of their similarity to the members of each category. In prototype theories assignment is also determined by a similarity process, but this time to the prototype of each category, where a category prototype encapsulates some measure of central tendency across the exemplars of the category (e.g., Homa, Sterling, & Trepel, 1981).

Despite the technical sophistication of this research, it does not cover the whole scope of categorization processes. Models such as the exemplar model or the prototype one could never be used to predict how a person would spontaneously classify a set of items. In fact, in an influential paper Murphy and Medin (1985) criticized models such as the above for failing to explain category coherence—why it is the case that certain groupings of items make better categories than others; for example, the categories of birds or cups are coherent, but a category consisting of dolphins born on Tuesdays together with pink tulips within 20 miles of London, and the Eiffel Tower would be nonsensical. Given that the exemplar or prototype models could not explain such observations, Murphy and Medin concluded that they are inadequate models of categorization (and thus made a case for the importance of general knowledge in categorization).

However, under the light of the present distinction between supervised and unsupervised categorization, it is not the case that the exemplar or the prototype modes are inadequate in that they fail to capture general knowledge effects. Rather, category coherence is a problem of unsupervised categorization, as it relates to how categories originate–a process which, necessarily, cannot be guided by a 'supervisor.'

To summarize this section, the distinction of categorization models into supervised and unsupervised serves the useful purpose of enabling a closer specifi-

cation of the type of results that we expect each model to be able to capture. Unsupervised models of categorization will fail in predicting how participants will classify a new instance into a set of existing categories; but such models could probably be used to ground a theory of category coherence. The converse applies to models of supervised categorization.

Previous work on unsupervised categorization

There has been an extensive experimental tradition on spontaneous classification, under the name of free sorting. However, the objective of free classification research is to identify the factors that appear to influence performance in sorting tasks, such as different types of instructions / experimental procedures and the structure of the stimuli (e.g., whether they are made of integral or separable dimensions, and the extent to which this affects the number of dimensions used in the classification task; e.g., Handel & Preusser, 1970; Wills & McLaren, 1998; Kaplan & Murphy, 1999). Thus, results from free sorting do not bear directly on the study of spontaneous classification, in the sense of actually predicting the classifications people are likely to come up with.

Trying to predict how objects are divided into groups has been a very frequently researched topic. While an exhaustive review of the different accounts by far exceeds the scope of the present work, we next discuss some of the qualifying factors of previous work with respect to its appropriateness for modeling unsupervised categorization.

Within machine learning and statistics, there is a long literature on clustering. There are two broad classes of clustering algorithms, agglomerative models and K-means ones. In the former case, for a set of N objects a hierarchy of clusters is produced whereby in the bottom level there are N clusters (a cluster for each object) and in the top level only one cluster (which includes all the objects). In the latter case, the number of clusters in which a set of objects is to be divided is set externally (this is why this approach is called "K-means"; for a review see Krzanowski & Marriott, 1995). In both approaches, knowledge of the number of groups sought is assumed; it must be pre-determined by the researcher. However, for a psychological model of unsupervised categorization we need to be able to predict both the number of categories and how the objects to be categorized are portioned into these categories within the same formalism.

This turns out to be an important limitation in terms of applying previous relevant modeling work in psychology directly to the problem of unsupervised categorization, as well. This applies, for example, to Ahn and Medin's Two Stage Model of Category Construction (Ahn & Medin, 1992), Michalski and Stepp's (1983) CLUSTER/2, and Anderson's rational categorization work (1991; additionally, Anderson's model is sensitive to order of presentation of the items to be categorized, so that his work is directed more towards dynamic aspects of categorization). This is not to criticize any of the excellent work cited above, but rather attempt to specify more precisely its modeling objective, with respect to how well it applies to unsupervised categorization.

Perhaps more directly relevant is Fisher's COBWEB (e.g., Fisher, 1996), which is based on the psychologically motivated principle of category utility (e.g., Corter & Gluck, 1992). Variants of the model can indeed determine the number of categories, as well as the way the items should be partitioned into the categories. However, three factors prevent its direct comparability to the present model. Firstly, category utility has been put forward to explain basic level categorization (e.g., Rosch & Mervis, 1985); the relation between basic level categorization is presently unknown. Secondly, COBWEB has been investigated—and to a large extent validated—as a statistical model, not a psychological algorithm. One of the differences between the two is that a psychological model is supposed to be founded on computational principles that make some statement about cognition. Finally, category utility assumes a representation of objects in terms of features; categorization predictions in this work are derived on the basis of empirically derived similarity information.

Perceptual organization and simplicity

Categorization and perceptual organization, albeit superficially dissimilar processes, are nevertheless quite interlinked. Clearly categorization depends on perceptual organization, as how we perceive a set of objects will by necessity determine how we will categorize them. However, there is also a very extensive research tradition on effects of categorization on perceptual organization, showing that the way we categorize a set of objects is likely to affect how we perceive them (e.g., Goldstone, 1994; Harnad, 1987; Schyns & Oliva, 1998). Thus, we could maybe usefully look for a principle in perceptual organization to ground our model of unsupervised categorization.

A very influential approach in perceptual organization is the simplicity principle (e.g., Pomerantz and Kubovy, 1986; Chater, 1999), according to which the perceptual system is viewed as finding the simplest perceptual organization consistent with the sensory input. In fact, the simplicity principle has been recently shown to be equivalent to the most influential alternative, the likelihood principle (Chater, 1996).

In a simplicity framework, the notions of "interpretation" and "encoding" are central. At an intuitive level, encoding of information results in some data; simplicity is just a strategy for choosing an interpretation for the data. If we have a sequence like "abababababab" we could interpret it as "5 x (ab)"; but, clearly, there are many alternative interpretations (e.g., "a, 2 x (baba), b"). According to simplicity, the preferred theory / in-

terpretation is the one that minimizes the sum of the (1) complexity of the theory and (2) the complexity of the data when encoded with the theory.

The simplicity model of unsupervised categorization

Full details of the model are given in Pothos & Chater (1998) and Pothos & Chater (in press). Here, we only attempt to qualitatively discuss the main features of the model.

There has been extensive research on the importance of information in categorization, other than similarity. However, there must be an important component of categorization research that is driven primarily by similarity as well. This would be particularly evident in the case of grouping novel objects, since there would be no a priori expectations for such objects. Also, incorporating general knowledge influences in models of categorization has been notoriously difficult. Thus, in this work we will restrict the simplicity model to a version whereby general knowledge effects are not taken into account.

We assume that the information encoded for a set of objects is information about how similar each object is to each other. A possible "interpretation" for this information is in terms of groups of categories; in other words, the cognitive system could attempt to recognize structure in the encoded similarity information that is best captured by dividing the objects into groups.

To determine which grouping is most suitable we need to consider the following terms:

code length for similarities in terms of grouping + code length for grouping (1)

code length for similarities without groups (2)

The simplicity principle will support the classification such that (1) is a lot less than (2).

Translating the above intuition into a computational model, we consider similarity information of the form (object A, object B) more or less similar to (object X, object, Y). The advantage of this approach is that the applicability of our categorization model is not restricted by representational assumptions for the objects to be categorized. For example, we can equally well apply the model, whether the items to be categorized are represented as bundles of features, points in some multidimensional space, or even simply in terms of pairwise similarities.

We define a group or a category as a collection of objects such that the similarities between any two objects in the group are greater than the similarities between any two objects between groups. In this way, the similarity relations that would have had to be specified without groups are reduced. For example, if we have objects A, B, and C, and we put objects A and B in one group, while object C is on its own, then by the above, this is equivalent to saying that the similarity between A and B is greater than between A and C, and B and C. In this way, we have an "operative" definition of a category.

Thus, with groups we have some information gain, or reduction in code length, since we do not need to specify as many similarity relations; this would be the "gain" associated with a classification. However, it will rarely be the case that all the specified similarity relations will be correct; in other words, a particular grouping might specify that objects A, B are more similar to objects X, Y, when in fact it is the other way around. Thus, the overall classification gain will be reduced by the costs of correcting the errors; there is an additional cost required to specify which is the particular classification used (for the actual formulae and derivations see Pothos & Chater, 1998).

Experimental investigation

We wish to illustrate the applicability of the model with empirically derived similarity information about the items to be categorized. This approach is consistent with a growing trend in categorization research to take into account the well documented similarity structure changes that take place as a result of categorization.

The simplicity model can be used to predict the classification that should be most psychologically intuitive to naïve observers for a set of objects. We can thus examine the extent to which the classifications spontaneously produced by naïve observers are compatible with the simplicity model predictions.

Materials

We used 11 items that varied along two dimensions (the physical space representation is shown is Figure 1; a 12th item had to be eliminated from analyses as it was not the same in the ratings and categorization tasks). The two dimensions defined the size of a square and the size of the filled-circles texture inside the square (see Figure 2 for an example). The stimuli were presented in a folder, printed individually on A4 paper in black ink for the categorization task, and on a 15'' Macintosh computer screen when participants were asked for similarity ratings.

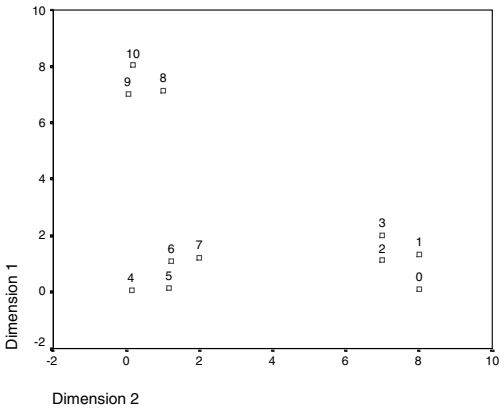

Figure 1: The parameter space representation of the stimuli.

Figure 2: An example of the stimuli used.

Procedure

29 University of Oxford students were paid for their participation. In the first part of the study, they received instructions saying that they were about to receive a set of items and that they would have to divide them into groups "in a way that seems intuitive and natural, so that more similar items end up in the same group." They were also told that although there was no limit on how many groups they could use, they should not use more that what they thought necessary. The order in which the stimuli were arranged in the folder was randomized for each participant.

After participants had classified the items, they performed the ratings task on a computer. They were instructed that they were about to see the items of the first part in pairs and that their task was to indicate the similarity between the items in each pair on a 1 to 9 scale, where a "1" would correspond to most similar items and a "9" to items that were most different. In particular, for each pair, the first item was presented for one and a half seconds, then there was a fixation point for 250ms, the second item appeared for one and a half seconds, a blank screen for 250ms, and a 1–9 ratings scale. The order in which each item appeared in a pair was counterbalanced so that we had two ratings per participant for each pair. Two randomized different orders were used for the ratings part of the experiment.

Results and Discussion

The similarity ratings were averaged into a large similarity matrix for all the items. This matrix was made symmetrical across the diagonal by using the arithmetic mean and also self-similarities were set to 0 (corresponding to maximum similarity). The simplicity model predictions were computed on the basis of these ratings. The best compression categorization involved three groups, with items 0–3, 4–7, and 8–10 in each group (item labels correspond to Figure 1).

In order to determine whether some of the observed categorizations were more likely than others we identified all the distinct categorizations produced by participants ("distinct" solutions), as well as the number of times participants divided the items in the way predicted by the simplicity principle. If there had been no preference for any particular categorization, we assumed that all distinct solutions would have been produced with a roughly equal frequency, given by the ratio (total number of groupings) / (number of distinct groupings). Using chi-square tests we can then examine whether the frequency of any of the classifications produced would be different from that computed by chance. This was the case only for the classification predicted by the model ($chi2(1) = 84.8$, $p<.001$; the frequency of this categorization was 11 times, out of 29).

To obtain some insights into participants' performance, we employed a non-metric MDS procedure to construct a putative internal spatial representation of the items; such a procedure is not related to the application of the simplicity model (which operates directly on the similarity ratings). Figure 3 shows the resulting MDS solution (all MDS procedures run with Euclidean metric). The three groups in the MDS solution correspond exactly to the three groups in Figure 1–but the items within each cluster are effectively indistinguishable in the internal space.

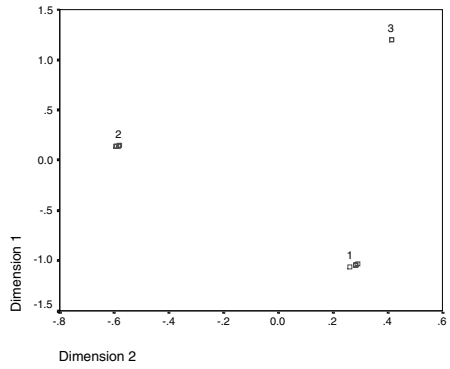

Figure 3: Labels items 0–3, "2" items 4–7, and "3" items 8–10, where item labels refer to Figure 1.

We next divided participants into homogeneous groups, and examined these groups individually. To do this, we looked at the groupings produced in the first part of the experiment, and then classified these groupings themselves (using the Rand index as a measure of the similarity between pairs of groupings, and the simplicity model as the clustering procedure). There were two main groups of categorizations, call them Group A (which contained the best compression solution; five different categorizations, that were produced by 14 out of the 29 participants) and Group B (nine solutions from 13 participants), as well as a smaller group which we shall not consider further (two other categorizations, from two participants).

