I have argued elsewhere (Raftopoulos, 2001a; 2001b) that many cognitive functions (e.g., imagery and spatial conceptualization) take place at the same neural areas that support early vision (see also Barsalou, 1999). In this sense, the mechanisms implementing perception and cognition cannot be divorced. Since the perceptual input systems are necessarily involved in higher cognitive tasks, our conceptual systems are severely constrained by the architecture of the perceptual modules. Perception does not serve only as the faculty that provides input to higher cognition and then comes on-line, after the cessation of the conceptual processing, in order to test empirically its outcome, but also constitutes an active participant of the conceptual processing itself.

This does not, mean, however, that perception and cognition function simultaneously, as Barsalou (1999) claims. There is ample neurospychological and neurophysical evidence suggesting that the perceptual processes precede cognitive processes of a scene, and that their outcomes differ. Thus, it makes sense to distinguish between perceptual and cognitive processes, even though cognition should be extended to include perception. But even if perceptual systems are cognitively penetrable, still a case cannot be made for incommensurability. For, according to Barsalou, the top-down information is overridden if in conflict with the bottom-up information coming from the perceptual modules. Thus, given some incoming information, different cognitive stances cannot cause different perceptions of a visual array.

Conclusion

I have argued in this paper that perceptual learning and the resulting rewiring of the early visual systems need not suggest the cognitive penetrability of early vision, since this form of learning is experience and task-driven and not theory-driven. This is so because perceptual learning, by being modulated by attention, is only indirectly affected by cognition. To the extent that attention can be controlled, the influence of cognition on early vision is neutralized.

We see the problem in the arguments against the cognitive encapsulation of perception. In attempting to demonstrate the cognitive penetrability of our perception and that the theoretical neutrality of observation is false, they confuse the plasticity of the brain and perceptual learning with cognitive penetrability. But the former does not entail the latter. The only way out is to argue that the experience-induced learning changes the way we observe the world, and this, in its turn, by means of some top-down flow of information which affects the way we perceive. Though it is true that our experiences shape our theories and the way we see the world, to say that these theories influence the way we *perceive* the world is question begging, since one must show that this top-down influences occur.

The influence of semantics on past-tense inflection

Michael Ramscar (michael@cogsci.ed.ac.uk)
University of Edinburgh, 2 Buccleuch Place
Edinburgh, EH8 9LW, Scotland.

Abstract

Previous theories of past-tense verb inflection have considered phonological and grammatical information to be the only relevant factors in the inflection process (e.g. Bybee & Moder, 1983; Rumelhart & McClelland, 1986; Kim, Pinker, Prince & Prasada, 1991). This paper presents three experiments that show that semantic information plays a decisive role in determining the inflection of both existing and novel homophone verb stems. These findings indicate that regular and irregular inflections are determined by semantic and phonological similarities in memory, and furthermore that people are not responsive to the kind of grammatical distinctions amongst verb roots that default rule theories of inflection (Pinker, 1999) presuppose.

Introduction

In most theories -- and studies -- of past-tense verb inflection, phonological and grammatical information have been considered to be the two relevant factors in the inflection process (e.g. Bybee & Moder, 1983; Rumelhart & McClelland, 1986; Kim, Pinker, Prince & Prasada, 1991; Pinker, 1991; 1999). However, in some models of inflectional processing (MacWhinney & Leinbach, 1991; Joanisse & Seidenberg, 1999), semantic processes have been included to help explain the processing of homophone verbs (e.g. *brake*/*break*). Since *brake* and *break* both sound the same, phonology alone cannot distinguish which of *broke* or *braked* is to be the correct past tense form for the input breɪk.

Although using semantic information to guide this process appears intuitively plausible, it has not been supported empirically, and indeed this suggestion has been fiercely criticised by Pinker and colleagues (Kim et al, 1991; Pinker, 1999), who put forward an alternative, natavist account of homophone inflection (Pinker, 1991; 1999). This predicts that the regularisation of irregular sounding verb stems is driven by innate grammatical sensitivity: verbs that are instinctively perceived to be denominal will be automatically regularised. This account is supported by results reported by Kim et al (1991) which indicate that grammatical factors correlate better than semantic factors with people's ratings of the acceptability of past tense forms in context, although these results do not rule out any semantic role in inflection.

So do semantics have any influence on the past tense forms speakers produce? This paper seeks to clarify and directly address this question.

Semantics and past-tense inflection

To initially test whether semantic similarity can affect the inflection of verb past tenses, Experiment 1 examines the past tense forms native English speakers produce for novel (nonce) English verbs whilst holding phonological factors constant and varying the semantic contexts in which the verbs are presented. The phonologically similar nonces *sprink* and *frink* are presented in contexts that primed either the existing phonologically similar regular forms *blink* or *wink*, or the existing phonologically similar irregular form *drink*. It is hypothesized that if semantic similarity played a part in the inflection process, then there will be significant differences between the proportion of regular and irregular forms produced, in line with whether the semantic context favored an existing regular or irregular verb.

Experiment 1

Participants. Participants were 120 visitors a shopping mall in Edinburgh, Scotland, and 40 students at the University of Edinburgh. All were native English speakers and participated voluntarily in the study

Materials. A set of cards were printed with a paragraph that contained a highlighted nonce verb (*sprink* or *frink*) in a context in which the nonce was in its infinitive tense, and a blank that later required its past tense. Two of the contexts were further manipulated so that they primed either two existing regular verbs -- *blink* and *wink* -- that are phonologically similar to the nonces, or an existing irregular verb -- *drink* -- that is phonologically similar to the nonces. The contexts constructed are shown in Table 1: in the *drink* context, the nonce was shown in a context that used it as a verb to describe the consumption of vodka and fish, whereas in the *blink* and *wink* context the nonce was shown in a context that used it as a verb to describe a symptomatic affliction of the eye-lid associated with a fictitious disease.

A third context was designed to semantically prime neither *drink* nor *blink* or *wink* (instead the nonce was used as a verb describing a hypnotic trance and was semantically similar to the regular verb *meditate*; see Table 1), whilst a control presented the nonce in a context that provided few semantic clues ("John likes to *frink*. Last week he _____").

In order to control the phonological properties of the nonces in the semantic contexts, both the initial presentation of the nonce, and the blank which was used to elicit the past tense form from participants were embedded in the same sentence substructure in each of the three

semantic contexts. Each nonce and blank was preceded by at least two identical words (containing at least three identical syllables), and succeeded by at least one identical word (containing at least one syllable).

Table 1. Examples of the semantic context passages used in Experiment 1. The nonce (in this case, *frink*) is italicized. The text highlighted in bold was used to phonologically control the presentation of the nonce and then later the blank, and is identical in all of the contexts.

In a traditional spring rite at Moscow University Hospital, the terminally ill **patients all** *frink* **in** the onset of good weather, consuming vast quantities of vodka and pickled fish. In 1996, his favourite vodka glass in hand, cancer **patient Ivan Borovich** _____ **around** 35 vodka shots and 50 pickled sprats; it is not recorded whether this helped in his treatment.

Passage 1 - irregular context - primes *drink*.

In a classical symptom of Howson's syndrome, **patients all** *frink* **in** their right eye if they are left handed or left eye if right handed, their eyelids opening and closing rapidly and uncontrollably. In 1996, in extreme discomfort due to his bad eye, Howson's **patient Ivan Borovich** _____ **around** 35 times per minute for two days, causing severe damage to the muscles in his left eyelid.

Passage 2 - regular context - primes *blink* and *wink*

In a controversial alternative therapy at Moscow University Hospital, the terminally ill **patients all** *frink* **in** the afternoons on alternate days, going into a trance-like state that lowers the heartbeat to alleviate pain. In 1996, emitting a steady, low humming sound, cancer **patient Ivan Borovich** _____ **around** two weeks or so (the nurses lost count!) without a day off. Afterwards, doctors claim, his cancer was cured.

Passage 3 - context primes neither *drink* nor *blink* and *wink* but rather is similar to *meditate*

Procedure. Participants were verbally briefed to "read a piece of text. As you read through the text, you will see a novel word that has been highlighted, and later a blank, where a word has been left out. We would like you to tell us the form of the highlighted new word that you think is appropriate to the context in which you find the blank. It is important that the form you choose matches the context of the sentence." Participants were also told to "concentrate on how the new form of the novel word 'sounds' in the context, not on how it might be spelled". After this briefing, participants were given a card containing the example "A single *wucterium* can be very dangerous. When they breed and multiply, a build up of _____ can prove lethal" and verbally informed that they might choose to fill in the blank with, *wucteriums* or *wucteria*, or anything else, depending on which seemed appropriate to them. These cards were then retrieved by the experimenter, and removed from the sight of the participant. Once this was done, the participant was given either a *frink* or a *sprink* card. Participants read the passage on the card and produced a verbal response to the fill-in-the-blank inflection task.

Participants verbalized all their responses, which were transcribed by the experimenter.

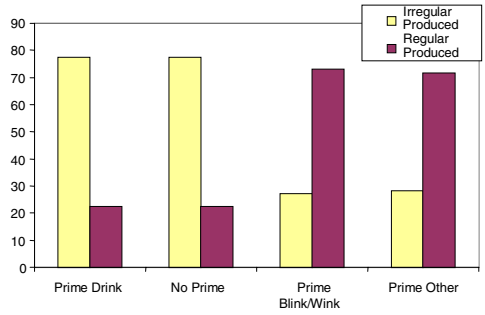

Figure 1. Percentages of each form of inflection for each condition in Experiment 1.

Results. The results obtained were consistent with the hypothesis that semantic similarity could affect the inflection of the past tenses of nonce English verbs when phonological similarity constraints were satisfied. Overall, 96.3% of participants produced a recognizable past tense form (3.7% produced inflected forms of the active past perfect progressive form, adding +/ *ing* to the nonce stem, and were discarded). Of those participants that produced past tense forms, 75.3% responded in a prime-consistent manner (see figure 1). The bias towards producing a form consistent with the past tense form of the existing verb primed by the semantic context was significant in a 2x2 chi-square analysis, $\chi^2(1, N=77) = 19.669$, $p<.0001$). Analyses of the individual nonces also showed the consistency bias to be significant: *sprink*, $\chi^2(1, N=39) = 9.776$, $p<.005$); *frink*, $\chi^2(1, N=38) = 7.204$, $p<.01$).[1]

Comparing the responses of participants who had seen the nonces in the context that primed *drink* to those who had inflected the nonces in the semantic context that primed neither *drink* nor *wink/blink* -- but rather indicated that the nonce verbs described a meditative state -- showed a significant trend towards regularization; 71.8% of participants in this condition produced a regular past tense form.

On the other hand, in the control condition in which participants encountered the nonce in a semantically neutral setting, 77.5% of participants produced an irregular past-tense. Comparing this to the 73% of participants produced *regular* form for the past tenses of *frink and* sprink when they encountered them in a context that primed the regulars *blink* and *wink* indicated a tendency to regularize in the latter case: $\chi^2(1, N=77) = 15.901$, $p<.0001$; *frink*, $\chi^2(1, N=38) = 5.743$, $p<.05$; *sprink*, $\chi^2(1, N=39) = 7.621$, $p<.01$). Similarly, comparing the neutral respondents to participants who encountered the nonces in a context that did not prime drink, but which did prime existing regulars such as *meditate* and *heal*, there was also a significant increase in the number of regular forms produced $\chi^2(1, N=79) = 15.5$, $p<.0001$; *frink*, $\chi^2(1, N=38) = 7.204$, $p<.01$; *sprink*, $\chi^2(1, N=40) = 7.621$, $p<.01$), see figure 1. This suggests that the

[1] The values given for the analysis of the individual nonces use Yates' corrected chi-square.

significant effect produced by semantically priming *wink* and *blink* was to increase the proportion of regulars produced, and that this effect was maintained when other regular forms were contextually primed.