We then separately considered the similarity ratings of participants whose groupings were in Groups A and B. The MDS procedure for Group A resulted in a spatial arrangement of the stimuli, identical to that shown in Figure 3. Figure 4, the MDS solution for Group B participants, is dramatically different; although some aspects of the nearest-neighbors structure seem to have been somewhat preserved (so that, for instance, points that were close to each other originally are still close to each other) the overall arrangement has been distorted so as to no longer reflect the obvious three groups category structure present in the Group A representation of the stimuli. In conclusion, it looks as if people who identified the best compression categorization (Group A), subsequently rated the similarity of different stimuli with each other in a way fully compatible with this category structure. This finding constitutes the first evidence that unsupervised classification affects the perceived similarity structure of a set of objects (see, e.g., Goldstone, 1995; Goldstone, Steyvers & Larimer, 1996 for corresponding evidence in supervised classification, that is categorization processes whereby categories are pre-specified). Future research will extend the present methodology to examine the extent to which simplicity might always be optimized with respect to how different individuals perceive the similarity structure of a set of objects.

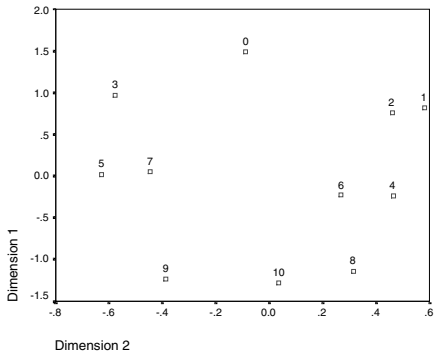

Figure 4: MDS solution for Group B participants.

To summarize, analysis of the similarity ratings of the stimuli confirmed the predictions of the simplicity model. Moreover, inspection of the MDS solutions showed that the categorization appears to have influenced similarity judgments, implying that perceived similarity may be affected by unsupervised classification.

Abstract

We present a model for generating a kind of neural synchrony in which the individual spike trains of one neuron or group of neurons closely match the spike trains of another. This kind of neural synchrony has been observed in animals performing auditory, visual and attentional information processing tasks. Our model is realized in a system of functionally identical, refractory spiking neurons. Larger systems with more sophisticated information processing capabilities can be constructed from aggregated instances of the basic network.

Introduction

Recently researchers ranging from neurobiologists (e.g. Ritz & Sejnowski, 1997) to computer scientists (e.g. Shastri, 1999) to psychologists (e.g. Hummel & Holyoak, 1997; Sougné, 2000) have studied the thesis that the synchrony of neural activity is one means by which bits of information are aggregated into the larger wholes necessary for complex information processing. In brief, neural synchrony is thought to implement the 'dynamic binding' of certain representations in the brain. It has also been suggested that neural synchrony is part of the process by which consciousness emerges from distributed brain activity.

But which neural dynamics are actually being synchronized? The answers provided by a decade of intensive research have generally all been variations on three basic themes. The first approach to synchrony intends the term to refer to coherence between 'oscillations' observed in the brain. In these cases it is the aggregated neural activity generated by the whole of a particular neural population that is deemed to be oscillating, not individual cortical neurons. Ritz and Sejnowski (1997) provide an excellent review of the conditions under which this mode of synchrony occurs, as well as its reputed significance in information processing tasks. Two representative examples include the observation of oscillatory synchrony in the brains of cats completing a sensorimotor task (Roelfsema, Engel, König & Singer, 1997), and its generation in an artificial neural network modeling the brain's solution of a figure-ground segregation problem (Sporns, Tononi & Edelman, 1991). Engel et al. have even speculated that oscillatory synchrony may be instrumental in bringing representations to consciousness, based on results showing that this mode of synchrony correlates with perceptual awareness in cats (1999).

Synchrony is understood elsewhere as correlated quasiperiodic activity occurring at a constant phase offset with respect to a persistent background oscillation. Different groups of neurons periodically become active during different phases of the background oscillation; neurons that become coactive during the same subperiods are said to exhibit phase synchrony. Phase synchrony allows the expression of phase-coded representations: representations in which information is coded in the relative timing of quasiperiodic neural activity. Gerstner, Kempter, van Hemmen and Wagner (1999) use empirical evidence for phase-coding's involvement in the sound source localization task in barn owls to build a successful mathematical simulation of the process. As well, Jensen and Lisman argue that data from psychological experiments and rat EEGs support accounts of short term memory capacity (1998) and position reconstruction in rats (2000), respectively, framed in phase-coding terms.

Phase synchrony is also exploited in a number of influential models of cognitive processes. Shastri, in his SHRUTI model of inference and reasoning, uses phase synchrony to bind neurons corresponding to role-filler words; e.g., John, with other neurons corresponding to specific roles in propositions; e.g., X in "X sees Y" (Shastri & Ajjanagadde, 1993; Shastri, 1999). Similarly, phase-coded bindings of roles to role-fillers underlie Hummel and Holyoak's IMM and LISA models of analogy formation (Hummel, Burns & Holyoak, 1994; Hummel & Holyoak, 1997).

Finally, there is a third synchrony phenomenon that we have termed 'spike train synchrony.' This synchrony is present when strong correlations exist between the individual firing times of different neurons or groups of neurons. There is no need that these firing times be quasiperiodic, as in phase synchrony. Nor is it generally possible to explain the aggregate synchronized activity as oscillatory; in fact, the mean overall activity of the neurons involved can remain close to constant except over very short time intervals.

DeCharms and Merzenich (1996) observed the spike train synchrony of neurons in the brains of anesthetized marmoset monkeys responding to a pure tone stimulus. For the duration of each tone, the firing patterns of selected neural regions became correlated, even though their mean firing rates remained unchanged. In addition, this correlation disappeared when the tone ended and was absent before it began. Tightly correlated spike trains have also been reported for neighbouring cells in two early vision regions: the retinal ganglia (Meister, 1996) and the lateral geniculate nucleus (Alonso, Usrey & Reid, 1996). More recently, Steinmetz et al. (2000) have found that certain somatosensory neurons in monkeys increase the correlation of their spike trains when performing visual and tactile tasks requiring increased attention.

All three modes of synchrony outlined here have been empirically observed under conditions which suggest a role for them in specific information processing tasks. Furthermore, previous research, as cited above, has resulted in working models demonstrating how the first two types, oscillatory and phase synchrony, may be generated. The design of computational simulations targeting the generation of synchrony at the level of individual spike trains, however, has received little attention.

Simulation-based research of this type should help to elucidate the structural and functional aspects of the brain necessary for spike train synchrony as it has been observed. Moreover, even in the absence of an artificial system mirroring the exact architecture of the brain, spike train synchrony models should provide insights and help researchers test hypotheses concerning information processing tasks whose realizations in the brain presumably require this form of synchrony. Advances generated by analogous models depending on other synchronies—Shastri's model of logical reasoning, for example—corroborate this claim.

In this paper we present an artificial neural network designed to exhibit spike train synchrony. The neurons in the network are all functionally identical, refractory neurons, and the connections between them are all of the same, standard type.

The controlled tracking network displays a simple behaviour: the *clone neuron* copies or 'tracks' the spike train of the *primary neuron*. The copying process is selective, meaning that it stops and starts in response to signaling from two *actuator neurons*. In this way, the *clone neuron* can be made to fall in and out of synchrony with the *primary neuron*.

The design of the network was completed in two stages. In the first, a basic network was built in which the clone neuron was made to copy the activity of the primary neuron at all times. Pausing or halting the copying is not allowed in this network. These operations were implemented in the second stage of network design, in which the control component of the system was integrated. Finally, in the last section, we highlight the contributions of the model to understanding the generation of biological spike train synchrony and its role in information processing. This includes a discussion of the merits of our model's representational capabilities over those used in other influential modeling approaches.

Mathematical Fundamentals

This section describes the dynamics of the neurons we use to build our spike-tracking networks. In brief, our neurons function like the Spike Response Model neurons developed in Gerstner (1999), with only slight modifications. We review the defining equations of our neurons here, drawing heavily from Gerstner's formulations.

The total membrane potential u_i of each spiking neuron i is given by:

$$u_i(t) = \sum_{t_i \in F_i} \eta(t - t_i) + \sum_{j \in \Gamma_i} \sum_{t_j \in F_j} w_{i,j} \varepsilon_{i,j}(t - t_j) . \quad (1)$$

The last term of this equation quantifies the contributions to the membrane potential of neuron i due to excitations and inhibitions from the set Γ_i of neurons with efferent connections to i. Each such neuron j will contribute to i's membrane potential due to post-synaptic potentials ε seen coming from j across the synapse connecting to i. The function $\varepsilon_{i,j}(s)$ equals the excitatory post-synaptic potential seen at post-synaptic neuron i at a time of s seconds after the firing of a pre-synaptic neuron j. The set F_i represents the set of all individual spike times t_i of the neuron i; likewise, F_j and t_j for neuron j. Finally, the constant $w_{i,j}$ represents the strength of the connection from neuron i to neuron j. In summary, the last term of Eq. (1) sums the contributions to membrane potential due to incoming post-synaptic potentials, after scaling these contributions by the appropriate connection weights.

The function $\varepsilon_{i,j}(s)$, introduced above is defined by:

$$\varepsilon_{i,j}(s) = \left[\exp\left(-\frac{s - \Delta_{i,j}}{\tau_m} \right) - \exp\left(-\frac{s - \Delta_{i,j}}{\tau_s} \right) \right] H(s - \Delta_{i,j}) , \quad (2)$$

where τ_m and τ_s are time constants determining the shape of the post-synaptic pulse, $\Delta_{i,j}$ is the propagation time of the electric potential signal between the beginning and end of a connection from i to j (also called the axonal delay or 'length') , and H is the Heaviside unit step function:

$$H(t) = \begin{cases} 0 & \text{for } t < 0 \\ 1 & \text{otherwise} \end{cases} \quad (3)$$

The left term on the right hand side of equation (1) accounts for the response of neuron i to its own previous spikes. This term quantifies the *refractoriness* of neurons; i.e., the decreased capacity of a neuron to spike soon after it has just spiked. Refractoriness is modeled as a short-term, decaying, inhibitory signal:

$$\eta(s) = -\eta_0 \exp\left(-\frac{s}{\tau_r}\right) H(s) - K[H(s)]H(\delta^{abs} - s) \quad (4)$$

The variable s is the time since a previous spike, while the parameters η_o and τ_r scale the amplitude and the decay rate, respectively. *H(s)* remains the Heaviside unit step function as discussed above. Finally, the constant K represents an arbitrarily large number and the parameter δ^{abs} designates the duration of absolute refractoriness. This represents the length of time after a spike during which a second spike is physically impossible.

A neuron spikes each time that its membrane potential u_i exceeds a threshold value ϑ, provided that u_i is increasing from a subthreshold value on the last discrete time step. Each spike results in a new spike time t_i being added to the set F_i of all spike times for neuron i.

Tracking Network

In this section, we describe a network where one neuron's spike train, the clone neuron, closely duplicates the spike train of another neuron, the primary neuron, at all times. We call this network the *tracking network*. Fig. 1 illustrates the architecture of our tracking network, in which auxiliary neurons serve to enable a clone neuron to synchronize its firing with the primary neuron. The complication of the network, primarily due to the many feedback connections, is necessary in a tracking system composed of refractory neurons. Refractoriness causes a transient desensitization of a neuron to incoming inputs shortly after that neuron's firing. Consequently, a pulse in an input signal will not elicit the same response from a refractory neuron that has just fired as it will from one that has not yet fired. This means that simply connecting the primary neuron to the clone neuron will not produce reliable tracking because the clone neuron will be biased to respond differently to different post-synaptic pulses sent from the primary neuron. The clone neuron will be slower to spike in response to an incoming superthreshold pulse coming a short time after the last one, in comparison to one coming a long time after the last one.

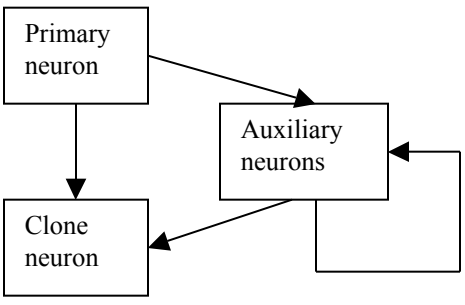

Figure 1. Spike tracking system.

To restore the efficacy of the external input to a refractory neuron, which in our system corresponds to the primary neuron's outgoing post-synaptic pulses, we construct an auxiliary signal that provides a second input to the clone neuron. This signal is implemented using the output pulses of *auxiliary neurons* connected efferently to the clone neuron. These auxiliary neurons are coerced to fire in such a way that the potential pulses they output individually to the clone neuron add up to a negative approximation of the η refractory term of Eq. (1).

Mathematically, each connection from an auxiliary neuron to the clone neuron results in an additional term in the expansion of the double summation of Eq. (1). Therefore, for the set A of auxiliary neurons to successfully mitigate refraction, the mathematical constraint to be satisfied is specified by Eq. (5) in the appendix. The variables $w_{c,a}$ and $\Delta_{c,a}$ represent the auxiliary to clone neuron connection strengths and time delays, respectively, while t_a represents the firing times of the auxiliary neurons. These three sets of variables remain to be specified, in addition to the total number of auxiliary neurons to be used. To determine acceptable values for these unknowns we first perform the following simplifying analysis. The analysis solves the approximation problem for only a limiting case, but we go on to show that straightforward modifications lead to a more general solution.

For now we assume a single, isolated refractory incident corresponding to a single, isolated firing of the clone neuron at time $t_c = 0$. Second, we require that pulses from the auxiliary neurons arrive instantaneously at the membrane of the clone neuron; i.e., we set the connection time delays $\Delta_{c,a}$ to 0. Finally, we tentatively prohibit each auxiliary neuron from firing more than once. These conditions allowed us to reformulate the constraint of Eq. (5) using Eq. (6) in the appendix. In graphical terms, this simplified constraint commits us to build up an approximation to the refractory function η by summing time-shifted and scaled postsynaptic pulses ε. The pulses are vertically scaled according to the connection strengths $w_{c,a}$. Their time shifting is specified by the times of firing t_a of the auxiliary neurons.

For convenience we chose to limit the maximum relative error of our particular approximation to less than 5%. Better approximations are possible, but as error decreases, the number of required auxiliary neurons increases, making the network larger. For our error tolerance of 5% we were able to construct a feasible solution set of values t_a and $w_{c,a}$ using 23 auxiliary neurons.

The set of solution values t_a indicate the time each auxiliary neuron must spike, *relative to the clone neuron*, in order to mitigate refractoriness. To force the neurons to spike at these times, we apply the same external input signal that the clone neuron experiences

to each of the auxiliary neurons, with a time delay of length t_a, the firing offset time for that neuron. In physical terms this means connecting the primary neuron to each auxiliary neuron. The strengths $w_{a,p}$ of these primary to auxiliary connections should be identical to the strength $w_{c,p}$ of the single primary to clone neuron connection. The lengths $\Delta_{a,p}$ of the primary to auxiliary connections, however, must equal the primary to clone neuron connection length *plus* the firing time offset t_a calculated for the particular auxiliary neuron *a* in question.

Returning to the assumptions we made earlier, the system thus connected is only strictly guaranteed to mitigate the clone neuron's refractoriness due to its very first spike. This is because the clone neuron was assumed to fire only once in isolation. To compensate for the refractoriness following *all* spikes, the auxiliary neurons need to spike—and with a precise time lag of t_a—not just the first time that the clone neuron spikes, but *every* time it spikes.

Though all the auxiliary neurons share the same external input as the clone neuron, they will fail to spike as required (i.e., every time the clone neuron spikes) because the clone neuron now has an additional input signal compensating for its internal refractoriness. It is no longer desensitized due to the refractoriness following from its first spike, but the auxiliary neurons still are.

We remedy this problem by feeding an additional input into each of the auxiliary neurons. Each of these additional input signals should be identical to the refractoriness compensation signal for the clone neuron, except that, as before, the signals should arrive with a time lag or delay of t_a specific to the auxiliary neuron *a* in question.

In terms of implementation, this translates into an additional bundle of connections to each auxiliary neuron. Each bundle consists of a set of connections leading from *each* auxiliary neuron to *one* of those auxiliary neurons. Therefore, if there are N auxiliary neurons, N feedback bundles are required, each containing N unique connections. This makes for N^2 auxiliary neuron feedback connections in total.

We should emphasize that we have been ignoring the absolute refractory component of the refractoriness signal corresponding to the second term in Eq. (2). Physiologically the absolute refractoriness of neurons could never be compensated for in biological networks in any event, because it arises from a fundamental electrochemical constraint on the availability of certain molecules (Paul, 1975). Furthermore, because all our neurons are identical, a clone neuron would never be expected to track a spike which would land itself in the absolute refractory period following a previous spike: the primary neuron would not be capable of producing such a spike train.

We tested the capacity of the clone neuron to copy the spike train of the primary neuron, as connected in the tracking network described above. The network was simulated using the SpikeSim program we designed in Java. As input to the tracking system, spike trains were evoked from the primary neuron that corresponded to an exponential distribution of spikes with a mean of 30 time steps between spikes.

The results indicate that missing spikes and bursts of spikes at inappropriate times ('ringing') seem to be the only symptoms of inaccurate tracking. In biological systems such aberrations could be explained by molecular and thermal noise.

A very strong cross correlation over a set of ten trials was observed between the spike trains of the primary and clone neuron. We found that the spike train of the clone neuron slightly lags the spike train of the primary neuron. A non-zero time lag is inevitable because it takes time for the post-synaptic pulses ε to peak. Nevertheless, it should not be of too much concern because the signals can be time-shifted so they coincide as seen from a third neuron's perspective. Setting appropriate connection lengths for the primary to third neuron connection and the clone to third neuron connection will implement the necessary shifting.

Discussion

We have presented a new computational model for synchrony generation, a model that implements controlled spike train tracking of one neuron by another. In this closing discussion, we investigate a possible variation of the model promising greater physiological plausibility. We then move on to compare the merits of this model to others in the field; namely, Shastri's and Hummel's. Finally, we argue that our basic model and its variations will likely prove helpful in the effort to develop larger scale simulations of cognitive processes.

To build the controlled spike tracking system, we constructed connections between the auxiliary neurons and the clone neuron of length (or time delay) zero. The connections between the primary neuron and the clone neuron, however, are variable in length and all non zero, in order to implement time lag delays. As a result of this configuration all the auxiliary neurons and clone neurons end up generating identical but time-shifted spike trains: these neurons fire in a wave-like or 'follow-the-leader' type manner.

Theoretic considerations suggest that an operationally identical network can be implemented in a way that is more physiologically realistic. Instead of implementing the time delays through lengthening the connections from the primary to auxiliary neurons, we can set these constant and stagger the lengths of two sets of connections: those in the feedback bundles, and those between the auxiliary neurons and the clone neuron. This removes the need for problematic zero-length connections across which electrical pulses would presumably need to instantaneously travel, while preserving the critical time-delay dynamics of the

refractoriness compensation signal. In this revised setup, the auxiliary neurons and the clone neuron would all fire identical spike trains, just as before, but with no time lag asynchrony.

We also reason that if auxiliary neurons exist in the brain to mitigate for refraction, they likely play roles in other brain circuits as well. If this is so, their mutually synchronous firing would help to maintain signal or information synchrony in all of these circuits. Such synchrony would not evolve from the original controlled tracking network, but would characterize the auxiliary neurons in the modified variation, as described above. In short, there are several reasons for believing that the proposed network variation should be superior to the original controlled tracking network.

The artificial neural networks whose results were presented above were simulated with the assumption of no noise. In later trials we investigated the effect of introducing noisy dynamics to the Spike Response Neuron model defining the neurons in our network. More specifically, the firing thresholds were made noisy by adding to the membrane threshold function a Gaussian random variable with mean of zero and standard deviation proportional to the degree of desired noisiness. This method of introducing noise is one of the standard ones discussed in Gerstner (1999).

When simulated, noisy neurons resulted in severely poor tracking performance, even when the noisiness was kept low. The largest errors in tracking were bursts of extraneous spikes occurring after a single premature firing. This initial firing was in turn due to a transient lowering of the membrane threshold of a single neuron when that neuron's membrane potential was close to the average threshold.

We expect that poor tracking under noise conditions can be mostly eliminated by a redesign of the feedback connections between auxiliary neurons, one which would not modify their basic role in the network. Our ideas are still only in an early stage of development, however. For now we have to concede that our system's spike tracking performance is poor under noisy conditions.

Future research could investigate the implications of the unique information encoding and processing properties our system possesses by nature of its design. For instance, the system allows for more versatile synchronic neural coding than that available in networks used in Shastri's SHRUTI model of logical reasoning or Hummel's LISA or IMM models of analogy formation. In these systems individual neurons are active for a maximum of one portion or 'phase' of each background oscillatory cycle, during which they may fire either alone or more generally in synchrony with a group of other neurons that are also active only during that phase. During other periods of the background oscillatory cycle all these neurons are inactive.

The neurons in the controlled spike-tracking system presented here can be made to synchronize in this way, but they are capable of more sophisticated synchronic dynamics as well, as the simulation results demonstrated. Through the control interface, variable length periods of transient synchrony were elicited from our system on demand. Furthermore, as will be demonstrated below, the clone neuron can be made to regularly switch between synchrony with different groups of neurons. In contrast, the other three models require a neuron to synchronize with only one group of neurons and only then during short, periodic time windows of constant width.

Another significant difference lies in the firing patterns during periods of synchrony. In the SHRUTI, LISA and IMM-based networks, the firing of a neuron within its interval of synchrony is only described in terms of its overall firing rate or 'level of activity.' But in controlled spike tracking systems, significant *subcoding* can take place within time intervals of synchronized activity. By subcoding we mean that additional information can be stored in the relative timing of spikes within each period or instance of neural synchrony. For the other models noted, supporting subcoding within periods of synchrony would effectively require system redesign. Consequently, we claim that our tracking system allows for more detailed elaboration of representations during synchronous neural firing.

Finally, we suggest that sophisticated neural networks for simulating higher level cognitive processes could be designed using the controlled tracking system as a reusable component, a repeated building block. Such networks would broaden our understanding of the processes they model, just as SHRUTI and LISA have provided insights into the reasoning and analogy-forming processes they were built to simulate.

Imagine a network with six inputs. Three of these are generated by three primary neurons, each of which we assume signals a separate and unique stream of representations coded within its spike train. The other three inputs are provided by three *switch neurons*, each corresponding to one of the three primary neurons. The network takes advantage of these inputs, and four spike tracking subsystems embedded within it, to implement a relatively complex behaviour: on receiving a single spike from one of the three switch neurons, the network begins to track the spike train of the corresponding primary neuron. When a different switch neuron spikes, the network switches inputs and starts tracking a different primary neuron. In effect, this network implements the ability to reorganize arbitrary parts of neural signals, corresponding to different temporally coded representations, in sophisticated ways. Such reorganization or 'splicing' mechanisms could prove quite useful for a number of information processing tasks. Compressions of

sequences of elaborate representations into more succinct streams could be one such task.

This network demonstrates the potential increase in information processing sophistication that emerges from constructing larger networks within which simple spike tracking subsystems work in coordination. We hope that the application of this kind of design approach will contribute to the future development of neural network models that carry out information processing tasks similar in complexity to those that the brain performs. Moreover, by shedding light on the internal mechanics of the processes involved, such models might not only demonstrate or mimic *what* the brain does but also help to further clarify just *how* it does it.

Abstract

Although there already exist traditional metaphors influencing human-computer interaction (HCI) such as the human-human interaction metaphor, some applications emerging in areas from intelligent agents to wearable and context-aware computing have prompted the authors to identify a new metaphor implicitly emerging in HCI. This will be referred to as the conscious-subconscious (C-S) metaphor. The explicit elucidation of this C-S metaphor poises HCI to speak to and leverage research in philosophy and cognitive science pertaining to consciousness and cognition.

Introduction

Although the characterization of consciousness and cognition, per se, are not the primary objectives of the applied field of human-computer interaction (HCI), the authors contend that emerging endeavours in HCI are poising it to speak, perhaps more directly than in the past, to such issues.

To address novel challenges as HCI applications have expanded and diverged, the field has developed a growing toolbox of metaphors to inform and interpret interface design. Two such, traditionally prevalent, metaphors for human-computer interaction are the human-tool interaction metaphor and human-human interaction metaphor (see Marchionini (1995) for a general overview). However, some of the applications in relatively new areas such as wearable, context-aware computing, and intelligent/autonomous agents seem to be promoting the implicit development of a new metaphor which will be referred to as the conscious-subconscious (C-S) metaphor.

In HCI, it is natural to partition computer activity into two classes: interface processes and underlying computational processes which are predominantly opaque to the interface/user. Just as much of the computation that goes on in a computer is not evident in any way through, or even to, the interface, so too, much of the computation that transpires in the mind is opaque; even to the individual's own introspection. This is evident in such activities as throwing a baseball, during which there are no conscious calculations of trajectories.

From this perspective, humans can be modelled as cognitively modular with a conscious process running concurrently with one or more subconscious processes. In some cases our conscious mind is completely unaware of the underlying computation, in other cases it is privy to the product or result of the computation, and sometimes it seems actively involved in the process. In light of it's intermittent and incomplete exposure to inner information, the conscious mind can be viewed in this regard as a form of interface itself.

The following example provides an illustration of how the C-S metaphor can be applied in HCI. The next generation of search engine interfaces will be information retrieval agents (e.g. Lieberman, 1995; Rhodes & Starner, 1996; Stenmark, 1997) which are able to proactively, that is, without an explicit query, search out and bring to the user's attention (consciousness) web documents that might be relevant in the current task context. For example, it might fetch pages on Hamlet while an individual is writing a paper on Hamlet in MS Word. In a similar spirit, subconscious memory processes proactively pop memories into mind (consciousness) that are relevant to the current context, such as when you enter a video store and spontaneously remember that your friend recommended that you should see *The Matrix*. In the sense that such interface agents perform tasks of a similar nature to those performed by human subconscious mechanisms, and exchange information with the conscious facet of the user in a similar manner, such agents could be regarded acting as supplementary or prosthetic subconscious systems.

The explicit elucidation of this C-S metaphor is significant in that, more directly than previous metaphors, it poises HCI to speak to and leverage research in philosophy and cognitive science

pertaining to consciousness and cognition.

A distinctive contribution of HCI in this regard, is that by virtue of it's agenda, it is geared toward actual operationalizations of the concepts and implementations of the processes. Such efforts yield impetus and insight towards identifying and characterising: a) information availability and internal interfacing aspects of conscious experience; and b) the underlying processes necessary to support such experience. It is beyond the scope of this paper to delve into the details of these characterizations beyond a few examples. It is hoped that the identification and systemisation of the metaphor will catalyse interdisciplinary impetus toward an integrated theoretical interpretation and framework.