Discussion. This experiment set out to examine whether semantic similarity might play a complimentary role to phonological similarity in inflection, i.e. whether it might have an influence on the form of semantically similar words alongside phonological constraints. The results obtained suggest that when people encounter a novel verb form that is phonologically and semantically close to an existing verb form, then the likelihood is that they will use the same pattern of inflection to form the past tense of the novel verb form as is used to inflect the past tense of the existing verb form. This finding neatly compliments the findings of Bybee and Moder (1983), who discovered that encountering a novel verb form that is phonologically similar to a cluster of phonologically similar irregulars increases the likelihood that the nonce verb form will be inflected irregularly. Once phonological similarity constraints have been met, semantic information also appears to play a role in inflection.

Semantics and grammatical analysis

The results of Experiment 1 suggest that semantic information does influence the past tense inflection process: the past tense forms of inputs that are phonologically similar to phonologically similar regular and irregular verb forms can be significantly influenced by semantic information. Given that this finding suggests that semantic information is at least sufficient for resolving the inflection patterns of homophone verbs, it raises the question of whether semantic information is also necessary for this to occur. Are semantics always used to determine the inflection of homophone verb forms? Or is other information, such as the grammatical status of the verb inputs, as suggested by Pinker and colleagues (Kim et al, 1991; Pinker, 1999) also sufficient to determine the outcome of this process?

To examine these questions, Experiment 2 was designed to test the hypothesis that semantic similarity, and not formal grammatical analysis, would be the important determining factor in the inflection of homophone verbs. According to Kim et al (1991; see also Pinker, 1999), in carrying out inflection people perform formal grammatical analyses on lexical input. As a result of these analyses, only verbs with verb roots (deverbal verbs) will be given an irregular past tense form; verbs with noun roots (denominals) will be inflected regularly.

> "People should regularize headless [denominal] forms only when they *perceive* the words to be headless… they should have a sense of when a word is based on another word... When they don't – when they are oblivious to the noun in a verb-from-a-noun and imagine that it is just a stretched verb root – the theory predicts that they *should* stick with the irregular." (Pinker 1999, p. 171.)

The findings obtained so far support the view that inflection is carried out as a result of competing constraints (involving phonology, semantics and word frequency) in memory. If such a similarity-based process was determining the inflection of verbs, it was predicted that when nonce verbs were presented to participants as denominal verbs in a context that semantically primed an irregular verb cluster, then they would be inflected irregularly (contrary to the 'formal grammatical analysis' hypothesis).

Experiment 2

Participants. Participants were 80 visitors to a shopping mall in Edinburgh, Scotland and 104 students at the University of Edinburgh. All were native English speakers and participated voluntarily in the study.

Materials

Inflection Task. The materials used in this study were modified versions of the cards used in experiment 2. For the purposes of this experiment, the contexts were modified so that the first sentence in each introduced the nonce as a noun, so that subsequent use of the nonce was clearly as a denominal verb. Kim et al (1991, p. 207) claim that this information is a "necessary and sufficient condition for the regularization effect." In the *drink* context, the nonce was shown in a context that used it as a noun (a kind of tapa comprising vodka and fish) and later as a verb to describe the consumption of the tapa (and by extension, vodka and fish), whereas in the *blink* and *wink* context the nonce was shown in a context that used it as a noun to describe a muscle, and later as a verb to describe a symptomatic affliction of that muscle. In the *meditate* context, which was designed to semantically prime neither *drink* nor *blink* or *wink* (the nonce was used as a verb describing a hypnotic trance), the nonce was first presented as the name of a Siberian religious sect that mediated.

Grammatical Analysis Task. 60 participants completed a questionnaire as part of a grammatical analysis measurement condition. Participants were given booklets containing one example of a "deverbal" nonce target context, one example of a "denominal" nonce target context and six other contexts relating to existing verbs. The verbs in these contexts were loosely pre-classified as either deverbal, denominal, or obscure but discenably denominal. The contexts were designed to provide participants with sufficient information to facilitate their making a meaningful denominal/deverbal analysis.

Procedure

Inflection Task. The procedure for this task was the same as for Experiment 1, above.

Grammatical Analysis Task. The presentation order of the contexts was randomized and ordered so that each participant saw one nonce denominal context and one nonce deverbal context from different scenarios, along with six other items. Participants were asked to indicate whether in their judgement, the verb was 'being used in a normal

'verb-like' way, or whether it is being used as a verb in relation to a noun. To take a word like 'drink' for example, in (1) 'John likes to drink beer'... you might decide that "drink" is being used as an ordinary verb. But, in the example… (2) It's always a good idea to relax your guests. Whenever guests arrive at my house, I immediately snack them and *drink* them. I find that refreshments set them at ease.' You might decide that 'drink' is being derived from the noun 'drink' (such that it means something like 'to serve drinks.'" Participants gave their ratings on a 7 point scale where 1 = definitely normal 'verb-like' use and 7 = definitely 'verb from noun' use.

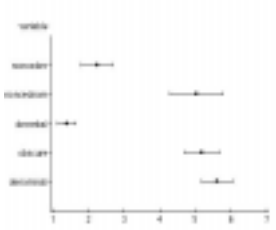

Figure 2. Means plot for the verb categories in the grammatical analysis condition in Experiment 2. The upper 2 plots show mean ratings for the nonces in denominal (noncedenom) and deverbal (noncedev) contexts. The bottom 3 plots show means rating for the existing verb categories

Results. The results obtained were consistent with the hypothesis that semantic similarity was affecting the inflection of the past tenses of nonce English denominal verbs when phonological similarity constraints were satisfied; they were not consistent with any effect of formal grammatical analysis affecting inflection.

Of those participants who encountered a novel denominal verb in a context that primed an existing irregular verb (i.e. in a context that made it appear semantically similar to that verb), 72.5% produced an irregular past tense for *sprink* or *frink*, whilst of those participants who encountered the novel denominal verb in a context that primed an existing regular, 75% produced a regular past tense for *sprink* or *frink* (this prime consistency effect was significant: $\chi^2(1, N=80) = 18.061$, $p<.0001$). The context which described a meditative or hypnotic state) also promoted a regular inflection of *sprink* and *frink* (71.8%).

The results of the grammatical analysis task are summarized in figure 2. It appears that that participants could distinguish the grammatical origins of the various verbs in these contexts (this is reflected by the variance in category means for the 'regular', nonce and obscure denominals with respect to the regular and nonce deverbals). A one way ANOVA indicated the variance in the scores assigned by participants to the verb categories with respect to their grammatical origins of the categories was significant $F(4) = 74.65$, $p<0.0001$. T-tests between the mean scores for the denominal and deverbal nonces in context showed that participants had detected significant differences in their grammatical origins $t(56) = 6.45$, $p<.0001$ (individual nonces in contexts: *nonce - drink*, $t(17) = 3.47$, $p<.005$; *nonce - wink/blink*, $t(17) = 3.19$, $p<.01$; *nonce - meditate*, $t(18) = 3.26$, $p<.005$). These findings indicate that the inflection results do not stem from any failure on the part of participants to perceive the grammatical categories of the nonce verbs.

Discussion. This experiment set out to establish whether semantic similarity or formal grammatical analysis would influence the inflection of novel denominals. The finding that patterns of inflection were consistent with semantic priming -- as found in experiment 2 -- is entirely consistent with the hypothesis that semantic similarity is an important constraint in determining inflection when phonological constraints have been met. Moreover, the fact that a majority of irregular forms were produced for both denominal nonces when the context they were presented in suggested that they were semantically similar to an existing irregular verb directly contradicts the formal grammatical analysis hypothesis, which predicted that because these verbs had a noun root they would be inflected with a regular past tense form.

Semantics or Grammar?

The evidence accrued against grammatical analysis in Experiment 2 appears to conflict quite drastically with the findings of Kim, Pinker, Prince & Prasada (1991) who report that participants in their experiments did use grammatical analysis in determining the past tenses of verbs. As noted above, an experiment by Kim et al (1991) appeared to show that grammatical analysis is a better predictor of past tense forms than semantics. Since these findings are clearly incompatible with the findings of Experiment 2, it seems worth considering in some detail this earlier study.

The most important thing to note about the experiment by Kim et al (1991) that sought to discriminate between the two competing accounts of homophonic inflection -- grammatical analysis versus semantics -- is that judgments of the grammatical status of verbs (whether they were denominal or deverbal) were not collected from impartial observers. Instead, the experimenters relied on their own intuitions for deciding which verbs are denominal and which deverbal. This practice raises several concerns when Kim et al's materials are subject to close scrutiny. To take one example, Kim et al classify the verb *to lie* (as in confabulate) as denominal (in their materials, "Sam always tells lies when he wants people to think he's better than he really is, He *lied/lay* to me last night about how good a golfer he is"). Presumably, this is because one can tell *a lie*; a *liar* is someone who tells *lies*, etc. However, Kim et al simultaneously classify the verb *to drink* as deverbal (presumably, given that *drink* is an irregular, and the grammatical analysis hypothesis suggests that all denominals will be regular, Kim et al assumed *drink* had to be deverbal). Yet it would appear that *any* reason that one can think of for suggesting that *lie* is denominal applies

equally to *drink*: one can drink a *drink*; a *drinker* is someone who imbibes *drinks* etc. Yet these factors -- and the potentially flawed assumptions behind them -- are critical to Kim et al's analysis of their results. If participants were to judge the past tense of *lie* as *lied* and the past tense of *drink* as *drank* (as indeed they did in Kim et al's experiments), then this would count as evidence *for* the grammatical analysis hypothesis in Kim et al's subsequent analysis. Grammatical analysis would be credited with predicting that *drink* is irregular whereas *lie* must be regular, even though as far as one can see, the only reason that *lie* was judged by Kim et al to be a denominal and *drink* a deverbal was because the former was a regular and a latter an irregular in the first place.

In the light of these considerations, the following experiment was designed to re-examine the findings of Kim et al (1991), subjecting both putative mechanisms for predicting the inflection of homophonous verbs to the same standard of testing. Participants in a semantic reminding condition were presented with a target verb in context, and an example of a homophonous irregular verb (the examples had been adjudged by another group of participants in a pre-trial to be very typical uses of the irregular). Participants were asked to rate the extent to which the action or activity associated with the verb in the target context reminded them of the kind of activity or action picked out by the example verb; participants were encouraged to think of all of the activities they usually associated with that use of the target. The semantic hypothesis tested in Experiment 3 was simply that these semantic reminding judgements would be a good predictor of the acceptability of irregular past tense forms.

In contrast to this, the grammatical analysis hypothesis tested in this experiment predicts that verbs that subjects' perceive to be denominal will be regularized, thus the grammatical analysis hypothesis would expect the grammatical analysis of verbs as being denominal would be a good predictor of the acceptability of regular past tense forms (see Kim at al, 1991).

Experiment 3

Participants. Participants were 101 native English speaking undergraduate students at the University of Edinburgh who participated voluntarily in the study.

Materials. 24 contexts were used to present 12 phonologically similar verb pairs in the present tense, (e.g. "Charlie Wilson of United is a real prima donna. He never gets on with the game. Instead, he just shows off. He tries to *grandstand* all the time, and it really gets on my nerves."). In each context, the target verb was italicized and underlined. A second set of 24 contexts presented the target word first in its present tense, and later as either a regular or an irregular past tense (e.g. " Charlie Wilson of United is a real prima donna. He never gets on with the game. Instead, he just shows off. He tries to grandstand all the time, and it really gets on my nerves. In the game with Rovers on Saturday he got an early goal and *grandstood* [or *grandstanded*] the rest of the match.").

Procedure. 3 groups of participants were used to obtain three rating measures: semantic reminding, grammatical analysis and acceptability of past-tense form.