Human-Computer Interaction: Catering to Consciousness

The flip side of the relevance of HCI to the characterization of consciousness, is the relevance of consciousness to the characterization of HCI. Although in cognitive models of computation, consciousness is often regarded as an aside or epiphenomenon (e.g. Jackendoff, 1987), the user's conscious experience often holds centre stage in the field of human-computer interaction. Familiar conscious experiences during computer use, such as effort, confusion, frustration and impatience are all relevant to the evaluation of an HCI design, and these are the types of experiences that HCI efforts endeavour to minimise.

This focus on phenomenology first is actually shared by an explicit methodological approach to the characterization of consciousness. It is one advocated by William James (1910) who advised that the researcher "begin with the most concrete facts, those with which he has a daily acquaintance in his own inner life".

The C-S Metaphor

Humans, as social animals, are equipped with substantial experience in interacting with each other. Designers can cater to this experience by following a human-human interaction metaphor, and attempt to make interacting with a computer resemble, in some sense, interacting with another individual. In terms of design, the practical implication was that making a better computer (interface) was synonymous with making it appear more human. This pursuit is evidenced in research involved with developing natural language interfaces, endowing computer interfaces with personality trait cues, facial expressions and imbuing them with emotions (e.g. Minsky, 1999; Picard, 1997). As users, we tend to meet the design effort halfway with our inclination to anthropomorphize.

However, some emerging applications in HCI require a phenomenological framework that does not fit well with the human-human, or other traditional interface metaphors. There is a trend for computers to become wearable and equipped with their own sensory systems, (e.g. Rhodes, 1997). They can thus be programmed to be context-aware in terms of both the task and physical environment (Dey & Abowd, 1999, is a good survey). Applications are also being programmed to absorb, and make inferences from, the behavioural patterns of their users. For example, web browsers can keep track of the URL's visited and proactively complete the URL string the user is currently typing by matching it to a habitual one. Extrapolating from the "short hand" ease of interaction enjoyed between close friends due to shared experiences, imagine the potential fluency of interaction with a context-aware, habit-aware, wearable device which could potentially accompany an individual at all times and share all "experiences". In this sense the interaction has the potential not only to be more intimate than ever before in HCI, but also in some respects more seamless than interpersonal interaction, and thus of a different, more continuous and customized character than human-human interaction paradigms could properly inform.

Although such a scenario may not be informed by interpersonal *interaction* paradigms, such an integrated, customized interface has aspects in common with the cognitive *intra*-actions that occur between the conscious and subconscious processes within an individual. Compare the experience of information retrieval from a computer search engine interface, or even by querying another person, with the spontaneous retrieval afforded by internal memory. Memories often pop into mind (consciousness) just as they are needed (Rhodes, 2000), before an explicit query need even be formulated. From the perspective of conscious experience, such retrieval is accomplished by an apparently context-aware unconscious process operating concurrently, autonomously and proactively.

In the human-human interaction metaphor for HCI, the human user is, in principle, regarded somewhat holistically. The computer (interface) is designed to simulate human interface characteristics (e.g. speech recognition, and speech output) by effectively acting as another human with "whom" the user can interact (in the spirit of the Turning Test). In contrast, in the C-S interface metaphor, the computer could be thought to be interacting in a more integrated way, simulating a service style akin to that of the user's *own* subconscious

processing. Several such subconscious systems could be simultaneously active. As with internal subconscious processes, it is not unreasonable to suppose that several could run simultaneously and have some form of intermittent 'interactions' projecting on, or guided from, the explicit stream of conscious experience. Although this is a fairly pre-theoretic model, it is at least consistent with two of the most familiar themes in cognitive science and the philosophy of mind: the modularity of mental processes (e.g. Fodor, 1983) and the introspective opacity of some processes and premises (e.g. Davidson, 1987).

The next section describes intelligent/autonomous interface agents (e.g. Lieberman, 1997) whose characteristics can be applied to C-S metaphor applications.

Intelligent Agents: Aspects of Autonomy and Implicit Interaction

Intelligent/autonomous interface agents (e.g. Liberman, 1997) are software processes/programs that can operate in parallel with the user and autonomously impact the interface. They are best described by example (as provided in the next section), but a brief prefacing discussion is appropriate to emphasise their key characteristics in the current context.

They are able in principle to operate without explicit initiation by the user, and/or continually and concurrently with other explicitly interactive activities of the user. By way of contrast, in strictly turn-taking conversational interfaces, such as the familiar traditional search engine interfaces, the user and the interface take turns (inter)acting, and are dormant while awaiting the response of the other. An agent's ability to act proactively sometimes includes the potential to initiate explicit interaction with the user. For example the agent may explicitly inform the user of a something it has detected in the course of it's independent (though often context-aware) activities.

Conversational interfaces are characterized by communication which tends to be fully explicit in both directions. For intelligent interface agents, there can be explicit and implicit aspects of interaction and information gathering. Though the user may or may not be aware of the agent's activities at any given moment, an agent can be programmed to attend to the user's activities, and base it's activity on such implicitly gleaned information, rather then requiring explicit instruction.

Interface agents can have a broad range of capabilities and characteristics. As such, they are not at all tightly or necessarily coupled to the C-S metaphor. An agent could perform autonomous activity but also employ a conversational interaction style, and fit under the auspices of the human-human interface metaphor. The relevance of such agents here lies in the fact their nature *permits* them to be tailored, if desired, towards applications which do fit with the C-S metaphor. For example, they can run concurrently and invisibly in the background, implicitly ingest information, adapt to the individual, interject with task-relevant information or initiate interruptions.

Analogies between Autonomous Interface Agents and Internal Subconscious Processes

The proposal of a C-S interface metaphor for HCI has been justified by the commonalties noted between the attributes of some such interface agents and those of subconscious processes. The parallels are best exemplified in agents which actually perform similar specific functions to those provided by our own subconscious system. Examples of such agents which are likely familiar to the reader include: (1) the information retrieval agents already alluded to; (2) automatic "typo" correction 'agents' as in MS Word; and (3) automatic string completion 'agents' such as provided in browsers for automatic URL string completion.

(1) The C-S interface metaphor is particularly well suited for information retrieval (IR) applications. For the most part, these electronic IR endeavours have been guided by paradigms from the library sciences. However, a very efficient, personally customised, information retrieval system - our own memory system - provides a nearer and dearer paradigm. It is a testament to the appropriateness of the C-S metaphor that when we forget something, we often assert that "it'll come to us", implying the involvement of an agent/process other than our(conscious)selves.

There are several other phenomena in memory which speak to the conscious/unconscious interaction issue. Most of our memories are subconscious most of the time. Otherwise we would be constantly actively engaged in experiencing all our previous memories (simultaneously)! It is a common experience to have an old memory resurface (not consciously bidden) when returning to an old haunt. It is also common not to be able to remember something, such as the location of one's car keys, despite the fact that one consciously wants to. Such experiences serve to remind us that we do not remember by conscious will alone, but rather through a collaboration (interaction) of the conscious and subconscious mediated by context.

Letizia (Lieberman, 1995) is an example of an autonomous interface agent for web search (also Rhodes, 2000; Stenmark, 1997). Letizia operates in

parallel with the user's browsing activity and is always active, sifting the web space that is "nearby" (linked to) the user's current page of focus. Letizia implicitly gleans the user's current web location by monitoring the user's explicit interaction with the browser, and conducts empirical observation of the user's past and present browsing behaviour to infer aspects of interest. The user profile can be saved, so knowledge persists and accumulates across sessions. This information is used to make relevancy judgements without (prior to) explicit presentation of information to the user. Based on this implicitly acquired information, Letizia proactively displays pages in a separate right frame of the browser that it judges might be of interest. Note that Letizia's search is context driven, such that whenever the user switches pages, Leteiza's context is refocused on the new page. In terms of the user's conscious participation in the interaction, the user is free to ignore or pursue the suggestions shown subtly in a window at the edge of the screen.

(2) Word processing applications such as MS-Word can now be set to automatically correct spelling mistakes as the user types[1]. The operation is subtle and unobtrusive, and in composing this document, this author has remained largely unaware of this corrective activity (though not due to a lack of 'typos').

In a similar vein, human musicians have been observed to automatically internally correct 'musical typos' when playing off sheet music without even being consciously aware of it (Jackendoff, 1987). In both cases, there is a concurrent automatic process that is functioning like a proactive proof-reader.

(3) Automatic string completion 'agents' exemplify other HCI activities that could be interpreted as serving as supplementary subconscious processes. Browsers now can be set to automatically/proactively attempt to complete the URL as the user types. Similarly, in the UNIX command-line interface shell "bash", users can type the first few letters of a filename or command and press tab to invoke the completion process (a beep will sound if there more than one possible match requiring the user to be more explicit). In the UNIX case the user has to explicitly invoke the completion process by pressing tab. In some respects, these examples could be interpreted according to the human-human interface metaphor. Conversing individuals often preemptively complete each other's sentences, and this could be considered an appropriate analogy for automatic string completion. However there are significant reasons why a C-S metaphor could be ultimately considered more appropriate. In principle, even in conversation, it is the speaker herself, not the other individual, who best knows what the correct completion will be. Thus, an intra-individual (subconscious) metaphor rather than an inter-individual metaphor is appropriate for achieving optimal performance. Furthermore, in practise, ultimately wearable computers will be privy to context and user history information on a scale that will make them more 'acquainted' with the user, in their head so to speak, than any human-human acquaintance protocol could be properly equipped to model.

[1] For example, automatically changing adn to and.

Implications for the Characterization of Consciousness and Cognition

A perspective on consciousness which revolves around the human conscious/subconscious (C-S) interface has been taken. The authors have proposed that a C-S metaphor is an emerging (though perhaps implicit) metaphor guiding HCI design. In the course of the discussion it was demonstrated that the operation of several existing autonomous interface agents, such as the type providing automatic URL string completion, can be readily interpreted according to this metaphor. However, the actual development of the existing applications was largely on a piecemeal basis and involved implicit or pre-theoretic application of the metaphor. To the authors knowledge, the C-S metaphor has not been labelled as such nor applied in a systematic manner. It lays the foundation for observing that the different disciplines of philosophy and HCI have converged to concentrate on some of the same issues, and thus are poised to mutually inform/influence each other.

There are two types of challenges inherent in implementations according to the C-S metaphor. First, it is necessary to determine and describe the exact nature of the conscious experience the interface is supposed to engender. This might include such factors as the degrees of implicit and explicit exchange, timing issues and information availability, format and salience. Then it is required to characterize and operationalize underlying computational processes to afford the desired interaction and information exchange. These two challenges are discussed in the following two sections.

Characterizing the Conscious Experience

In the human-human metaphor, much of the interaction is typically conversational and of a very explicit nature. That is, it involves direct, deliberate "communication" with the computer. The user has a conscious experience of ongoing active involvement in the interaction. This includes not only awareness of the information exchanged itself but also

(phenomenology of) intentional initiation and interpretation of exchanges. In contrast, for applications in the C-S style, the trend is towards less (experience of) explicit effort, and greater emphasis on fine tuning on the phenomenological aspects of the information availability.

The HCI endeavour of making interacting with a computer more like interaction with one's subconscious processes provides pressure to make the phenomenology of such interactions more explicit. That is, what are the various types and features of phenomenological projections of unconscious computation processes?

Phenomenology is often exemplified by reference to qualia of sensory experiences such as pain. Considerations regarding the phenomenology of interacting with our subconscious process or computers promote the characterization of a different family/modality of phenomenal experiences. These are the less sensory-centric, conscious correlates of computation and internal communication. For example, there is something it is like to consciously, with effort, conduct some reasoning, or to generate and receive explicit communication.

Some such characterizations, especially in terms of memory, have already preceded the HCI efforts. For example, meta-memory models (Kihlstrom, 1987), the feeling of knowing[2] (Hart, 1965), and tip of the tongue experiences (e.g. James and Burke, 2000). Endeavours in HCI according to the C-S metaphor may catalyse more full characterizations and/or operationalizations of such phenomenology.

For example, with regards to information agents, there are several relevant aspects of memory phenomenology at the level being imitated by the agent. It is necessary that the information become accessible to conscious reasoning and declaration, which falls under the auspices of Block's (1995) access consciousness. Another characteristic is that the time course of it's arrival with respect to changing context be such that it ideally arrives when it is relevant and before the user has a conscious sense of missing or wishing for it. This is a motivating premise of Rhodes' (2000) Just-In-Time information retrieval system. Also it is intended to be rendered accessible in such a way that it enters discretely onto the Cartesian stage without upstaging the focus of the current train of thought. The user is free to disregard or ignore the information. Lieberman (1997) points out the significance of this spontaneous subtle suggestion system in Letizia which avoids having the user make the "context switch" required by conversational interfaces from browsing the space of web pages to explicitly interacting with the search agent.

In some respects interaction with C-S style interface agents cannot possibly be experienced exactly like interaction with internal processes. The information from the interface agent starts out on the screen and is subject to absorption via our sensory system. But what is noteworthy is that some of the convenient and customised character is achieved nonetheless. When viewing memory phenomenology at this level, what seems to matter is that the right data be brought to mind at the right time regardless of whether it was a subconscious or sensory delivery channel.

While such input modality issues might not be brought to the fore in operationalizing the semantic access of declarative memory, such issues might become relevant in postulated cases of agents acting as artificial sensory systems. Consideration of attributes and implications of such artificial sensory agents might shed light on some important phenomenal issues and delineations. It provides a good connection point between HCI inspired insights and existing theoretical frameworks about consciousness such as the one proposed by Block (1995).

Characterizing the Underlying Computation

Determining the character and components of the desired conscious experience, which was discussed in the pervious section, might be far less than half the battle. When it comes to cognition, the portion which projects onto conscious is just the tip of the iceberg. Having established what the desired experience is like, the question becomes: how to make it like that? In order to serve as the subconscious does, it becomes necessary to operationalize the attributes and information resources of the underlying process, at least at a functional level. HCI has faithfully followed this trail far from it's initial focus on the conscious experience. Along the way, it (though perhaps inadvertently) produced computational models that act as unconscious computational processes.

The details are beyond the scope of this paper, but the crux of the matter amounts to characterizing the catch-all notion of context. A preliminary framework within HCI for such a characterization is provided by Dey and Abowd (1999). When it comes to memory, we are unaware of what contextual cues our subconscious process might be using to prompt recall. In HCI mediated memory, the nature of the contextual cues in the computational process need not be identical

[2] The feeling of knowing refers to a scenario in which, although the individual is experiencing difficulty retrieving a memory, they nonetheless feel that it is in there (their subconscious) somewhere.

to the ones leveraged by our subconscious, provided that from a functional perspective they are sufficiently correlated. For example, content stored on a computer can be tagged with time of day and date. Unconscious processes may involve some form of temporal tagging of memories, but not in the same format.

Conclusions

The authors have identified the emergence of an implicit C-S metaphor in HCI, which seems more appropriate to interpret and inform certain context-aware and autonomous agent applications than the traditional human-human interface metaphor. The C-S metaphor was inspired by the observation that, from the perspective of the conscious human experience, autonomous interface agents (e.g. Lieberman, 1997) often have attributes in common with subconscious processes. Most notably they exhibit autonomy, and the capacity for implicit interaction. Despite the existence of various applications that fit the bill, to the authors' knowledge the C-S metaphor has not been systematically identified and exploited. Remembrance Agents (Rhodes & Starner, 1996; Rhodes, 1997) were the closest encountered approximation in this regard.

In the application of the human-human metaphor to HCI, fairly operationalized models already existed on the nature of human-human interaction itself. This is not so much the case for human C-S interactions. This situation provides an opportunity for HCI and cognitive science to mutually inform and give impetus to each other on the C-S interface issue.

Probing the C-S metaphor fosters greater appreciation and awareness of the contribution and role of non-conscious processes in cognition. Newton's quote in homage to his predecessors can be aptly adapted to salute the support structure provided by actual and simulated subconscious processes.

If I have seen farther, it is because I have stood on the shoulders of giants.

Abstract

In this paper we propose a mental models theory of syllogistic reasoning which does not incorporate a falsification procedure and clearly specifies which conclusions will be generated and in what order of preference. It is assumed the models constructed vary in terms of the number of uncertain representations of end terms, and the directness of the representation of the subjects of valid conclusions. These key factors determine which quantified conclusion will be generated, as well as the varying tendency to respond that "nothing follows". The theory is shown to provide a close fit to meta-analysis data derived from past experiments.

Introduction

The categorical syllogism is a deductive reasoning problem comprising two premises and a conclusion (see example below).

> Some artists are beekeepers
> All beekeepers are carpenters
> Therefore, some artists are carpenters

The premises feature three terms which refer to classes of items or individuals: an end term in each premise, and a middle term which appears in both premises. The formal structure of a syllogism is determined by its mood and its figure. The term mood refers to the different combinations of quantifer that can be featured in the premises and conclusion. Four standard quantifiers are used in English language syllogisms: All, Some, No/None, or Some... are not. The term figure refers to the four possible arrangements of the terms within the premises: A-B, B-C; A-B, C-B; B-A, C-B; and B-A, B-C (where A refers to the end-term in the first premise, C refers to the end-term in the second premise, and B refers to the middle term). As each premise can contain one of four quantifiers, and there are four figures, 64 standard premise pairs are possible. The logically valid conclusion to a syllogism is a statement which describes the relationship between the two end terms in a way that is necessarily true, given that the premises are true.

The principal challenges for a theory of syllogistic reasoning are: (1) to explain how people are able to reach the right conclusion for the right reason (i.e., logical competence), and (2) to explain the systematic variations in difficulty and responding between different forms of syllogism (i.e., performance). Responses to syllogisms vary both in terms of the forms of quantified conclusion generated, and in the tendency to respond that there is no valid conclusion. One theory that provides a good fit for the data, and that has received considerable support and attention in the literature is the mental models theory (e.g., Johnson-Laird & Byrne, 1991).

This theory, which can be said to have its routes in early Euler circles, set-based accounts (e.g., Erickson, 1974, 1978), is one of the most comprehensive theories of syllogistic reasoning competence and performance. It assumes that the reasoning process begins with the construction of a mental model of the premises within working memory that makes explicit the minimum amount of information. From this initial model a parsimonious conclusions is formulated, the validity of which is tested in a search for counter-examples– a process which may involve 'fleshing out' the initial model. If a falsifying model cannot be constructed, then the conclusion is generated (since it must be valid), otherwise it is rejected. Reasoners who experience difficulty whilst reasoning will be inclined either to respond with an incorrect quantified response that is consistent with current models, or to say that there is no valid conclusion.

A central assumption of the mental models theory is that syllogisms vary in terms of the number of mental models it is necessary to construct in order to test putative conclusions. With some syllogisms a single model is sufficient for a valid conclusion to be generated (termed one-model syllogisms), with others it is necessary to construct two or three models (termed multiple-model syllogisms). Multiple-model syllogisms

place greater, and less manageable demands on limited working memory resources than one-model syllogisms, and consequently, yield the smallest proportion of valid conclusions and the largest proportion of erroneous no valid conclusion (NVC) responses.

Although good support has been found for mental models accounts of performance (e.g., Johnson-Laird & Bara, 1984), the theory does have some notable weaknesses. First, the theory does not clearly specify how conclusions are formulated, and so cannot adequately explain the clear preference for some conclusions over others. For example, according to Johnson-Laird and Steedman (1978), the theory predicts an average of 3.3 different responses per syllogism. Second, there is increasing evidence to suggest that reasoners construct only a single mental model and do not engage in a falsification process at all (e.g., Polk & Newell, 1995; Bucciarelli & Johnson-Laird, 1999; Newstead, Handley & Buck, 1999).

In spite of these weaknesses, we find many assumptions of the mental models theory to be intuitively plausible, and believe that there is scope for a new Euler-circle inspired mental models account which retains some of these assumptions, specifies the manner in which conclusions are generated more precisely, and incorporates the idea that conclusions are generated after the construction of a single minimal mental representation.

A Cognitive Uncertainty Theory

In accordance with the mental models theory, we propose a theory that assumes people reason with syllogisms by constructing abstract analogical models of the logical relationships between the terms described in the premises within working memory. We would argue that the goal of reasoners when constructing models of syllogisms is to represent mentally both the semantic meaning of each premise and the order of the terms within each premise in the simplest and most probable form. Simple models are those which do not explicitly represent all of the different possible relationships between the end terms. These are constructed for reasons of cognitive economy, since they should not place such high loads on limited working memory capacity as would the consideration of more complex alternative models. Probable models are those which represent the most likely or 'available' situation where a number of alternatives are possible.

Just as the written and spoken forms of terms within premises are read or heard in a particular serial order, so the mental representations constructed of terms within premises are intended to be scanned mentally in a direction which corresponds with these forms of presentation. For ease of explanation we shall refer to this intended scanning direction as 'left to right'.

The Representation of Quantifiers

If a 'universal' quantifier (all or no/none) precedes a term, then the complete class of items or individuals to which the term refers will be represented in the model. For example, in our notation, "All A" would be represented as: [A]

When a premise has the universal, affirmative quantifier all (e.g., "All A are B"), we suggest that reasoners represent the premise as: [A B]

This representation (and the representations constructed for all other forms of premise) is intended to represent both the meaning of the premise and the order of the terms within the premise. It features a description of the class A (the subject of the premise) in terms of the class B. This is the simplest most economical way of representing this premise, since it avoids the need to represent members of the B class who are not also members of the A class. The representation is equivalent to the conditional statement "If it is an A, then it is a B". Just as the statement "All A are B" is intended to be read from left to right (or spoken in a corresponding serial order), so this representation is intended to be scanned from left to right. When scanned from left to right, this representation is unambiguous. However, when scanned from right to left, the representation is ambiguous, suggesting a fallacious identity interpretation of the premise (i.e., ambiguity in the representation leads to the assumption that "All A are B" also means "All B are A").

Twenty eight syllogisms have at least one premise featuring the All quantifier. Eighteen of these are determinate syllogisms. For fourteen of these, the ambiguity of this representation does not affect valid conclusion generation. However, the assumption that participants construct ambiguous representations of All premises can account for all preferred conclusions for the remaining fourteen syllogisms.

The premise "No A are B" (featuring the universal, negative quantifier) would be represented as: [A] [B]

If an 'existential' quantifier precedes a term, then an incomplete class of items or individuals to which the term refers will be represented in the model. For example, "Some A" would be represented as: A) or (A

Grice's (1975) maxim of quantity states that speakers should be as informative as possible, and should not deliberately withhold information which they know to be true. It follows from this notion that it would be wrong for speakers to use the word "some" when they know "all" to be true (see also Begg, 1987; Newstead & Griggs, 1983). We argue, therefore, that although a logician's definition of the quantifier some is "at least one and possibly all", complete classes of items or individuals are not represented when a term is preceded by "some". Hence, we suggest that the premise "Some

A are B" (featuring the existential, affirmative quantifier) would be represented as: [A)B]

With this premise, the possibility that there could be A's that are not B's is not represented in the model, although this may be understood implicitly.

The premise "Some A are not B" (featuring the existential, negative quantifier) would be represented as: (A [B]

In this instance, the possibility that there could be A's that are B's is not represented in the model, but again, this may be understood implicitly.

Model Construction

It is suggested that the construction of models occurs as follows:

1) One of the two premises is picked to be the first premise represented in the model.
2) A model of the first premise is constructed in which the first term in the premise is described in relation to the second term.
3) The model of the first premise is augmented so that it features a representation of the first term in the second premise described in relation to the second term in the second premise. When a universal set is represented in the model of the first premise, and the term referring to that set is preceded by some in the second premise, the universal representation is reduced to an existential representation in the combined model (e.g., syllogisms 3 and 5). As with the first premise, the model is constructed such that the semantic meaning of the quantifier and the serial order of terms in the second premise are retained within the model (see examples below).

1.	2.	3.
Some A are B	Some A are B	No A are B
All B are C	No C are B	Some B are C
[A)B C]	[c] [A)B]	[a] [B)c]
Some A are C	No C are A	No A are C
(valid)	(invalid)	(invalid)
4.	**5.**	**6.**
Some A are not B	No B are A	All B are A
All C are B	Some B are C	No B are C
(A [c B]	[B)c] [a]	[B A] [C]
Some A are not C	Some C are not A	No A are C
(valid)	(valid)	(invalid)

Syllogism 1 exemplifies a situation in which it is necessary to represent members of one end-term class who are also members of the other end-term class in order to construct a model in which the semantic meaning of each premise and the order of the terms within each premise is represented. In contrast, syllogisms 2 to 6 exemplify situations in which it is not necessary to represent members of one end-term class who are also members of the other end-term class.

We acknowledge that the model shown for syllogism 5 is not the only possible model that could be constructed. For example, the possible intersection between the A term and C term, or the possible containment of the A term within the C term could be represented in a model. We would suggest, however, that if it is not necessary to represent an overlap in class membership in a model in order to represent the meaning of each premise and the order of the terms, then no overlap will be represented. The model for syllogism 5 shows no overlap between the A term and the C term, and so, the relationship between these terms shown in the model is equivalent to "No C are A" or "No A are C". This may be considered a rational approach to model construction, since the situation "No X are Y" (where X and Y are two properties picked at random) is almost always true (cf. Chater & Oaksford, 1999). Hence, the model shown for syllogism 5 represents the most probable situation out of a number of possible alternatives.

Certainty and Uncertainty within Models

In some instances, the representation of one end term in relation to the other end term in a model is 'certain'. By this we mean that the class represented by one end term (e.g., the A's in syllogism 4) cannot incorporate members of the class represented by the other end term (e.g., the C's in syllogism 4) unless members of one end-term class (e.g., the A's in syllogism 1) are already members of the other end-term class (e.g., the C's in syllogism 1). In other instances, however (e.g., in syllogisms 2, 3 4 and 5), the representation of one end term is 'uncertain' in relation to the other end term. That is, members of one end-term class who are not represented as being members of the other end-term class could possibly be members of that other end-term class– in our notation, lowercase letters denote uncertain representation of a term. For example, in the model for syllogism 2, as the possibility that there could be some A's that are not B's is not explicitly represented, it is possible that some or all of the C's represented could be A's– hence, the C term is represented by a lowercase letter. In the models for syllogisms 3 and 5, the only certain representations are of the B's that are C's. As some or all of the A's that are represented could be C's, and some or all of the C's that are not B's could be A's, both the A's and the C's are shown in lowercase.

Suggested Conclusion Generation

The conclusion that is initially 'suggested' by a model is the one that follows the serial order in which the terms are represented (left-to-right in our notation). The subject of this conclusion will be the end term on the left. The quantifier that is chosen is determined by the representation of that term. If an existential set is represented, then the conclusion will have an existential quantifier (either some or some... are not), otherwise the conclusion will have a universal quantifier (either All or No). If the first end term in the model is represented outside the second end term, then the conclusion will be negative (either No or Some... are not), otherwise it will be affirmative (either All or Some).