Semantic Reminding. Participants were presented with an example 'typical use' of the irregular form of the homophonic verb for comparison purposes (e.g. " The soldiers were told to *stand* at ease."). Each of the examples had been rated by 12 participants in a pre-test for typicality and achieved a mean score of > 5.8 on a scale where 1 = not at all typical and 7 = very typical. Participants were instructed to compare the comparison verb (e.g. stand) and the highlighted verb in the target (e.g. *grandstand* above) and to rate the extent to which "the activity or action described by the *underlined* word … -- *taken in the whole context* -- remind[ed… them] of the comparison word." Participants were additionally instructed to " to consider all the possible things [they] *usually* associate with this use of the word." Ratings were given on a 7 point scale where 1 = strong reminding and 7 = no reminding.

Grammatical Analysis. Participants were asked to indicate whether a verb was 'being used in a normal 'verb-like' way, or whether it is being used as a verb in relation to a noun.' Participants gave their ratings on a 7 point scale where 1 = definitely normal 'verb-like' use and 7 = definitely 'verb from noun' use.

Acceptability Of Past-Tense Form. The instructions in this task mirrored those in Kim et al (1991). Participants were told to "to concentrate on how the words 'sound' in their context, as you read them, not on how they might be spelled." Participants were asked to indicate "how likely it is that the form you have seen is the correct one for that context. By 'correct', we mean the one that other native English speakers would naturally and intuitively use (i.e. the form - or sound - that comes most naturally to you)." Participants were also asked to note that correct did not "refer to the kind of 'proper' English that gets taught in grammar lessons or style manuals." Participants gave their ratings on a 7 point scale: 1=not acceptable; 7=highly acceptable.

Results. A multiple regression analysis of the relationship between semantic reminding, grammatical analysis and irregular past tense acceptability indicated that both predictor variables accounted for 68% of the total variance in the irregular rating scores ($F(1, 21)=25.14$, $p<.0001$). For comparison purposes, a regression analysis of semantic reminding to irregular past tense acceptability was performed, which accounted for 67% of the total variance in the irregular rating scores: $F(1, 22)=47.71$, $P<.0001$), indicating that grammatical analysis uniquely accounted for only 1% of the total variance observed. A regression analysis of grammatical analysis to irregular past tense acceptability accounted for 37.5% of the total variance in the irregular rating scores: $F(1, 22)=14.87$, $p<.001$),

indicating that semantic reminding uniquely accounted for a significant 29.5% of the total variance observed.

A multiple regression analysis of the relationship between semantic reminding, grammatical analysis and regular past tense acceptability indicated that both predictor variables accounted for 36% of the total variance in the regular rating scores ($F(1, 21)=7.479$, $p<.005$). Again as a comparison, a regression of semantic reminding to regular past tense acceptability was performed, which indicated that semantics alone could account for 35% of the total variance in the regular rating scores: $F(1, 22)=13.52$, $p<.005$), indicating that again, just 1% of the observed variance could be uniquely accounted for by grammatical analysis. A regression analysis of grammatical analysis to regular past tense acceptability accounted for 1.7% of the total variance in the irregular rating scores: $F(1, 22)=1.397$, $p>.2$), indicating that semantic reminding uniquely accounted for a significant 33.3% of the total variance observed

Discussion. In the light of some potential flaws identified in the study comparing the predictive power of semantics versus grammatical analysis reported by Kim et al (1991), this experiment set out to re-examine those previous findings using a suitably modified experimental paradigm. Strikingly, once both predictor variables were subject to the same standard of empirical scrutiny, the predictive effect of grammatical analysis on past-tense acceptability reported by Kim et al in their study has almost entirely vanished. In this study unconfounded grammatical analysis predicted only a very marginal, insignificant amount of the data collected in the past-tense rating condition. On the other hand, it appears that semantic reminding is a good predictor of the acceptability of inflected forms. Semantic reminding uniquely predicts a significant proportion of participants' irregular and regular past tense acceptability scores (29.5% and 33.4% respectively).

General Discussion

Inflectional morphology has become the example domain -- and hence the battleground -- for wider debates about the nature of linguistic knowledge and knowledge representation, and in particular connectionist versus symbolic (and particularly, rule-based) theories of mental representation (Pinker & Prince, 1988; MacWhinney & Leinbach, 1991; Pinker, 1999). Although single-route (connectionist) and dual-route (symbolic) accounts of inflection largely agree on the processes that determine irregular inflection (a phonological pattern associator in memory) the dual-route account differs from single-route theories by claiming that only irregular forms are processed in memory, and that a symbolic default rule determines regular inflection.

The results presented here indicate: Firstly, that semantic information derived from similarity measures in memory plays a significant role in inflection. Secondly, that these similarity measures seem to involve all verbs, both regular and irregular. Thirdly, that grammatical information regarding whether verbs are denominal or deverbal does not have a significant effect on inflection patterns. And fourthly, and finally, that semantic similarities between a nonce verb and an existing regular verb in memory can result in an increase in the amount of regular forms produced.

What is interesting about these findings is that contrary to earlier claims regarding the inability of single-route models of inflection to account for the processing of homophone verbs (Pinker & Prince, 1988; Pinker, 1991; 1999), these results are entirely compatible with a single, similarity based inflection process. On the other hand, they are not compatible with a processing model where only irregular inflections are processed according to similarity in memory. The evidence presented here regarding the role of semantics in inflection suggests that contrary to some recent claims (Pinker, 1999), a full account of the processes governing inflectional morphology has yet to be put forward. The question of whether abstract mental rules are necessary in morphological processing remains very much open; the past-tense debate is still very much alive.

Abstract

Children change in their word-learning abilities sometime during the second year of life. The nature of this behavioral change has been taken to suggest an underlying change in mechanism, from associative learning to a more purely symbolic form of learning. We present a simple associative computational model that accounts for these developmental shifts without any underlying change in mechanism. Thus, there may be no need to posit a qualitative mechanistic change in the word-learning of young children. More generally, words, as symbols, may emerge from associative beginnings.

Overview

Word-learning is likely to rely heavily on associative learning, such that the child comes to associate the sound "dog" with dogs, the sound "cat" with cats, and so on. However, children's word-learning abilities change significantly during the second year of life, and some have proposed that this behavioral change reflects an underlying mechanistic shift away from a purely associative base. In particular, it has been proposed that sometime during the child's second year, a conceptual insight into the symbolic, referential nature of words occurs (McShane, 1979). This insight then supports a more purely symbolic form of learning, in contrast with the simple associative learning that preceded it.

A number of changes in word-learning occur at around this age. When viewed as a totality, this array of behavioral changes does suggest a mechanistic change of some sort. We shall argue, however, that these changes may be accounted for without recourse to any posited conceptual insight, or any qualitative mechanistic change in the nature of word-learning. Instead, they flow naturally from a purely associative mechanism, operating over similarity-based representations. As these representations gradually become more peaked and finely differentiated, the child's linguistic behavior becomes more recognizably "symbolic". We argue this point by presenting an associative computational model, and demonstrating that it matches the developmental shifts of 1- to 2-year-old children. Thus words, as discrete arbitrary symbols, may emerge from fundamentally associative, similarity-based mental material.

We are not the first to propose this general idea, nor to present a computational model supporting it (Cottrell and Plunkett, 1994; Elman et al., 1996; Merriman, 1999; Plunkett et al., 1992). However, the specific cluster of behavioral issues we address have not, to our knowledge, yet been accounted for computationally.

We begin by briefly outlining the empirical evidence for a change in word-learning during the child's second year of life. We then present an associative computational model, and demonstrate that it accounts for this change. We also highlight predictions made by the model, and some preliminary evidence in favor of them. We conclude with a discussion of the ramifications of this account.

Empirical Evidence

During the second year of life, the child's word-learning behavior changes in at least four respects: ease of learning, honing of linguistic form, honing of linguistic meaning, and the learning of synonyms.

Ease of learning

As children first begin to produce words, their acquisition of new words is slow and errorful. New words are added at the rate of 1 or 2 every few weeks (Gershkoff-Stowe and Smith, 1997). Then between 18 and 22 months (when the child has about 50 words in productive vocabulary), the rate of new word acquisition accelerates dramatically, with reports from detailed diary studies of children learning as many as 36 words in a single week (Dromi, 1987). Experimental studies replicate this shift in the laboratory. At the beginning of word learning, 13- to 16-month-olds can acquire a word-object linkage in comprehension based on 4-8 training trials (Bird and Chapman, 1998). By the time children are 2 to 3 years of age, a single learning trial is sufficient for word learning in comprehension and production, and for generalization to an appropriate range of referents. Thus, children appear to shift from learning as a gradual process to the sort of all-or-none process that often characterizes symbolic learning.

Honing of linguistic form

Infants must learn what counts as a word in the language they are learning, and what does not. The developmental evidence suggests that in the beginning, words function as ordinary members of the open set of possible associates. Later, however, the range of acceptable word

forms becomes narrower. For example, Namy and Waxman (1998) found that 18-month-olds readily accepted a hand gesture as a word form — in that they learned to associate the gesture with a referent. Older children however, 26-month-olds, did not learn the association. This developmental trend has been replicated using other non-phonological "words" (Woodward and Hoyne, 1999).

There is other evidence that the process is one of "honing" or narrowing the set of possible forms. Although infants readily discriminate between individual phonemes in perceptual tasks, they do not exploit this level of detail in their initial representations of words (Stager & Werker, 1997; see also Bird & Chapman, 1998). Specifically, at the beginning of word learning, at 14 months, babies cannot learn that *bih* and *dih* refer to different items, although they can learn this for globally different forms such as *lif* and *neem*. Thus children seem to move from a state in which they are sensitive primarily to overall similarity or difference between word forms to one in which they are acutely sensitive to minor differences.

Honing of meaning

Just as forms become progressively restricted with development, so do meanings. Early in word learning, 13- and 18- month old children generalize a newly learned object name to new referents by overall similarity across all dimensions (Smith, Jones, Gershkoff-Stowe & Samuelson, 1999). But older children systematically generalize novel names for artifact-like things using the specific dimension of *shape* (Smith et al., 1999). Thus, children come to pay attention to particular dimensions of referents and disregard others - much as they do with word forms. (A distinction however is that this "shape bias" holds for object names and not other sorts of names.)

Synonyms

Children assume that two different forms carry two different meanings. This has been termed the *mutual exclusivity assumption*. One specific manifestation of this assumption is that young children tend to resist learning synonyms. Liittschwager and Markman (1994) found that 16-month-olds, who can learn a new word for an as-yet-unnamed object, have trouble learning a new word for an already-named object (i.e. a synonym). However, 24-month-olds learn novel names and synonyms equally well - they do not exhibit a particular resistance to learning synonyms. Thus, there is a shift in the ease of learning synonyms, one that occurs at about the same age as the other changes in word-learning outlined above.

These roughly simultaneous changes, in ease of learning, form-honing, meaning-honing, and synonym-learning, may suggest an underlying change of mechanism sometime near the second birthday. However, we shall argue that no qualitative change in mechanism is necessary to account for these parallel developmental trajectories. They emerge naturally from a single fundamentally associative mechanism.

Foundational Assumptions

As we have seen, children do not enter the world with a clear sense of what counts as an acceptable word form. But if this is the case, what differentiates word forms from meanings in the first place, in the mind of an infant? Both are experiences of events or objects in the world. We assume that the answer lies in the child's awareness of her interlocutor's stance as a social other. Specifically, we assume that the child will take the object of the interlocutor's *attention* as a potential referent (Baldwin et al., 1996). Further, we assume that those intentional actions of the interlocutor to which the interlocutor is *not* attending are taken as potential forms – this will include verbal utterances, gestures, and any other unattended action. It is known that pre-linguistic infants are sensitive to the object of attention of another person (Corkum and Moore, 1998). Thus, the deployment of the interlocutor's attention serves as a plausible starting-point for the development of the form/meaning distinction.