Although conclusions that are suggested by a model will be the preferred responses, the initial conclusion suggested by left-to-right scanning is not always the one that is generated. The initial conclusions suggested by left-to-right scanning of the models constructed for the six example syllogisms are shown beneath the models.

With some syllogisms the representation of the subject of the conclusion suggested by left-to-right scanning is uncertain (e.g., the C term in syllogism 2 and the A term in syllogism 3). Uncertainty of this nature in a model should cause reasoners to lack confidence or certainty over the validity of an initial conclusion, and should motivate them to scan the model from right-to-left in search of an alternative conclusion. If the subject of the conclusion suggested by right-to-left scanning has a certain representation, then this conclusion will be favoured over the conclusion initially suggested (when scanned from right to left the model for syllogism 2 suggests the valid conclusion "Some A are not C" and the model for syllogism 3 suggests the valid conclusion "Some C are not A"). Since two stages of conclusion generation are required with these problems, they load cognitive resources more heavily than those with models where the subject of the conclusion suggested by left-to-right scanning is certain (e.g., syllogism 1). Consequently, they should yield more logical errors– in particular, the generation of invalid conclusions that are consistent with left-to-right scanning (which should be the second most common quantified response)– lower feelings of certainty in participants, and high levels of fallacious NVC responding.

With some indeterminate syllogisms, the subjects of conclusions suggested by both left-to-right and right-to-left scanning have uncertain representations (see syllogisms 8 to 12). With these problems we suggest that the conclusion suggested by left-to-right scanning will be generated more frequently than the one suggested by right-to-left scanning. This is because some reasoners will fail to generate a conclusion through right-to-left scanning due to the extra cognitive demand involved, while most reasoners will be able to generate an initial conclusion through left-to-right scanning. These syllogisms should yield lower feelings of certainty in participants and more NVC responses than syllogisms with models containing one or no uncertain representations.

Direct and indirect representation of the subject With most determinate syllogisms the subject of the valid conclusion is represented 'directly' in the model by members of the class referred to by the subject of this conclusion. For example, the subject of the valid conclusion to syllogism 2 is "Some A", and the representation of this in the model is also "Some A". With some determinate syllogisms, however, the subject of the valid conclusion is represented 'indirectly' in the model by members of the middle-term class who are also members of the class referred to by the subject of this conclusion. For example, the subject of the valid conclusion to syllogism 3 is "Some C", although the representation of this in the model is "Some B". In this instance it is necessary to convert mentally the representation of the subject of the conclusion from "Some B" to "Some C" before a valid conclusion can be generated. As this additional step in the reasoning process is necessary, we suggest that these problems are more difficult than those where the subject is represented directly. Hence, syllogism 3 should yield more logical errors (including a greater proportion of NVC responding) and lower feelings of certainty in participants than syllogism 2.

Implied Conclusion Generation

Not all individuals respond with a conclusion that is suggested directly by a model. A small proportion will respond with a conclusion that is implied by a model. We suggest that implication affects responding in the following way:

- As some and some... are not are given similar interpretations (e.g., see Begg & Harris, 1982), whenever a some conclusion is suggested by a model, a some... are not conclusion will often be generated, and whenever a some... are not conclusion is suggested by a model, a some conclusion will often be generated.
- Conclusions with universal quantifiers (all and no) imply that existential alternatives are also true (some and some... are not respectively).

Categorising Syllogisms

When models are constructed and conclusions generated according to the assumptions we have outlined, five types of determinate syllogism (assigned

labels D1 to D5 in Table 1) and four types of indeterminate syllogism (assigned labels I1 to I4 in Table 1) can be identified. Example syllogisms 1 and 4 are classified as D1 problems, syllogism 6 is a D2 problem, syllogism 2 is a D3 problem, syllogism 5 is a D4 problem, and syllogism 3 is a D5 problem.

Examples of indeterminate syllogisms together with models and suggested conclusions are given below.

7.	8.	9.
All A are B	Some B are not A	Some A are not B
Some B are C	No C are B	Some C are B
[A B) C]	[c] (B [a]	(a [c) B]
Some A are C	NVC	NVC
	No C are A	Some A are not C
10.	11.	12.
No B are A	Some B are not A	Some B are A
No B are C	Some B are C	Some C are B
[B] [a] [c]	(B [a] [B) c]	[B) a] [c) B]
[a] [B] [c]	(a [B) c]	[c) B) a]
or	or	NVC
[c] [B] [a]	((c B [a]	Some C are A
NVC	NVC	
No A are C	Some A are not C	
or	or	
No C are A	Some C are not A	

Example syllogism 7 is an I4 problem, syllogisms 8 and 9 are I1 problems, syllogisms 10 and 11 are I3 problems, and syllogism 12 is an I2 problem. With two of these (types I4 and I1), it is possible to construct a model in which the semantic meaning of each premise and the order of terms in the premises are represented with little difficulty. With the remaining two, however, the construction of a 'unified' model is less straightforward, as either: (1) the premises suggest models with a split representation of the middle term (type I2 and some I3), or (2) the premises do not dictate the order in which the end terms should be represented in a model (type I3). With type I2 and I3 problems, reasoners may feel highly confident that there is no necessary relationship between the end terms, and so, respond that there is NVC. However, as reasoners display a bias towards the generation of quantified responses where NVC responses are appropriate (e.g., Johnson-Laird & Steedman, 1978; Johnson-Laird & Bara, 1984), with I2 and I3 syllogisms we have considered strategies reasoners may adopt in order that models might still be constructed and quantified conclusions generated. With I2 syllogisms a quantified conclusion may be generated if reasoners construct a model in which a representation of the end term which forms the subject of a some premise (e.g., "Some C are B" in syllogism 12) is contained within the class referred to by the middle term in the other premise (see second model for syllogism 12). There are good reasons for assuming that models of this nature are constructed: (1) they are able to represent the semantic meaning of each premise and the order of the terms within each premise, and (2) they feature a representation of a highly probable relationship between the end terms.

With I3 syllogisms, a unified model may be constructed after applying a simple conversion procedure to one of the premises (i.e., by switching the two terms in a premise around without changing the quantifier). Once conversion has taken place, it is possible for reasoners to construct models like those constructed for I1 or I2 syllogisms (depending upon mood) and to generate quantified conclusions (see second models for syllogisms 10 and 11).

Table 1: Nine types of syllogism as a function of figure, together with NVC rankings.

Type	AB BC	BA CB	AB CB	BA BC	Total	NVC Rank
D1	4	4	4	4	16	1
D2	1	1	0	3	5	2
D3	0	0	2	0	2	3
D4	0	0	0	2	2	3
D5	1	1	0	0	2	4
I1	5	5	2	0	12	5
I2	2	2	0	0	4	6
I3	0	0	5	7	12	6
I4	3	3	3	0	9	2.5

Rank values have been assigned to each type of syllogism in Table 1 according to the level of NVC responding that should be associated with them according to the theory (a 1 ranking denotes a low level of NVC responding). With the exception of I2 and I3 syllogisms (where high levels of NVC responding should be associated with strong feelings of certainty), these rankings should correlate negatively with the levels of certainty associated with each type of syllogism.

Predicting performance

We have used Chater and Oaksford's (1999) meta-analysis data (on conclusion quantification and NVC responding) together with Johnson-Laird and Steedman (1978, Experiment 1 and 2), and Johnson-Laird and Bara's (1983, Experiment 3) data (on conclusion term order) in order to test how well the cognitive uncertainty theory explains syllogistic reasoning performance.

Quantification

The theory makes ranking predictions for most common conclusions, as well as second, third and fourth most common conclusions. Predicted rankings match data rankings in 175 out of 256 cases. When the proportions of quantified responses associated with correct matches are summed, the theory accounts for nearly 91% of quantified responses in exact order of commonality.

Term Order in Preferred Conclusions

The theory makes a definite prediction about the order of terms in preferred conclusions for 50 of the 64 premise pairs. It matches the term order for preferred conclusions in 47 of these, and therefore, directly predicts the term order for over 73% of preferred quantified responses in the data—although the theory can accommodate over 95% of these.

NVC responding

Rank values have been assigned to each syllogism based on predicted feelings of certainty in participants, and how much NVC responding would be expected according to the theory (see Table 1). There is a significant correlation between these rankings and the percentages of NVC responses in the meta-analysis data (Spearman's Rho = .885, $p < .001$). The theory, therefore, accounts for 78% of the variance in the NVC data.

Discussion

A new theory of syllogistic reasoning, inspired by early Euler circles, set-based, explanations has been proposed. The theory has been shown to provide a good fit to meta-analysis data derived from past experiments, in terms of: (1) predicting order of preference for quantified responses, (2) predicting term-order in preferred conclusions, and (3) accounting for the varying tendency to give NVC responses.

The new theory was developed in response to an increasing awareness that key assumptions of the mental models account proposed by Johnson-Laird and colleagues were failing to receive support in the literature. In particular, serious doubts have been raised concerning the conclusion falsification and fleshing out processes outlined in the mental models theory. The new account overcomes this problem by suggesting that only a single model is constructed based on an interpretation of the semantic meanings of the premises. Models may be logically accurate, or suggest a fallacious or ambiguous interpretation of All quantifiers. Difficulty is said not to be caused by cognitive loads associated with model construction, but instead by the cognitive loads associated with 'searching' a model in order to identify a conclusion that does not feature an uncertain representation of the subject.

The mental models account may also be criticised for not adequately specifying the manner in which conclusions are formulated, and hence, not explaining why clear orders of preference for different quantified conclusions are evident in the data (e.g., see Chater & Oaksford's meta-analysis of past experiments). The new theory clearly specifies which conclusion will be identified first from a model, whether other conclusions will be identified that are also suggested by a model, and which conclusions will be generated to a lesser degree after being implied by a model. Importantly, clear psychological justifications are given for the predicted orders of preference for these quantified responses.

Using a Triad Judgment Task to Examine the Effect of Experience on Problem Representation in Statistics

Abstract

This research investigated whether the differences found between novices and experts in using surface and deep structures to categorize problems applied to the domain of statistics. Also explored was whether the methodology of a triad judgment task was reliable in discriminating how beginning and advanced students represent statistics problems. The task was designed in which source problems shared either structural features (t-test, correlation, or chi-square) or surface similarity (story narrative) with the target problem. Graduate students (N = 101) with varying levels of experience in the domain of statistics were asked to chose which source problem "goes best" with the target problem for each triad. Students with advanced experience in statistics tended to represent the problems on the basis of deep, structural features while beginning students tended to rely on surface features. Discussion on the effectiveness of the methodology employed and potential uses in other domains is presented.

Introduction

Students learning statistics are required to learn a set of interacting skills. First, they need to become familiar with statistical procedures and how to use them (computing formulas). Second, they need to be able to recognize when to use those statistical procedures. The first set of skills is procedural in nature, i.e., they need to learn formulas and know how to execute the computation (or the statistical packages). The latter type of skill is representational, i.e., they need to be able to perceive and represent features within contexts that suggest which procedures should be used.

Previous research (Adelson, 1981; Chi, Feltovich & Glaser, 1981; Chase & Simon, 1973; Hardiman, Dufresne & Mestre, 1989; Schoenfeld & Herrmann, 1982) has shown that experts and novices within a domain represent problems within that domain on the basis of a different set of features. Bransford, Brown & Cocking (1999) report that this difference, in part, lies in knowledge organization. Expert knowledge centers on core concepts and big ideas found within the domain while novices rely on isolated facts and do not connect these facts in a way that allows them to generate inferences. For example, Chi and colleagues (1981) found that participants with advanced experience in physics sorted problems in their discipline on the basis of structural features, including the laws and principles of physics. When asked to sort the same problems, novices represented, and subsequently sorted the problems on the basis of surface features, such as the object being manipulated in the problem.

Quilici and Mayer (1996) argue that while surface features are generally more salient than structural features for novices, successful analogical transfer is dependent upon the recognition of structural similarities among problems. Consequently, they investigated the role of examples in how students learn to categorize statistic word problems. Their findings suggest that exposure to examples influences inexperienced students' structural schema construction, particularly when the example problems emphasize structural characteristics versus surface characteristics. Quilici and Mayer contend that their study merits further research concerning the conditions under which students rely on surface features or structure features in categorizing problems. In that Quilici and Mayer's participants were limited to those with little or no knowledge about statistics, further research concerning the effect of experience on problem representation is warranted.

This study was designed to replicate the expert/novice difference in perception and representational skill in the context of statistics problems. The purpose of this study was two-fold. First, the study investigated whether the differences found between novices and those with advanced experience in statistics use surface and/or deep structures to categorize problems applied to the domain of statistics. Second, this research explored whether the methodology of a triad judgment task was reliable in discriminating how beginning and advanced students represent statistics problems. Consequently, this study extended Quilici and Mayer's research (1996) by determining if those with advanced training in statistics

do indeed cue in on the structural features of a statistical word problem.

To complete this extension, a triad judgment task was designed and administered to individuals with varying levels of statistical experience. According to Hardiman, Dufresne & Mestre (1989), the triad judgment task offers several advantages over the traditional sorting task used in previous research (Chi et. al, 1981; Quilici & Mayer, 1996). First, participants are able to concentrate on individual problem sets rather than being presented with a stack of cards to sort simultaneously. Second, the task allows for large-group administration and ease in scoring. The design of the triad task in this study was similar in nature to that employed by Hardiman and colleagues' research (1989). However, it differed in that this research examined problem representation in the domain of statistics while theirs was grounded in the field of mechanics.