The Model

The model, shown in Figure 1, builds on these social assumptions. It accepts as input a potential form and a potential referent, which are assumed to have been determined by the interlocutor's deployment of attention. These inputs are each represented by a bank of nodes, corresponding to features of experience. Form and referent are associated in the top layer of the network, which holds a localist lexicon - in which each node stands for a distinct pairing of form and meaning. The form and meaning for a given lexicon node are encoded on its incoming weights. New nodes are added to this lexicon as new form-meaning pairings are encountered (Carpenter and Grossberg, 1988).

The central concept of the model is that different dimensions of experience acquire different degrees of *communicative significance*, or selective attention (Nosofsky, 1986). This is true of both form and meaning, which are represented in the same psychological space. At the beginning of learning, all dimensions are equally, and weakly, weighted, and the model responds in a graded fashion, on the basis of overall similarity. Later in learning, however, some dimensions become very significant, and others insignificant. The model then responds categorically, in the all-or-none fashion characteristic of symbolic representations. It is this transition that we suggest underlies the emergence of words, as symbols.

Formal presentation: Given any input, the model computes the distance of the current input from the weight vector of each lexicon node:

$$d_i = \sqrt{\sum_j s_j (i_j - w_{ij})^2}$$

Here s_j is the communicative significance of dimension j, i_j is the current value (+/-1) of input dimension j, and w_{ij} is the weight on the connection from input node j to lexicon node i. Note that distance is computed over both

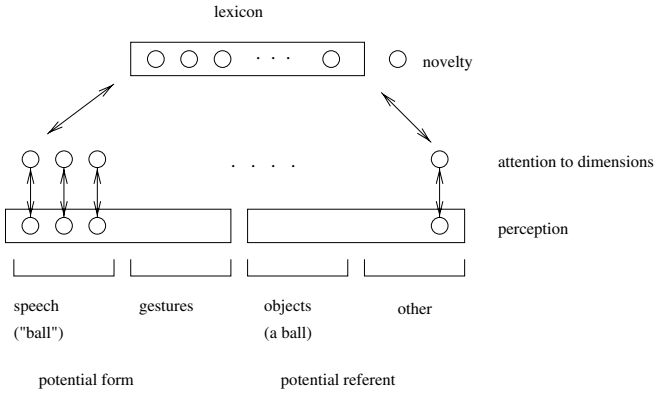

Figure 1: A model of early word learning.

form and meaning dimensions, together. The activation of the lexicon node is then an exponential function of this psychological distance (Shepard, 1987):

$$a_i = exp(-d_i)$$

Thus, the activation for a lexicon node i will be at its maximum (1.0) when d_i is zero - which will occur when the input and weight vectors are identical along significant dimensions. There is also a "novelty node", a novelty detector that is activated to the extent that no existing lexicon node is activated:

$$a_{novelty} = 1 - max_i(a_i)$$

Given these activations, we can compute a probability distribution over the lexicon, including the novelty node, using the Luce choice rule:

$$p_i = \frac{a_i}{\sum_j a_j}$$

A new lexicon node is then created with probability $p_{novelty}$ – the probability associated with the novelty node. If this node-creation does occur, the newly-created node k is incorporated into the lexicon, and its weights are set by the current input values, multiplied by $p_{novelty}$ (Hebb, 1949). Thus, the more clearly novel the input is, the stronger the weights on the newly allocated nodes will be.[1]

$$w_{kj} = i_j \times p_{novelty}$$

If a new node is not created, the most highly activated node k in the lexicon is selected for training. The model is then trained under gradient descent, with a target value of 1.0 for p_k, and target values of 0.0 for all other $p_i, i = k$. This will reinforce node k's representation of the form-meaning pairing currently presented as input, moving its weights w_k closer to the current input, and those of competing nodes farther away. Similarly, the s values (significance weights) will be adjusted to help discriminate lexicon nodes from each other. We then train again with only the form as input, and with the same target outputs. And finally, we train again with only the referent as input, and with the same target outputs. This three-step training causes the selected node k to act as a category node for both form and referent - and thereby to link the two.

The equations above, with the exception of the novelty node activation and creation, are adapted from existing models of categorization (Kruschke, 1992; Nosofsky, 1986). Merriman (1999) has shown that a similar formalism can account for the mutual exclusivity bias and shape bias in word-learning – the present model builds on this work. The combination of form and meaning in a single representation echoes the linguistic production model of Dell et al. (1997). This links theoretically central aspects of our model to existing models of related processes, models that have already received empirical support in their own right.

Testing: Once a set of words has been learned, one may test the model on either comprehension or production of a learned word. In a comprehension test, the word form is supplied to the network, but no referent is supplied. A winning lexicon node k is selected, as above, but from a competition based on the form dimensions only. The referent dimensions of node k's weight vector w_k are then projected down to the referent inputs:

$$i_j = w_{kj}$$

This reconstructed referent constitutes the model's response to the word form supplied as input. Production tests proceed analogously, but with the referent supplied as input, and the form produced as output.

Accounting for Existing Data

In the simulations reported here, the model was trained on a dataset of form-meaning pairings, and tested at various points during training. There were 6 dimensions for form: 4 were significant (such that a pattern over these dimensions was predictive of the referent), and 2

[1] Nodes that are created but not revisited within a given number of epochs are pruned from the lexicon. In current simulations, that number of epochs is 1.

were insignificant (not predictive). Similarly, there were 6 dimensions for meaning: 4 significant (such that a pattern over these dimensions was predictive of the form), and 2 insignificant (not predictive). The training set consisted of 75 variants of 5 words; a variant of a word preserved the significant dimensions of the word while altering insignificant dimensions. The words and their variants were represented by either +1 or -1 on each dimension. The specific values were chosen randomly, subject to the constraint that patterns over the significant dimensions of form be predictive of significant dimensions of meaning, and vice versa. The model was trained on this dataset for 100 epochs. The learning rate was 0.05. As expected, the significance weights differentiated significant from insignificant dimensions increasingly clearly over the course of training. At epoch 6, the difference between the average significance weight over dimensions intended to be significant and the average significance weight over dimensions intended to be insignificant was 1.06608. By epoch 60, this difference was 2.74704, reflecting clearer differentiation with training.

During training, tests were performed in order to probe the model's behavior on the four empirical trends noted at the beginning of the paper. In all cases, this involved presenting a new form-meaning pairing for the model to learn, and then determining the probability of correct comprehension or production. We define a "correct" response to be one that is within 0.9 of the target along all significant dimensions (which generally vary from -1 to 1), using the comprehension and production output rules outlined above. We then calculate the summed probability across all lexicon nodes that would produce a correct response: this yields the probability of correct response.

Ease of learning: We first tested how easily the model could learn a novel form for a novel object, and how that ease changed with age. A new word was created that was representationally distant from the existing words in the training set – specifically, each of form and meaning in this new word differed from those for existing words along all significant dimensions. We shall refer to this word henceforth as the "novel" word. We examined the probability of correct comprehension of this new word after simulating one learning trial on the word at two points during the learning of the training set mentioned above: after 6 epochs, and after 60 epochs. The results are displayed in Figure 2(a). As the model's space stretches along significant dimensions, this new word is increasingly easily learned, eventually being reliably correctly comprehended given only 1 training trial. This progression into 1-trial learning reflects the behavior of 1-2 year old children. Importantly, once the model had learned the novel word, it was removed from the lexicon; thus, later "ages" of the model did not have the benefit of earlier training on the novel word – only of an appropriately stretched psychological space, which caused the word to be perceived as distinct, and therefore easily remembered.

Honing of linguistic form: We next examined the learning of a new word that was *similar in form* to an existing word in the training set. The form of this new word differed from that of an existing word in the lexicon by only 1 significant dimension, while the meaning dimensions differed from other words along all significant dimensions. Thus, this test simulates the potential confusion of learning "bih" and "dih" associated with different sorts of objects (Stager and Werker, 1997). The probability of correct comprehension after one training trial is shown by the crosshatched bars in Figure 2(b). In this figure, the solid bars duplicate the presentation of the model's behavior on the novel (dissimilar) word in (a), for purposes of comparison. As is true of children, similar words are initially somewhat more difficult to learn than are globally dissimilar words. However, eventually these similar words are also successfully learned given one training trial, as the relevant dimensions of space are highlighted, counteracting the confusing similarity. This allows fast learning of minimal pairs such as "bit" and "pit".

Honing of meaning: We were interested in determining whether the model would exhibit a strengthening shape bias, as children do. To test this, as before, we trained the model on the novel word, and then tested the probability of producing the novel word for a different object, which differed from the original in meaning along insignificant (non-shape) dimensions only. This probability of generalization is shown in Figure 2(c). The increasing strength of generalization along the significant dimensions follows directly from the increasing perceived communicative significance of those dimensions (see Merriman (1999) for a similar demonstration). This is analogous to the honing of linguistic form. This account is incomplete however. In actuality the shape bias applies only to object names; thus an additional mechanism would be required to determine whether a given word is an object name, and therefore whether the model's bias should apply.

Synonyms: A synonym for an existing word in the lexicon should be difficult to learn, since it is similar (identical in meaning) to that existing word. Figure 2(d) shows that this is the case in the present model; Merriman (1999) reports similar results with a similar model. The probability of correct comprehension after one training exposure is initially lower for a synonym of an existing word in the lexicon than it is for the (dissimilar) novel word examined above. This matches the findings of Liittschwager and Markman (1994). Eventually however the synonym and the non-synonym are approximately equally likely to be learned – as is eventually true with children. In the model, this is accounted for by the stretching of the underlying psychological space with age, such that even similar lexical entries are kept distinct, and thereby effectively learned.

Predictions

The model makes two predictions. The first is that young children should experience difficulty learning *homonyms* (a single form with multiple meanings, such as the "bank" of a river, and a "bank" as a financial institution). Moreoever, this difficulty should be correlated

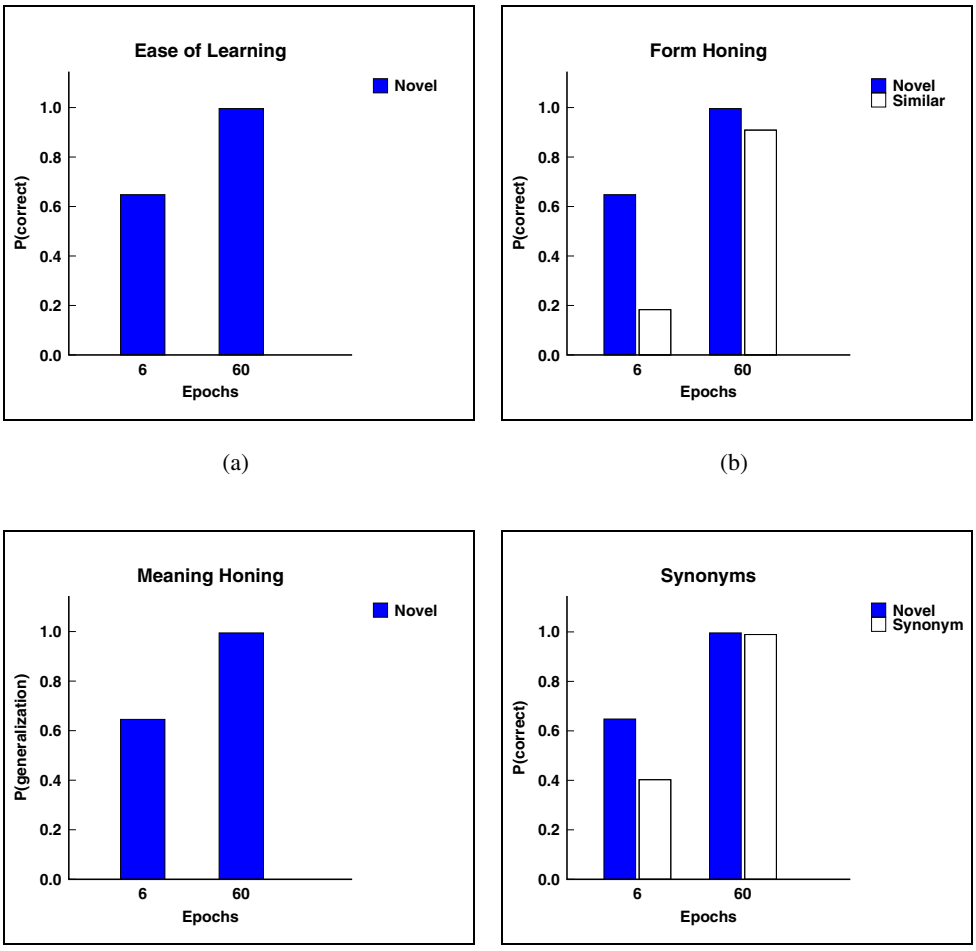

Figure 2: Developmental trends, as exhibited by the model.

with the difficulty of learning synonyms, as the reason for the difficulty is analogous. Half of the model's lexical representation for a homonymous or synonymous word will be identical to that for another word in the lexicon: the identical half is the form for homonyms, and the meaning for synonyms. This means that the two lexical entries in question will tend to be nearer each other in psychological space than two non-homonyms or two non-synonyms, and will therefore interfere with each other. Doherty (2000) has found that understanding of homonymy is strongly associated with understanding of synonymy, in 3-4 year old children.[2] Similar tests on younger children would more directly test this prediction.

The second prediction also concerns the interaction of form and meaning. As we have seen, 14-month-olds have trouble associating similar sounds such as "bih" and "dih" with different referents (Stager and Werker, 1997). On the model's account, this is because the forms are too similar, such that the two lexical representations lie confusingly near each other in psychological space. But since that space contains both form and meaning dimensions, the model predicts that an exaggerated *semantic* difference between the referents should compensate for the confusing formal similarity of "bih" and "dih" in such a task, and should make learning easier. This prediction has not yet been tested.

Discussion

1- to 2-year old children seem to undergo a qualitative change in the manner in which they learn words. It has been suggested that this behavioral change reflects a conceptual insight into the symbolic nature of words. The model we have presented, however, suggests a different, and more parsimonious, account of the same phenomenon. The behavioral change may result not from

[2]These were both also correlated with understanding of false belief.

an abrupt insight, but rather from an associative learner gradually determining which aspects of the world are relevant for communication. In this manner, the symbolic use of words may emerge from an associative base.

Abstract

In this article we present a connectionist model of category learning that takes into account the prior knowledge that people bring to many new learning situations. This model, which we call the *Knowledge-Resonance Model* or *KRES*, employs a recurrent network with bidirectional connections which are updated according to a *contrastive-Hebbian learning rule*. When prior knowledge is incorporated into a KRES network, the KRES activation dynamics and learning procedure accounts for a range of empirical results regarding the effects prior knowledge on category learning, including the accelerated learning that occurs in the presence of knowledge, the reinterpretation of features in light error correcting feedback, and the unlearning of prior knowledge which is inappropriate for a particular category.

A traditional assumption in category learning research is that learning is based on those category members people observe and is relatively independent of the prior knowledge that they already possess. According to this *data-driven* or *empirical learning* view of category learning, people associate observed exemplars and the features they display (or a summary representation of those features such as a prototype or a rule) to the name or label of the category. In this account there is neither need nor room for the influence of the learner's prior knowledge of how those features are related to each other or other concepts on the learning process. In contrast, the last several years has seen a series of empirical studies that demonstrate the dramatic influence that a learner's prior knowledge often has on the learning process in interpreting and relating a category's features to one another and other concepts. Indeed, knowledge effects have been demonstrated in every area of conceptual processing in which they have been investigated (see Murphy, 1993, for a review).

The goal of this article is to introduce a theory of category learning that accounts for the effects of prior knowledge on the learning of new categories. This theory, which we refer to as the *Knowledge-Resonance Model*, or *KRES*, is a connectionist network that specifies prior knowledge in the form of existing concepts and relations between concepts. We will show that when knowledge is incorporated into a KRES network, KRES's activation and learning procedures account for a number of empirical results regarding the effects of prior knowledge on category learning.

Other connectionist models have been proposed to account for the learning of new categories (e.g., Gluck & Bower, 1988; Kruschke, 1992), and these models have generally used feedforward networks (i.e., activation flows only from inputs to outputs) and learning rules based on error signals that traverse the network from outputs to inputs (e.g., backpropagation). KRES departs from these previous models in two regards. First, rather than feedforward networks, KRES uses *recurrent networks* in which activation is allowed to flow not only from inputs to outputs but also from outputs to inputs and back again. Recurrent networks respond to inputs by each unit iteratively adjusting its activation in light of all other units until the network "settles," that is, until change in units' activation levels ceases. This settling process can be understood as an interpretation of the input in light of the knowledge encoded in the network. As applied to the categorization problems considered here, a KRES network accepts inputs that represent an object's features, and interprets (i.e., classifies) that object by settling into a state in which the object's correct category label is active.

Second, rather than backpropagation, KRES employs *contrastive Hebbian learning* (CHL) as a learning rule (Movellan, 1989; O'Reilly, 1996). Backpropagation has been criticized for being neurally implausible because it assumes nonlocal information regarding the error generated from corrective feedback in order for connection weights to be updated. In contrast, CHL transmits error by using the same connections that propagate activation. During an initial *minus phase*, a network is allowed to settle in light of an input pattern. In the ensuing *plus phase*, the network is provided with what serves as error-corrective feedback by being presented with the output pattern that should have been computed during the minus phase and allowed to resettle in light of that (correct) output pattern. Connection weights are then updated as a function of the difference between the activation of units in the two phases.

In the following sections we first describe KRES and then present three simulations of human category learning data. We will show how KRES's successes can be attributed to its recurrent network that allows category features to be interpreted in light of prior knowledge, and the CHL learning algorithm that allows (re)learning of all connections in a network, including those that represent prior knowledge.

The Knowledge-Resonance Model (KRES)

An example of a KRES model is presented in Figure 1. In Figure 1, circles depict *units* that represent concepts that are

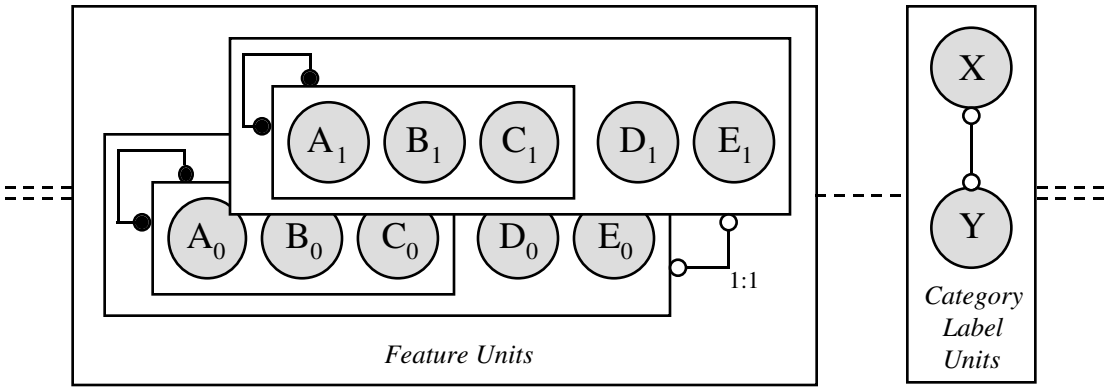

Figure 1. A sample KRES model.

either category labels (X and Y) or features (A_0, A_1, B_0, B_1, C_0, C_1, etc.). To simplify the depiction of connections among units, units are organized into *layers* specified by rectangles. Solid lines between layers represent connections among units. Solid lines terminated with black circles are excitatory connections, whereas those terminated with hollow circles are inhibitory connection. Dashed lines represent new, to-be-learned connections. Two connected layers are fully connected (i.e., every unit is connected to every other unit), unless annotated with "1:1" (i.e. "one-to-one") in which case a unit in a layer is connected to only one unit in the other layer. Finally, double dashed lines represent sources of external inputs. As described below, both the feature units and the category label units receive external input, although at different phases of the learning process.

We now describe the basic elements of KRES, which include its representation assumptions, activation dynamics (i.e., constraint satisfaction), and learning via CHL.

Representational Assumptions

At any time a unit has a level of activation in the range 0 to 1 that represents the activation of the concept. A unit *i*'s activation act_i is a sigmoid function of its total input,

$$act_i = 1 / [1+ \exp (-total\text{-}input_i)]$$

and its total input comes from three sources,

$$total\text{-}input_i = net\text{-}input_i + external\text{-}input_i + bias_i.$$

Network input represents the input received from other units. External input represents the presence of (evidence for) the concept in the external environment. Finally, a unit's bias can be interpreted as a measure of the prior probability that the concept is present in the environment.

In many applications, two or more features might be treated as mutually exclusive values on a single dimension. In Figure 1 the stimulus space is assumed to consist of five binary valued dimensions, with A_0 and A_1 representing the values on dimension A, B_0 and B_1 the values on dimension B, etc. To represent that these feature pairs are mutually exclusive they are linked by inhibitory connections. The category labels X and Y are also assumed to be mutually exclusive and are linked by an inhibitory connection.

Connections between units are symmetric, that is, $weight_{ij} = weight_{ji}$. A unit's network input is computed by multiplying the activation of each unit to which it is connected by the connection's weight, and then summing over those units in the usual manner,

$$net\text{-}input_i = \sum_j act_i * weight_{ij} .$$

KRES primarily represents prior knowledge in the form of prior relations between features. For example, in Figure 1 it is assumed that features A_0, B_0, and C_0 are related by prior knowledge, as are features A_1, B_1, and C_1. These relations are rendered as excitatory connections between the features. In KRES prior knowledge can also be represented in the form of preexisting concepts (i.e., units) and excitatory connections that link those preexisting concepts to the feature units (see Simulation 3 below).

Classification via Constraint Satisfaction

Before a KRES model is presented with input that represents an object's features, the activation of each unit is initialized to a value determined solely by its bias. The external input of a feature unit is then set to 1 if the feature is present in the input, -1 if it is absent, and 0 if its presence or absence is unknown. The external input of all other units is set to 0. The model then undergoes a multi-cycle constraint satisfaction processes which involves updating the activation of each unit in each cycle in light of its external input, its bias, and its current network input. (In each cycle, the serial order of updating units is determined by randomly sampling units without replacement.) After each cycle the *harmony* of the network is computed, given by,

$$harmony = \sum_i \sum_j act_i * act_j * weight_{ij} . \qquad (1)$$

Constraint satisfaction continues until the network settles, as indicated by a change in harmony from one cycle to the next of less than 0.00001.

The activation of units X and Y that result from this settling process represent the evidence that the current input should be classified as an X or Y, respectively. These activation values can be mapped into a categorization decision in the standard way, that is, according to Luce's choice axiom,

$$choice\text{-}probability\ (X, Y) = act_X \ / \ (act_X + act_Y) .$$

Contrastive Hebbian Learning (CHL)

As described earlier, the settling of a network that results from presenting just the feature units with input is referred to as the minus-phase. In the plus-phase, error-correcting feedback is provided to the network by setting the external

inputs of the correct and incorrect category label units to 1 and –1, respectively, and allowing the network to resettle in light of these additional inputs. We refer to the activation values of unit i that obtain after the minus and plus phases as act_i^- and act_i^+, respectively. After the plus phase the connection weights are updated according to the rule,

$$\Delta weight_{ij} = lrate * (act_i^+ * act_j^+ - act_i^- * act_j^-) \qquad (2)$$

where *lrate* is a learning rate parameter.