The judgment task required participants to identify which of two given source problems "goes best" with a target problem (Figure 1). The source problems shared

Target Problem	
Source Problem 1	Source Problem 2

Figure 1
Structure of Triad Problems

either similar surface features or structural features with the target problem. Surface features were similar in that the story narrative shared common characteristics while similar structural features involved the requirement of the same statistical test (t-test, correlation and chi-square). Surface features included similar story characters (personnel expert, meteorologist, college dean and psychologist) and similar dependent/independent variables (words typed per minute/experience of typists, annual rainfall/average yearly temperature, grade point average/reading score, number of errors on a test/amount of sleep). The structural features included the nature of the independent variable (one group or two independent groups) and the nature of the dependent variable (continuous or categorical).

Using the statistics word problems from Quilici and Mayer's study (1996), 18 triads were designed to investigate whether this judgment task would discriminate between those representing the problems using deep, structural features with those relying on surface features. To do this, we administered the task to students with varying levels of experience in the domain of statistics. We hypothesized that students with more advanced statistical experience would predominantly represent problems based on structural features while students with less statistical experience would tend to represent the problems based on surface features.

Method

Participants

The participants were 101 graduate students with a varied amount of experience in statistics. Those with no prior statistics courses totaled 27 participants, 33 participants completed one course, 13 finished two courses, 10 had completed three courses, six participants completed four courses, eight participants finished five courses, three participants had completed six courses and one participant completed eight courses. All individuals who volunteered to participate in this study earned course extra-credit.

Problem Task

A triad judgment task was used to investigate the features that people use to represent common statistics problems. The task involved the presentation of three statistical problem statements- one target problem and two source problems. Participants were asked to read each set and judge which of the two source problems "goes best" with the target problem. Comparisons were based upon two features: surface and structure. Surface features were defined by the narrative characteristics (i.e., "After comparing weather data for the last 50 years, a meteorologist claims...") and structural features were defined by requisite statistical tests (t-test, correlation, chi-square).

There were three sets of comparison types that participants were asked to evaluate (Appendix). In the first comparison, one source problem shared only similar surface features to the target problem while the other source problem shared only similar structural features. Thus, Comparison One was considered Similar Narrative / Dissimilar Structure - Similar Structure / Dissimilar Narrative (SN/DS-SS/DN). In the second comparison, one source problem shared no similarities in either surface or structure while the other shared only similar structure to the target problem. Thus, Comparison Two was considered Dissimilar Narrative / Dissimilar Structure - Similar Structure/Dissimilar Narrative (DN/DS-SS/DN). In the third comparison, one source problem shared only similar surface features to the target problem while the other shared neither surface nor structural similarities. Thus, Comparison Three was considered Similar Narrative / Dissimilar Structure - Dissimilar Structure /

Dissimilar Narrative (SN/DS-DS/DN). Each participant was presented six triads per comparison for a total of 18 triads.

Procedure

Participants were given a packet that contained the 18 triad problems and a cover sheet. On the cover sheet, the participants recorded background information including prior statistics courses, education level, and gender. Participants were tested during class and were given as much time as needed to complete the task.

Scoring

A maximum score of 18 points, at six points per comparison type was possible. Participants scored one point per triad under Comparison One (SN/DS-SS/DN) and Comparison Two (DN/DS-SS/DN) if they selected on the basis of structural features. For Comparison Three (SN/DS-DS/DN), participants scored one point if they selected similar surface features in that neither comparison problems shared structural features with the target problem. Thus, a higher score implies a tendency towards choosing the structural dimension or the surface dimension where appropriate.

Results

A correlation analysis was conducted to examine in greater depth the relationships between the level of experience (as measured by the number of statistics courses an individual completed) and the three comparison types. Findings suggest a significant relationship between number of courses and total score, $r = .39, p < .01$. This suggests that the more experience an individual has in statistics, the more likely they are to make more structural comparisons between two statistical passages.

While there was a significant correlation between the number of courses completed and total score on the triad judgment task, there were differences found among the three comparison types. Specifically, only Comparison One (SN/DS-SS/DN) and Comparison Two (DN/DS-SS/DN) were significantly correlated with the number of courses ($r = .35, p < 01, r = .39, p < .01$, respectively). These results, taken together, suggest that the more experience one has in statistics, the more likely he/she is to group statistical passages according to similar methodologies. As expected, there was no significant correlation between experience level and Comparison Three (SN/DS-DS/DN). If neither of the two source problems shared structural features with the target problem, individuals, regardless of experience, choose upon the basis of surface features.

In addition, to investigate whether individuals with more experience in statistics performed differently on the three comparison types as did novices, a repeated measures ANOVA was conducted. Individuals were grouped into three levels of experience in the domain of statistics. Level One included participants who had taken either zero or one course (n=60), Level Two reflected participants that had completed either two or three courses (n=23) and Level Three included participants that had completed four or more statistics courses (n=18). Means and standard deviations for scores on the three comparison types for each experience level are presented in Table 1. The

Table 1: Means and Standard Deviations for Comparison Type by Experience Level.

Level	n	Type I		Type II		Type III	
		M	SD	M	SD	M	SD
One	60	1.73	1.68	3.87	1.24	4.87	1.32
Two	23	2.13	1.94	4.04	.88	4.52	1.20
Three	18	3.44	1.61	4.94	1.06	4.16	1.50

significant interaction between experience level and comparison type suggests a relationship between the level of experience and the way the individual represents the particular statistical problem, $F(2, 98) = 4.94, p < .01$. Tukey's HSD test indicated that those in level three performed significantly different than those in levels one and two. The significant main effect of experience level indicates that individuals with more training in statistics represent statistical passages in ways that are more expert, $F(2, 98) = 6.67, p < .01$. The significant main effect of comparison type suggests that individuals, regardless of level of experience, do not respond in the same way to the different problems found in the triad judgment task, $F(2, 98) = 44.89, p < .01$.

Discussion

In this study, two questions were tackled. The first question was, How do beginning and advanced students in statistics compare in the way they represent statistical word problems? The analyses revealed several contrasts. It was shown that those with advanced experience tended to look for similar deep structures in the word problems presented within the triads. Conversely, the findings suggest that novices relied more heavily on the surface features to match a source problem with a target problem. However, when presented with comparisons types where neither of the source problems shared deep structural features with the target problem, all students, regardless of experience, selected on the basis of similar surface features.

The second question was, Can a triad judgment task be used to reliably discriminate how beginning and advanced students represent statistics word problems on

either the basis of structural features or surface features? On the basis of earlier research (Chi, Feltovich & Glaser, 1981; Hardiman, Durfresne & Mestre, 1989), we reasoned that those with advanced training in statistics would make selections based on structural features while those with less training would select on the basis of surface features in a triad judgment task. Findings were consistent with our prediction. This suggests that the triad judgment task may indeed be a promising methodology to employ in studies where sorting tasks are traditionally used.

This study yields implications for educators of statistics. First, instruction in statistics should address the nature of problems and their structural components (e.g., type of data presented and the driving question of the problem). Second, learners should be provided with explicit instruction in recognizing similarities of problems based on core concepts, a skill requisite of experts (Bransford, Brown and Cocking, 1999).

This study certainly contributes to the relatively narrow research base of experts-novices in statistics, yet further studies are needed. Specifically, more studies are needed to explore the circumstances that promote the transition from using surface characteristics to deep structural features in representing problems.

Appendix

Comparison One: Similar Narrative/Dissimilar Structure - Similar Structure/Dissimilar Narrative (SN/DS-SS/DN)

Target: After examining weather data for the last 50 years, a meteorologist claims that the annual precipitation is more likely to be above average in years when the temperature is above average than when temperature is below average. For each of the 50 years, she notes whether the annual rainfall is above or below average and whether the temperature is above or below average.

Source 1: After examining weather data for the last 50 years, a meteorologist claims that the annual precipitation varies with the average temperature. For each of 50 years, she notes the annual rainfall and average temperature.

Source 2: A college dean claims that a group of good readers contains more honors students than a group of poor readers. For each of 100 first year college students, a reading comprehension test was used to determine whether the student was a good or poor reader and grade point average (GPA) was used to determine whether or not the student was an honors student.

Comparison Two: Dissimilar Narrative/Dissimilar Structure – Similar Structure/Dissimilar Narrative (DN/DS-SS/DN)

Target: A college dean claims that good readers earn better grades than poor readers. The grade point averages (GPA) are recorded for 50 first-year students who scored high on a reading comprehension test and for 50 first-year students who scored low on a reading comprehension test.

Source 1: A psychologist tests the hypothesis that people who are fatigued also lack mental alertness. An attention test is prepared which requires subjects to sit in front of a blank TV screen and press a response button each time a dot appears on the screen. A total of 110 dots are presented during a 90-minute period, and the psychologist records the number of errors for each subject. Twenty subjects are selected; half are tested after being kept awake for 24 hours and half are tested in the morning after a full nights sleep. Based on the number of errors on their test, each subject is also labeled as high or low in mental alertness.

Source 2: A personnel expert wishes to determine whether experienced typists are able to type faster than inexperienced typists. Twenty experienced typists (i.e., with 5 or more years of experience) and 20

inexperienced typists (i.e., with less than 5 years of experience) are given a typing test. Each typists average number of words typed per minute is recorded.

Comparison Three: Similar Narrative/Dissimilar Structure - Dissimilar Structure/Dissimilar Narrative (SN/DS-DS/DN)

Target: After examining weather data for the last 50 years, a meteorologist claims that the annual precipitation varies with the average temperature. For each of 50 years, she notes the annual rainfall and average temperature.

Source 1: After examining weather data for the last 50 years, a meteorologist claims that the annual precipitation is greater in years with below average temperature than in years with above average temperature. She notes the annual rainfall for each of 25 years that had above average temperatures as well as 25 years that had below average temperatures.

Source 2: A psychologist tests the hypothesis that people who are fatigued also lack mental alertness. An attention test is prepared which requires subjects to sit in front of a blank TV screen and press a response button each time a dot appears on the screen. A total of 110 dots are presented during a 90-minute period, and the psychologist records the number of errors for each subject. Twenty subjects are selected; half are tested after being kept awake for 24 hours and half are tested in the morning after a full nights sleep. Based on the number of errors on their test, each subject is also labeled as high or low in mental alertness.

Perceptual Learning Meets Philosophy: Cognitive Penetrability of Perception and its Philosophical Implications

Abstract

The undermining of the cognitive impenetrability of perception has led to the abolition of the distinction between *seeing* and *seeing as*, clearing the way for the relativistic theories of science and meaning, since perception becomes theory-laden. Hence the existence of a theory-neutral basis, on which a rational choice among alternative theories could be based, is rejected and scientific theories become incommensurable. One of the arguments against the cognitive impenetrability of perception is based on evidence from neuroscientific studies that suggest the plasticity of the visual cortex, in the sense that there can be some local rewiring of the neural circuitry of the early visual system, as a result of experience. This is taken to constitute evidence that the early vision is cognitively penetrable. In this paper I argue that the evidence concerning perceptual learning does not entail the cognitive penetrability of perception. To that end I discuss the issue of perceptual learning and claim that this learning is task and data-driven and not theory-driven. The process is mediated by the allocation of attention, which though cognitively penetrable, allows only an indirect form of cognitive penetrability of perception. In the last part I elaborate on the significance of this indirect penetrability, as opposed to the direct penetrability by cognition, and discuss its implications for the issue of the incommensurability of scientific theories. My conclusion is that attention can be controlled across different theoretical backgrounds, and thus, that the indirect cognitive penetrability does not entail incommensurability.

Introduction

The undermining of the cognitive impenetrability of perception has led to the abolition of the distinction between *seeing* and *seeing as* (Gregory, 1974; Hanson, 1958; Kuhn, 1962), clearing the way for the relativistic theories of science and meaning, since perception becomes theory-laden (what we see depends on our expectations, beliefs, and so forth). Hence the existence of a theory-neutral basis, on which a rational choice among alternative theories could be based, is rejected and scientific theories become incommensurable. There can be no communication between scientists that belong to different scientific paradigms, because there is not a theory-neutral perceptual basis that could resolve matters of meaning. Instead, empirical evidence, becomes part of a paradigm or a theoretical research program, being modulated by its theoretical commitments. Thus, proponents of different paradigms or research programs either perceive different worlds (strong version of relativism; Kuhn, 1962), or cannot compare their theories on the basis of some neutral empirical evidence but must search for other criteria of theory evaluation (medium version of relativism; Churchland, 1989).

One of the arguments against the cognitive impenetrability of perception and in favor of its theory-ladenness is based on evidence from neuroscientific studies that suggest the plasticity of the visual cortex, and more specifically, on evidence that there can be some local rewiring of the neural circuitry of the early visual system, as a result of experience (the phenomenon of perceptual learning).

The plasticity of the brain and the possibility of rewiring of the neural circuitry of the perceptual systems, as a result of acquiring knowledge, goes against the view (Fodor, 1983; Pylyshyn, 1999) that some part of vision, the early vision, is cognitively impenetrable, and shows (Churchland, 1988) that perception is cognitively penetrable, in so far as learning, which is a cognitively driven process, affects even those circuits that are involved in early vision.

In this paper I argue that the evidence concerning perceptual learning does not entail the cognitive penetrability of perception. To that end I discuss the issue of perceptual learning and claim that this learning is task and data-driven and not theory-driven.

Being the former it allows only an indirect form of cognitive penetrability of perception. In the last part I elaborate on the significance of this indirect penetrability, as opposed to the direct penetrability by cognition, and discuss its implications for the issue of the incommensurability of scientific theories. My conclusion is that this indirect penetrability does not entail incommensurability.