Network Training

Before training a KRES network, all connections weights are set to their initial values. In the following simulations, all to-be-learned connections are initialized to a random value in the range [-0.1, 0.1], and the biases of all units are initialized to 0. As in the behavioral experiments we simulate, training consists of repeatedly presenting a set of training patterns in blocks with the order of the patterns randomized within block. Training continues until the error for a block falls below an error criterion of 0.10. The error for a block is computed by summing the errors associated with each training pattern in the block and dividing by the number of patterns. The error associated with a training pattern is the sum of the squared differences between the activation levels of the category label units and their correct values (0 or 1).

KRES Simulation of Empirical Data

We present KRES simulations of three empirical data sets that illustrate the effect of prior knowledge on category learning. The KRES model was rerun ten times with a different set of random weights, and the results reported below are averaged over those ten runs.

Simulation 1: Murphy and Allopenna (1994)

In the literature on category learning with prior knowledge, perhaps the most pervasive effect is that learning is dramatically accelerated when the prior knowledge is consistent with the empirical structure of training exemplars. For example, Murphy and Allopenna (1994, Experiment 2), presented examples of two categories the features of which either could (Theme Condition) or could not (No Theme Condition) be related to one another. In the Theme condition one category had six typical features that could be related because they could be construed as features of arctic vehicles ("drives on glaciers," "made in Norway," "heavily insulated," etc.) whereas the other category had six typical features that could be construed as features of jungle vehicles ("drives in jungles," "made in Africa," "lightly insulated," etc.). In the No Theme condition, the typical features of the categories could not be related to one another. Exemplars also possessed three knowledge-irrelevant features which were not predictive of category membership. Murphy and Allopenna found that participants reached a learning criterion in fewer blocks in the Theme (2.5) versus the No Theme condition (4.1), a result the authors attribute to the knowledge relating the features in the Theme condition.

This experiment was simulated by a KRES model like the one shown in Figure 1 with 18 features representing the two values on 9 binary dimensions. In the Theme but not the No Theme condition the six related features in each of the two

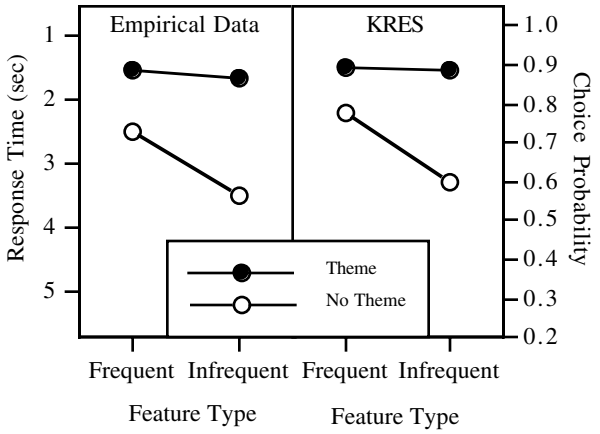

Figure 2. Results from Murphy & Allopenna (1994).

categories were linked with excitatory connections. The weight on these excitatory connections was initialized to 0.4, the inhibitory connections were initialized to –2.0, and the learning rate was set to 0.10.

The results indicated that KRES reproduces the learning advantage found in the Theme condition: The error criterion was reached in fewer blocks as compared to the No Theme condition (2.0 vs. 4.0). This advantage can be attributed to KRES's use of recurrent networks: The mutual excitation of knowledge-relevant features in the Theme condition resulted in higher activation values for those units, which in turn led to the faster growth of the connection weights between the features and category label units (according to the CHL learning rule Eq. 2). Once some learning of those connections has occurred, the higher activation of the features also leads to greater activation of the category labels themselves.

Murphy and Allopenna also varied the frequency with which the six knowledge-relevant features appeared during training, and then tested how subjects classified those features during an ensuing test phase. The left side of Figure 2 indicates that, as expected, RTs for these single-feature classification trials were shorter for frequent versus infrequent features in the No Theme condition. In contrast, in the Theme condition RTs were insensitive to features' empirical frequency. This pattern of results was also reflected in subjects' categorization accuracy. (Note Figure 2's RT scale has been inverted to facilitate comparison with KRES's choice probabilities presented below.)

To determine whether KRES would also exhibit these effects, after training the model was presented with single features. That is, the unit representing that feature was given an external input of 1, the unit representing the other feature on the same dimension was given an input of –1, and all other units were given an input of 0. The right side of Figure 2 indicates that KRES's choice probabilities reproduce the pattern of results for the single-feature tests. In KRES, infrequently presented knowledge-relevant features are classified nearly as accurately as frequently presented ones because during training those features were activated by inter-feature excitatory connections even on trials in which they were not presented, and hence were associated with the category label nearly as strongly as knowledge-relevant features that were frequently presented.

Simulation 2: Kaplan and Murphy (2000)

Simulation 1 provides evidence in favor of KRES's use of recurrent networks to accelerate learning by amplifying the activation of features interconnected by prior knowledge. However, another distinctive characteristic of KRES is that the category label units are also recurrently connected to the features. In this section we provide evidence that activation also flows backwards from category label units.

Using a modified version of the materials used in Murphy and Allopenna (1994), Kaplan and Murphy (2000, Experiment 4) provided an especially dramatic demonstration of the effect of prior knowledge. In that study, participants were presented with training examples that contained only *one* of the knowledge-relevant features and up to six knowledge-irrelevant features that were predictive of category membership. That is, the single knowledge-relevant feature in each exemplar had prior associations only to features in other category exemplars. Under these conditions, one might have predicted that participants would be unlikely to notice the relations among the features in different exemplars, especially given that those features were each embedded in an exemplar with many knowledge-irrelevant features. In fact, participants in this Intact Theme condition reached a learning criterion in fewer blocks (2.7) than did those in a No Theme condition (5.0) in which the categories had the same empirical structure but no relations among features.

We simulated this experiment with a KRES model with 22 features on 11 binary dimensions. In the Intact Theme condition the features within the two sets of six knowledge-relevant features were inter-related with excitatory connections, as in Simulation 1. The weight on these excitatory connections was initialized to 0.35, the inhibitory connections were set to –2.0, and the learning rate was set to 0.10.

KRES reproduced the learning advantage found in the Intact Theme condition (3.0 blocks) as compared to the No Theme condition (5.4). This advantage obtained because even though each training pattern in the Intact Theme condition contained only one knowledge-relevant feature, that feature tended to activate the knowledge-relevant features to which it was connected, and hence the connections between each knowledge-relevant feature and its correct category label were strengthened on every trial to at least some degree.

After each training block, Kaplan and Murphy also presented test blocks in which participants classified each of the 22 features. The left side of Figure 3 indicates that as expected after the final block of training participants in the No Theme condition were faster at classifying those features that appeared in several training exemplars (Characteristic features) than those that appeared in just one (Idiosyncratic features). In contrast, in the Intact Theme condition participants were faster at classifying the Idiosyncratic features, because they were also knowledge-relevant. Unexpectedly, Intact Theme participants were also faster at classifying the Characteristic features (i.e., the knowledge-irrelevant features) even though those features were not related via prior knowledge, and even though Intact Theme participants had experienced fewer training blocks on average (2.7 vs. 5.0).

This latter result is a challenge for many standard connectionist accounts of learning, because in such accounts the better learning associated with knowledge-relevant features would be expected to *overshadow* the learning of knowledge-irrelevant features (Gluck & Bower, 1988)–that is, these features should be worse with knowledge than without as a result of them competing with the stronger knowledge-relevant features. In contrast, Figure 3 indicates that KRES is able to account for the better learning (or in some experiments, equal learning) of the knowledge-irrelevant features in the Intact Theme condition. This result can be attributed to the use of recurrent connections to the category label units. After some excitatory connections between the knowledge-irrelevant features and category labels have been formed, the knowledge-relevant and -irrelevant features began to activate each other through the category node. This greater activation of the knowledge-irrelevant features leads to accelerated learning of their connection weights to the category labels. That is, KRES's use of recurrent networks compensates for the effects of cue competition found in the usual feedforward network.

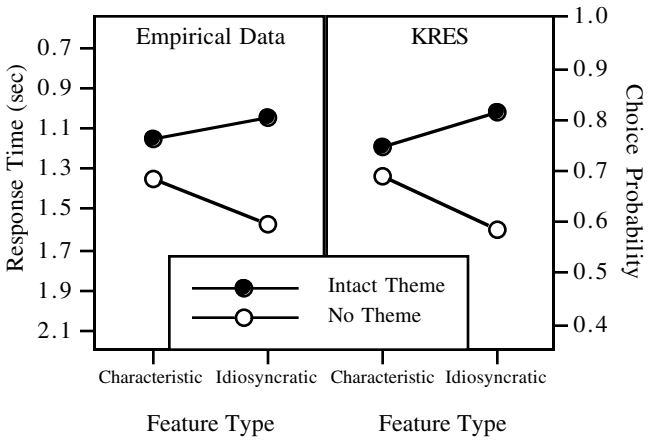

Figure 3. Results from Kaplan & Murphy (2000). In the Intact Theme condition Idiosyncratic features are knowledge-relevant and Characteristic features are knowledge-irrelevant.

Simulation 3: Wisniewski and Medin (1994)

In a final simulation we demonstrate the efficacy of contrastive-Hebbian learning to update weights on connections not involving the category label units. In particular, we examine KRES's ability to update connections representing prior knowledge that is inappropriate in the current context.

Wisniewski and Medin (1994, Experiment 2) present empirical results that call into question the assumption of standard theories of category learning that features can be identified prior to learning. Participants were shown two categories of line drawings of persons that were described as drawn by *creative* and *non-creative children* or by *farm* and *city kids*. Wisniewski and Medin chose to use line drawings to illustrate that what constitutes a feature in a stimulus depends on the prior expectations that one has about its possible category membership. For example, they found that participants would assume the presence of *abstract features* about a category depending on the category's label (e.g., creative children's drawings depict unusual amounts of detail and characters performing actions) and examine the drawings for concrete evidence of those abstract features in order to

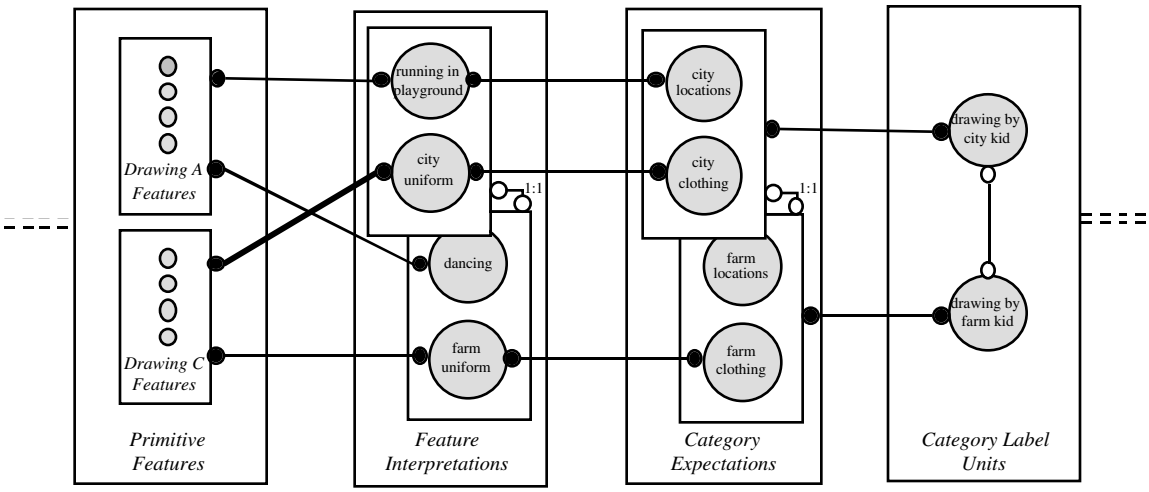

Figure 4. KRES model for Simulation 3.

determine its category membership. They also found that the feedback participants received about category membership led them to change their original interpretation of certain features of the line drawings. For example, after first interpreting a character's clothing as a farm "uniform" (and categorizing the picture as drawn by a farm kid), some participants reinterpreted the clothing as a city uniform after receiving feedback that the picture was drawn by a city kid.

To demonstrate these effects with KRES, we imagined a simplified version of the materials of Wisniewski and Medin's in which there were only two drawings. One drawing (Drawing A), was of a character performing an action interpretable either as climbing in a playground or dancing. In the other (Drawing C), a character's clothing could be seen as a farm uniform or a city uniform. These alternative interpretations are represented in the left side of the KRES model of Figure 4. Whereas we assume the two interpretations of Drawing A are equally likely, we assume that a city uniform is the more likely interpretation of Drawing C (as depicted by the heavier line connecting the features of Drawing C and their city uniform interpretation). The alternative interpretations are connected with inhibitory connections representing that only one interpretation is correct.

The model of Figure 4 was presented with the problem of learning to classify Drawing A as done by a city kid, and Drawing C by a farm kid. We represented the expectations or hypotheses that Wisniewski and Medin found that learners form in the presence of meaningful category labels such as *farm* or *city kids* as units connected via excitatory connections to the category labels, as shown in the right side of Figure 4. In Figure 4, city and farm kids are expected to be in locations and wear clothing appropriate to cities and farms. These expectations are in turn related by excitatory connections to the picture interpretations that instantiate them: climbing in a playground instantiates a city location, and city and farm uniforms instantiate city and farm clothing, respectively. In Figure 4, all inhibitory connections were set to –3.0 and all excitatory connections were set to 0.25, except for those between Drawing C's features and their city uniform interpretation, which were set to 0.30.

Before a single training trial is conducted, the prior knowledge incorporated into this KRES model is able to decide on a classification of both drawings. Upon presentation of Drawing A, its two interpretations, climbing-in-a-playground or dancing are activated, and climbing-in-a-playground in turn activates the city location expectation, which in turn activates the category label for city kids' drawings. The drawing is correctly classified as having been drawn by a city kid. Moreover, as the network continues to settle, activation is sent back from the category label to the climbing-in-a-playground unit. As a result, the climbing-in-a-playground interpretation of Drawing A is more active than the dancing interpretation when the network settles. That is, the top-down knowledge provided to the network results in the resolution of an ambiguous feature (i.e., the action is interpreted as climbing in a playground rather than dancing). Wisniewski and Medin found that the same drawing would be interpreted as depicting dancing instead when participants were required to classify the drawings as having been done by creative or noncreative children.

Similarly, upon presentation of Drawing C, its two interpretations are activated, but because the city uniform interpretation receives more input as a result of its larger connection weight, it quickly dominates the farm uniform interpretation. As a result, the category label for city kids' drawings becomes active (via the city clothing expectation). That is, the drawing is *incorrectly* classified as having been drawn by a city kid. However, error feedback results in the model changing its interpretation of Drawing C. During the model's plus phase, the farm kids' category label is more active than the city kids' label as a result of the external inputs those units receive. The activation emanating from the farm kids' label leads to the activation of the farm clothing expectation and then the farm uniform feature interpretation, which ends up dominating the city uniform unit.

This result indicates that KRES can reinterpret features in light of error feedback. The more important question, however, is whether KRES can *learn* this new interpretation so that Picture C (or a similar picture) will be correctly classified in the future. The left side of Figure 5 shows the changes to the connection weights brought about by the CHL learning rule with a learning rate of 0.3 as a function

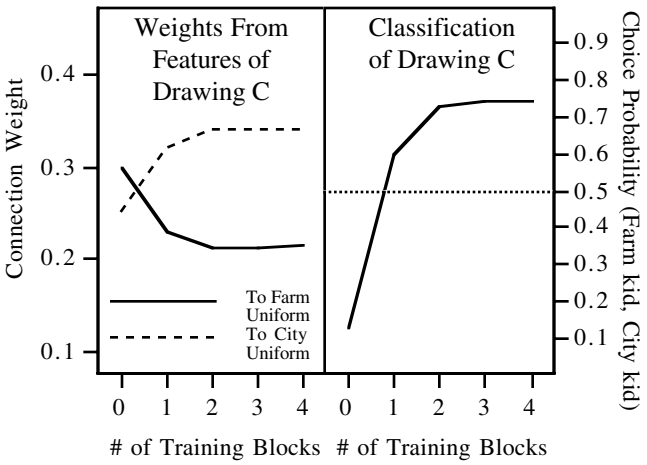

Figure 5. Results from Simulation 3.

of number of blocks of training on the two drawings. Figure 5 indicates that the connection weights associated with the interpretation of Drawing C as a city uniform rapidly decrease from their starting value of 0.30, while the weights associated with Drawing C's interpretation as a farm uniform increase from their starting value of 0.25. As a result, after just one training block KRES's classification of Drawing C switches from being done by a city kid to a farm kid (as indicated by the choice probabilities shown in the right side of Figure 5). That is, KRES uses the error feedback it receives to learn a new interpretation of Drawing C.

General Discussion

We have presented a new model of category learning that attempts to account for the influence of prior knowledge that learners often bring to the task of learning a new category. KRES utilizes a recurrent network in which knowledge is encoded in the form of connections among units. We have shown the changes brought about by this recurrently-connected knowledge to the interpretations and reinterpretations of a category's features provides a reasonable account of three data sets exhibiting the effects of prior knowledge on category learning. In Simulation 1 we demonstrated how KRES's recurrent network provides a pattern of activation among features that accounts for the finding that knowledge accelerates the learning of connections to category labels. In Simulation 2 we demonstrated that the presence of knowledge does not inhibit the learning of knowledge-irrelevant features, a striking result in light of well-known learning phenomena such as cue competition. In Simulation 3 top-down flow of activation was instrumental in KRES's success in resolving the ambiguity surrounding the interpretation of a perceptual features. Moreover, the CHL learning rule allowed the knowledge responsible for one interpretation of an ambiguous feature to be unlearned and a new interpretation learned when the network was provided with feedback regarding the stimulus's correct category.

KRES departs from previous connectionist models that attempt to account for the effects prior knowledge with feedforward networks. For example, Heit & Bott (2000) have proposed a model, *Baywatch*, that assumes that features send activation to prior concepts, that both the features and the prior concepts send activation to the category label units, and that learning consists of learning the connections to the category labels. Although we believe that existing categories often aid the learning of new categories (e.g., our knowledge of VCRs helps us understand DVD players), the Baywatch approach is limited to the learning of new categories that are essentially refinements of existing concepts. In contrast, KRES only assumes the presence of relations between features to account for the data in Simulations 1 and 2, and hence is able to learn truly new concepts, not just refinements of existing ones.

There remains much to be discovered about the properties of recurrent networks and contrastive Hebbian learning with regard to the learning of categories. However, we believe that recurrent networks are likely to be critical to any attempt at accounting for the effects of prior knowledge on category learning. For example, standard feedforward networks seem intrinsically unable to account for (a) the accelerated learning produced by prior knowledge without presupposing prior knowledge of the to-be-learned category, (b) the effects of top-down knowledge on resolving ambiguous features, and (c) the reinterpretation of ambiguous features in light of feedback regarding category membership.

Regularity and Irregularity in an Inflectionally Complex Language: Evidence from Polish

Abstract

We report two experiments which address the question of whether there is support for single or dual mechanisms in the processing of Polish regular and irregular nouns and verbs. The data from an immediate cross-modal priming experiment (verbs and nouns) revealed that there was significant priming, irrespective of regularity, for both verbs and nouns. The results for verbs were replicated in a second experiment using delayed repetition auditory-auditory priming. The outcome from both experiments is in line with the results reported from research on Italian and French but not with English and German, and suggest that Polish regulars and irregulars are processed by a single underlying cognitive system.

Introduction

There has been a long lasting debate as to the implications of English regular and irregular verbs for the universal properties of human cognitive mechanisms (Marslen-Wilson & Tyler, 1998; Pinker, 1999). The protagonists of a dual mechanism approach (Pinker & Prince, 1991) have claimed that English regular past tense forms are processed by a symbolic rule, which concatenates allomorphic suffixes (*-ed* or *-d* or *-t*) to the verb stem, while the irregular past tense forms are processed as whole forms in an associative memory. In contrast, the proponents of the single mechanism (Plunkett & Marchman, 1993; Rumelhart & McClelland, 1986) claim that regular and irregular English verbs are processed and represented in the same way, by a distributed connectionist system, operating without symbols and syntax.

We focus here on the experimental work probing the online processing and representation of regular and irregular forms in the adult mental lexicon. Much of this work has of course focused on English, chiefly using a variety of priming paradigms. In early work, for example, Stanners, Neiser, Hernon and Hallet (1979) tested the representation of regular and irregular verbs using visual priming with a delay. The authors found that regular inflected verbs primed their bases as effectively as identity primes. In contrast the irregular past tenses primed their bases significantly less than identity primes. Marslen-Wilson, Hare and Older (1995) investigated the representation of English regular and irregular verbs using a cross-modal lexical decision paradigm. The authors contrasted regular verbs (*jumped/jump*), with irregular verbs which fell into two classes: semi-weak verbs (*burnt/burn*) with irregular alveolar inflection, and vowel change verbs (*gave/give*). The results showed that there was significant priming for the regulars, but no priming for either sub-class of irregular verbs.

Evidence for behavioural differences of this type, suggesting asymmetries in the underlying systems supporting the processing of regular and irregular forms, can be interpreted as support for a dual mechanism approach. It is important, however, to apply these techniques cross-linguistically, to develop a broader perspective on the processing consequences of regularity and irregularity, and to evaluate the universality of the claims being made.

Cross-linguistic behavioural studies

Although cross-linguistic research is in its early stages it has already suggested interesting contrasts between English and German as opposed to Italian and French.

Sonnenstuhl, Eisenbeiss and Clahsen (1999) probed the representation of regular and irregular German verbs as well as regular and irregular noun plurals, using the cross-modal paradigm. Significant priming for both regulars and irregulars was obtained. The regulars were as effective as identity primes, whereas the irregulars were significantly less effective than identity primes. The authors argued that these data, consistent with English, provide support for the dual mechanism where the regulars are processed as a stem and an affix, generated by a rule, whereas irregulars are processed as full lexical items.

Both English and German belong to the same West Germanic language family and share many similarities. In additional research we have begun to look at languages from different sub-families which show different distributions of regulars and irregulars as well as of inflectional suffixation.

Significant cross-modal priming has been found for Italian regular and irregular verbs (Orsolini & Marslen-Wilson 1997). For regular verb pairs, the prime was typically a first or third conjugation past definite form, paired with either an infintive target (as in ***gioc****-a-rono/****gioc****-are* 'they played/to play') or with a past participle target (as in ***am****-a-rono/****am****-a-to* 'they loved/loved'). These conditions were contrasted with irregular verb pairs, such as *sce-s-ero/scend-ere* 'they got down, past definite'/to get down, infinitive', with idiosyncratic alternations, comparable to English irregular alternations, but occurring in a much more constrained and predictable morphological environment. Significant priming

was found across the board, with no differences between conditions in the magnitude of priming. There was no evidence here, or in an accompanying study using elicitation techniques, to suggest underlying differences in the processing and representation mechanisms evoked by regular and irregular forms.

Comparable results were obtained for French, where Meunier and Marslen-Wilson (2000) investigated the processing of French verbs with regular and irregular alternations in both cross-modal priming and masked priming experiments. They distinguished three levels of irregularity, ranging from phonologically triggered alternations such as *sème/semer* 'I sow/to sow', through sub-regularities such as *teignent/teindre* 'they dye/to dye', to highly idiosyncratic alternations such as *iront/aller* 'they will go/to go. As in Italian, these irregularities are linguistically embedded in extensive, primarily regular inflectional paradigms. Again, strong priming, without significant differences in the effects for regulars and irregulars, was found across the board. These results, similar to those from Italian, provide no support for the view that different mechanisms handle the processing of regulars and irregulars.