I have spoken of perception. This term is not employed consistently in the literature. Sometimes "perception" purports to signify our phenomenological experience, and thus, "is seen as subserving the recognition and identification of objects and events" (Goodale 1995, 175). Since I do not use the terms the same way, I will introduce some terminology.

I call *sensation* all processes that lead to the formation of the retinal image (the retina's photoreceptors register about 120 million pointwise measurements of light intensity). This image, which initially is cognitively useless, is gradually transformed along the visual pathways in increasingly structured representations (such as, edges, boundaries, shapes, colors) that are more convenient for subsequent processing. I call these processes that transform sensation to a representation that can be processed by cognition *perception.* Perception includes both low-level and intermediate-level vision and, I claim, is bottom-up. In Marr's (1982) model of vision the *21/2D sketch* is the final product of perception. As I shall argue next perception is non-epistemic, that is, it is independent of specific-object knowledge. All subsequent visual processes fall within *cognition*, and include both the post-sensory/semantic interface at which the object recognition units intervene as well as purely semantic processes, that lead to the identification of the array (high-level vision). At this level we have observation (Marr's *3D model*), which is a cognitive activity.

Perceptual Learning

There is growing evidence for the diachronic penetrability of perceptual systems and for local rewiring of their neural circuits (Ahhisar and Hochstein, 1993; Antonini, Strycker, and Chapman, 1995; Karni and Sagi, 1995; Stiles, 1995). Is there a way to reconcile the notion of cognitive impenetrability of perceptual systems with this evidence? Fodor thought that there is not any, and that this issue would be resolved with the findings of empirical research. Should empirical research show perceptual learning to be possible, then the encapsulation of his input modules would have been proved false. The evidence suggests that perceptual systems are indeed diachronically, in the long run, open to some rewiring of the patterns of their neural connectivity, as a result of learning. These systems are to some extent plastic. But this does not mean that they are cognitively penetrable. Let us see why.

Research shows that changes can be induced in visual cortical neural patterns in response to learning. More specifically, visual processing at all levels may undergo long-term, experience-dependent changes. The most interesting form of learning is "slow learning", because it is the only type that causes structural changes in the cortex (formation of new patterns of connectivity). Such learning can result in significant performance improvement. For example, one may learn with practice to perform better at visual skills involving target and texture discrimination and target detection, and to learn to identify visual patterns in fragmented residues of whole patterns (priming). Performance in these tasks was thought to be determined by low-level, stimulus-dependent visual processing stages. The improvement in performance in these tasks, thus, suggests that practice may modify the adult visual system, even at the early levels of processing. As Karni and Sagi (1995, 95-6) remark "[L]earning (acquisition) and memory (retention) of visual skills would occur at the earliest level within the visual processing stream where the minimally sufficient neuronal computing capability is available for representing stimulus parameters that are relevant input for the performance of a specific task."

Karni and Sagi (1995) suggest that slow learning is independent of cortico-limbic processing, which is responsible for top-down processes and, through the interaction of the limbic system with the visual pathways, responsible for conscious object recognition. It is also independent of factors involving semantic associations. Yeo, Yonebayashi, and Allman (1995) suggest that priming facilitates the neural mechanisms for processing images and that the cortex can learn to see ambiguous patterns by means of experience-induced changes in functional connectivity of the relevant processing areas. Thus, priming involves a structural modification of basic perceptual modules. Practice with fragmented patterns leads to the formation of the "priming memory" which may be stored in the cortical visual areas. Long-term potentiation (LTP) may be the mechanism implementing these architectural changes by establishing experience-dependent chains of associations and dissociations.

Slow learning-induced architectural modifications are "experience dependent" (Greenough, et al., 1993), in that they are controlled by the "image" formed in the retina. But, although learning and its ensuing functional modifications occur in those neuronal

assemblies that are activated by the retinal image, still some extra-retinal factor should provide the mechanism that will gate functional plasticity. Although many neuronal assemblies are activated by the retinal image, learning occurs only in those assemblies that are behaviorally relevant. This is called the "gating of neuronal plasticity".

The factor that modulates gating is the demands of the task. They determine which physical aspects of the retinal input are relevant, activating the appropriate neurons. Functional restructuring can occur only at these neuronal assemblies. The mechanism that accomplishes this is attention. Focusing attention ensures that the relevant aspects of the input are further processed. Attention intervenes before the perceptual processes; selective attentional shifts to specific parts of the visual field precede saccadic eye movements directed to these parts (Hoffman and Subramaniam, 1995). Attention seems to determine the location at which search will be conducted and/or the relevant features that will be picked-up, since focal attention may enhance the output of the salient feature detectors by lowering firing thresholds (Egeth, *et al*., 1984; Kahneman and Treisman, 1992; McCleod *et. al*., 1991). There is indeed ample evidence for the necessary role of attention in perceptual learning (Ahissar and Hochstein, 1995) and for the role of attention in learning to perceive ambiguous figures (Kawabata, 1986; Peterson and Gibson, 1991).

Recall that slow learning is independent of recognition and semantic associative memory. Most of the priming effects are associated with identification and discrimination of relative spatial relations and extraction of shapes. This brings to mind Hildreth and Ulmann's (1989) *intermediate level* of vision. The processes at this level (the extraction of shape and of spatial relations) are not bottom-up, but do not require the intervention of specific-object knowledge, since they require the spatial analysis of shape and spatial relations among objects. This analysis is task dependent but not theory-driven, that is, it is not directly penetrated by cognition.

I have spoken of "specific-object knowledge" and claimed that this kind of knowledge does not intervene in slow learning, and does not threaten cognitive impenetrability of perception. I would like to explain the qualification "knowledge about specific objects". Even if perception turns out to be bottom-up in character, still it is not insulated from knowledge. Knowledge intrudes on perception, since early vision is informed and constrained by some general world principles that reduce indeterminancies in information. They are general assumptions about the world constraining visual processing (Marr, 1982; Ulmann, 1979). These principles however are not the result of explicit knowledge acquisition about specific objects but are general reliable regularities about the optico-spatial properties of our world.

This knowledge is implicit, in that it is available only for the processing of visual information, whereas explicit knowledge is available for a wide range of cognitive applications. Implicit knowledge cannot be overridden. The general constraints hardwired in the visual system can be overridden only by other similar general constraints with which they happen to compete (although no one knows yet how the system "decides" which constraint to apply). Still, one cannot decide to substitute it with another body of knowledge, even if one knows that under certain conditions this implicit knowledge may lead to errors (as is the case with the visual illusions). This theoretical ladenness, therefore, cannot be used as an argument against the existence of a theory-neutral ground, because perception based on a shared theory is common ground.

Slow learning, thus, takes place under specific retinal input and attention-dependent conditions. Although the allocation of attention is clearly cognitively driven (that is, it is shaped by knowledge, beliefs, expectations, needs etc.), it operates before the onset of perceptual processing, and therefore, does not imply the cognitive penetrability of perception. One could say at most that cognition indirectly affects perception, in the sense that the modifications in perceptual circuitry are connected to cognitive factors mediated by attention. This is an indirect form of cognitive penetrability of perception, in that the contents of our cognitive stances do not affect the kind of the neural modifications but only determine, as it were, the conditions of learning by means of attentional mechanisms. As Pylyshyn (1999) remarks, to argue that this is a form of cognitive penetrability is like arguing that, because the decision to wear glasses is cognitively determined and because wearing glasses affects perception, perception is cognitively penetrable. We will discuss in the next section the philosophical implications of the distinction between direct and indirect cognitive penetrability.

So, the perceptual systems are to some extent plastic, as Churchland argues. But this plasticity is not the result of the penetration of the perceptual modules by higher cognitive states, but rather, the result of learning-induced changes that are modulated by the retinal input and task-demands. Fodor (1983), given his view that the perceptual modules have a fixed architecture, had to concede that if evidence is found for diachronic changes in the functional architectures of the modules, then the modularity of perception would collapse. But this is not necessarily so.

First the data-driven changes can be accommodated by the notion that the modules are semi-hardwired. All this view requires is that the functional changes reshape the microcircuitry and not the macrocircuitry of the modules. Bearing in mind that priming enhances performance, one cannot see how such learning could reshape their basic macrocircuitry. Second, even though the perceptual systems do not have a fixed architecture, the factor that modulates the rewiring is task-driven and not cognitively driven. This bars any movement from the possibility of rewiring of the perceptual systems to the cognitive penetrability of these systems, and thus, to the incommensurability of scientific theories.

Philosophical Implications

Let me now turn to the implications of the possibility of learning-induced changes in the visual system as these relate to the issue of the existence or not of a theory-neutral basis on which the issue of rational choice among scientific theories and scientific relativism rest. The question boils down to whether scientists with different experiences could form a different *perception* of the same retinal image. Suppose that, as a result of learning through repeated experience in her field, a scientist has somewhat shaped her perceptual sensitivity according to her specific professional needs and can recognize patterns that others cannot. She has learned which dimensions of visual analysis to attend to, and this process has reshaped her basic sensors by selecting the output of certain feature detectors. Suppose further that this learning has induced changes in the circuitry of her early vision, altering her visual perception (the part of vision, which is supposedly cognitively impenetrable). Hence, the answer is *yes*; some scientists who are trained in certain fragmented patterns and have stored them in the so-called "priming memory" may be able to recognize patterns that others could not. Suppose further that these changes affect her assessment of experiential evidence about theory evaluation.

Does this pose a threat to the possibility of creating a theory-neutral perceptual basis, and thus, does it constitute a basis on which the incommensurability of scientific theories could be established? I think that it does not, since as I have argued, this neural change is task or data-driven and not theory-driven. The difference is an important one for the following reasons:

First, all humans have roughly similar perceptual circuits (barring some damage or other). Thus, despite the fact that no two humans share identical brain circuits, we all cut the world in roughly similar ways. We all share, for instance, the same neural mechanisms for perceiving colors, and thus, we have the same conceptual representations of colors (Barsalou, 1999; Lakoff, 1987). Rosch's (Rosch, et. al., 1976) findings that there exists a "universal" basic-level categorization of objects in the world, which in the case of living things corresponds to the categorization into natural kinds, seem to confirm the contention that humans cut, at some level of analysis, the world roughly in the same way. The existence of universal natural kinds can be attributed to many causes, one of which is that the animals that belong to the same natural kind have roughly the same overall shape. Since shape is one of the attributes that matters the most with regard to the human-environment interaction, shape plays an important role categorization. The fact that we all cut the world into the same natural kinds supports the thesis that we all perceive shapes the same way, undoubtedly because we share (ceteris paribus) the same visual circuits.

Second, all scientists have had experiences of more or less the same objects; they share more or less the same scientific education, and work with roughly the same objects and instruments. Thus, their brains share a roughly similar basic microcircuitry, as far as this circuitry bears on the practice of their profession, since the circuitry is formed as a result of experience.

Third, even if some of them have acquired some particular priming memory, and as a result can *perceive* patterns that others cannot, nothing precludes the latter from undergoing the same training and reestablishing a common *perceptual* ground. Learning of this kind is data- and task-driven, which means that the same training will almost certainly produce the same "priming memory". It is at this point that the difference between the direct cognitive penetrability of perception by beliefs and expectations and the indirect penetrability through task-driven learning, which in its turn is shaped by cognitive is cashed out. In task-driven learning, cognition indirectly mediates the process through the allocation of attention. Attention, can be controlled though, since people can be instructed to focus their attention on such and such a location and scan for such and such a feature, despite the fact that these people may have entirely different intentional stances. Once this factor has been controlled, differences in beliefs etc., do not affect the course of the "priming" training, and thus, of perceptual learning. This implies that similar training will induce similar brain changes. Thus, experience-induced plasticity of the brain does not threaten the possibility of a theory-neutral perceptual basis.

The difference between data-driven and theory-driven learning in general is important. The task and what one should attend to can be specified

intersubjectively in groups with varying theoretical commitments. Since the whole enterprise is data and task-driven, the same task is bound to induce similar changes. This allows scientists to perceive the same things after some training, even if initially one of them was more capable than the other to perceive certain patterns. This way a channel of communication is established, since now they perceive similar things, no matter how they interpret them, which importance they attribute them and so forth. This explains why scientists working within very different paradigms can test one the experiments of the other, compare their results etc., even though they may disagree as to their importance and confirmatory role, a finding that receives ample support from research in the history of science (Gooding, 1990; Nersessian, 1984). This finding shows that even though different theoretical frameworks shape the design of experiments and their interpretations still scientists within different paradigms can understand what others scientists are doing.

By introducing a distinction between a bottom-up and non-semantic perception and a semantic cognition I join a long tradition of similar distinctions. Jackendoff (1989) distinguishes "visual awareness" from "visual understanding". Similarly Dretske (1995) distinguishes a "phenomenal sense of see" from a "doxastic sense of see". To the extent that the first parts of the pairs clearly correspond to a non-epistemic sense of perception, and the second parts of the pairs to an epistemic sense of perception, these distinctions are coextensive with the "perception-observation" distinction that I introduced in the introduction.

I would like to close the discussion regarding the philosophical implications of perceptual learning with a remark on the dichotomy between perception and cognition. In the introduction I defined perception as the set of processes that transform sensations to cognitively usable structures, and distinguished between perception and cognition, by claiming that the former is bottom-up, whereas the latter is not. This dichotomy however, should not be taken to imply a functional and even a neural distinction between perception and cognition.