The aim of this paper is to extend these cross-linguistic investigations to Polish, a representative of the Slavonic language family, where very little behavioural research has been conducted. A striking characteristic of Polish is the great richness of its inflectional systems and the wide distribution of phonological and morphophonological alternations, varying considerably in regularity. In addition, note that in Polish, as in French and Italian, but in contrast with English, both regular and irregular verbs are inflected by concatenation of an inflectional suffix with a stem. In English, this is true for regular past tenses, e.g. *jump/jump-ed*, but not for irregular past tense forms, e.g. *give/gave*. The distinction between Polish regular and irregular forms is made on the basis of a vowel or consonant change (an alternation) in inflected forms. Regular inflected forms have morphophonological alternations which are predictable from Polish morphophonology. Irregular forms have morphophonological alternations which are idiosyncratic and are not predictable from the rules of Polish morphophonology.

We report two preliminary studies which probe the processing of Polish regular and irregular verbs and nouns (Experiment 1) and verbs (Experiment 2). Before moving on to the experiments, a description of the relevant characteristics of Polish is necessary.

Polish inflectional morphology and alternations

Almost every word in Polish exists within a very extensive morphological paradigm: declensional for nouns, adjectives, numerals and pronouns and conjugational for verbs. Every verb in Polish is inflected according to one of the three conjugational paradigms (Laskowski, 1998). The basis of the division of verbal themes into conjugations is their ability to concatenate with the complex morpheme of the present tense. The themes which are members of conjugation I take in the present tense the endings *'-ę', '-e-sz', '-e', '-e-my', '-e-cie'* and *'-ą'* for the 1st, 2nd and 3rd person SG[1] and the 1st, 2nd and 3rd person PL, respectively. The themes which are members of conjugation II take the endings: *'-ę', '-i-sz', '-i', '-i-my', '-i-cie', '-ą'*. The verbs which belong to conjugation III have the endings: *'-m', '-sz', '-0', '-my', '-cie'* and *'-ą'*. Every conjugation is divided into classes, depending on the ending of the verbal theme. For instance, conjugation I consists of five classes and the fifth class consists of verbs which exhibit unproductive, idiosyncratic alternations.

Every Polish noun is inflected according to an extensive declensional paradigm. Each paradigm consists of seven cases. There are three declensional groups for SG nouns: masculine, feminine and neuter and two for PL nouns - nonpersonal and personal (Zagórska-Brooks, 1975).

Fully two-thirds of words in Polish exhibit changes which are consonantal and/or vocalic. Broadly speaking there are two sources of alternations in Polish: phonological and morphophonological (Zagórska-Brooks, 1975; Kowalik, 1998). Our focus here is on the second type, the morphophonological alternations. This type of alternation is caused by an interaction between morphology and phonology during concatenation of morphemes with other morphemes (e.g. in conjugation or declension). There are two kinds of morphophonological alternations in Polish verbs and nouns: regular and irregular. The regular alternation is predictable and usually productive. For instance, the postalveolar consonants - [ʃ] and [ʒ] in *pro**sz**-ę* [prɔʃ-ɛ̃] 'I ask' and *wo**ż**- ę* [vɔʒ-ɛ̃] 'I transport' alternate with the palatal consonants - *ś* [ɕ] and *ź* [ʑ] when the stem is concatenated with the vowel *-i-*, as in *pro**si**-ć* [prɔɕi-t͡ɕ] 'to ask' and *wo**zi**-ć* [vɔʑi-t͡ɕ] 'to transport'. The reason for this is that the alveolar place of articulation in the inflected forms (1st person SG, present tense) changes to the palatal place of articulation, because of the following front vowel *i*. In contrast, the irregular alternations cannot be predicted and are usually unproductive. For instance, the stem ***trze**-ć* [tʃɛ-t͡ɕ] 'to grate' alternates with the stem ***tr**-ą* [tr-ɔ̃] 'they grate'. There are two kinds of alternation here: the consonantal and the vocalic, where the vocalic alternation e : 0 is an idiosyncratic one, which is unpredictable from the morphophonology of contemporary Polish.

The fact that the morphophonological alternations in Polish verbs have a different distribution to those found in English is worth emphasising. In English, alternations in verbs occur between the present and past tense forms, for instance *give/gave*. In Polish, on the other hand, there can be several different alternations in verbs in the same and different tenses, depending on person, number and so forth. For the verb *wieś-ć* [vɛ́ɕ-t͡ɕ] 'to lead', there are two types of alteration: consonantal and vocalic. There are three consonantal alternants: *wie**ś**-ć* [vɛ́ɕ-t͡ɕ]: *wio**d**-ą* [vio**d**-ɔ̃]: *wie**dzi**e-sz* [vie**d͡ʑ**ɛ-ʃ] 'to lead: they lead: you lead'. And there are also three vocalic alternants, two in the present tense: wi**e**ś-ć: *wi**o**d-ą* and the third in the past tense: *wi**ó**d-ł* [vʲ**u**d-w] 'he led'.

[1] The following abbreviations are used: SG - Singular number, PL - Plural number, NOM - Nominative, DAT - Dative, LOC - Locative, VOC - Vocative;

The alternations in Polish have a more even distribution than in English. All classes, despite regular or irregular alternations, concatenate with the same conjugational endings, which are characteristic for a given conjugation. Polish is very similar to French in this respect. This does not occur in English, where the concatenative process applies to regular past tense forms but not to irregular ones. Neither does it happen in Italian, where the irregular forms conjugate using a different set of endings than the regular forms.

Experiment 1

The aim of Experiment 1 was to investigate processing of Polish verbs and nouns with regular and irregular alternations. We chose cross-modal priming as a starting point because most cross-linguistic and English data come from this paradigm. The question that we asked was whether the pattern of results for Polish items with no alternations, regular alternations, and irregular alternations would be comparable with the Italian and French or with the English and German results. In contrast to all of these languages, Polish also provides an opportunity to investigate the processing of regular and irregular nouns which are inflectionally suffixed; the suffix occurs in both singular and plural and denotes case, gender and number. Taking advantage of this characteristic of Polish nouns, we contrasted verbs and nouns. This served firstly, to test whether the representation of verb and noun alternants in Polish correspond to each other, and secondly, to obtain a broader picture of the representation of alternants cross-linguistically.

Irregularity in Polish verbs is defined on the basis of the alternation which occurs in the stem and not on the basis of which conjugational morphemes are selected for a given verb. The difference between regular and irregular verbs lies in that regular verbs exhibit an alternation in the stem which can be derived by the phonological rules of contemporary Polish or is conditioned by a specific morphophonological context. For irregular verbs, the alternations in the stems cannot be predicted. All Polish nouns belong to one of the declensional paradigms and their membership depends on the gender of a noun and on the last consonant of the theme. Irregularity and regularity in Polish nouns is defined in the same way as for Polish verbs[2].

To test the processing of words with alternation we covaried regular and irregular alternations in verbs and nouns and contrasted them with verbs and nouns without alternations. Conditions 1 to 3 were concerned with verbs, while conditions 4 to 6 were concerned with nouns. **Condition 1** consisted of verbs with no alternations, such as *czyt-a-sz/czyt-a-ć* 'you read/to read'. The aim here was to select as homogenous a group of items as possible, to serve as a baseline for verbs. **Condition 2** consisted of verbs with regular alternations, which can be predicted from the morphophonological rules of contemporary Polish, as in *nos**sz**-ę/nos**-i**-ć* 'I carry/to carry'. The alternation involved dental consonants, such as *c, dz*; postalveolar consonants, such as *sz, ż;* and palatal consonants - *ć, dź, ś, ź*. The reason for selecting this particular type of alternation is that it is regular and occurs in verbal stems which belong to a productive conjugation. This contrasts with the verbs in **Condition 3** with irregular alternations, as in *trz-e-ć/tr-ą* 'to grate/they grate'. Six types of irregular alternation were included in this condition[3]: **1)** a : e, **2)** ą : n' and ą : m', **3)** a : 0, **4)** o : e, **5)** ą : ę and **6)** e : 0. The motivation for selecting these types of alternation was that they could not be predicted from the morphophonological rules of Polish. These alternations are peculiar to a specific group of verbs, which belong to the unproductive classes of conjugation I.

Conditions 4 to 6 concentrated on nouns. **Condition 4** consisted of nouns with no alternation, e.g. *plac-u/plac* 'a square, GEN, LOC, VOC/a square, NOM, ACC' and served as a baseline for the other noun conditions. **Condition 5** was designed to investigate the representation of nouns with regular alternations. It consisted of nouns with three types of alternation, all of which are predictable from the context. These included the alternation of hard labials to soft labials, as in *chłop/chłop-i* 'peasant/peasants', the alternation of coronals, as in *studen**ci**-e/studen**t*** 'a student, LOC, VOC/a student, NOM', and the alternation of velars, as in *no**dz**-e /no**g**-a* 'a leg DAT, LOC/a leg, NOM'. **Condition 6**, in contrast to Condition 5, concentrated on alternations which are not fully predictable from the morphophonological rules of Polish. Three types of irregular alternation were included: **1)** a : e, **2)** ę : ą and **3)** o : ó. All three alternations exist nowadays as fossilised historical remnants. The alternations ę : ą and o : ó are based on a very old phonetic change.

Finally **Condition 7** consisted of words with phonological overlap, without semantic or morphological relationship, e.g. ***kot**let/**kot*** 'cutlet/cat'. This was designed to test whether priming could be due just to pure phonological overlap between the prime and the target.

Procedure

We used the cross-modal immediate lexical decision task. The participants heard binaurally an auditory prime, at the offset of which they immediately saw a visual target (for 500 ms) and had to decide, by pressing an appropriate button, whether a target word was a real word or a non-word. The subjects were allowed 2500 ms from the onset of the target for their response.

Targets were preceded either by a related prime or by an unrelated control prime. The control prime was matched for lemma frequency and number of syllables to the related prime. The priming effect was measured as a difference in the reaction time to the target word when preceded by the control prime as opposed to the related prime. Each target only occurred once in the experiment, and two experimental versions were run, alternating control and related primes for each target.

---

[2] There is also a second type of irregularity in Polish nouns which originates from the fact that nouns which are for instance masculine, e.g. *mężczyzn-a* 'a man' are inflected in SG according to one of the feminine declensional paradigms. This type of irregularity was not the focus here.

[3] The vocalic alternations were in some cases accompanied by consonantal alternations. For instance an alternation of *rz : r* co-occurs with *e : 0* in *trz-e-ć/tr-ą* 'to grate/they grate'. Pairs of this type were included here, because there are very few verbs with an irregular alternation which are not accompanied by the consonantal alternation.

The experiment was run in Kraków using DMASTR/VMASTR software[4]. A 486/33 NIMBUS PC was used for running the experiment and collecting participants' RTs and error rates. A Digital Audio Tape Corder TCD-D3, Sony Walkman was used to present the auditory primes.

Results

Three subjects from version 1 and one subject from version 2 were discarded from the analyses because of a high error rate in the lexical decision task. This gave 21 subjects per version. All participants were Polish native speakers who were studying in Kraków. The majority of them were in their twenties and some were in their thirties. Out of the total of 580 items per version, 5 experimental pairs had to be discarded from the analyses; two because of high error percentage, two because they were erroneously classified as having a certain type of alternation, and one item because of homophony. Every data point has been inversely transformed to reduce the influence of outliers. (see Table 1 for details of the descriptive statistics).

Table 1. Priming effects and error rates in Experiment 1.

Condition	N	Prime (Mean RT)	Control (Mean RT)	Priming
1 No Alternation Verb	20	527 (1.0)	610 (5.5)	83***
2 Regular Alternation Verb	26	534 (0.8)	622 (3.4)	88***
3 Irregular Alternation Verb	26	542 (1.1)	615 (4.2)	73***
4 No Alternation Noun	20	512 (0.5)	573 (3.3)	61***
5 Regular Alternation Noun	30	518 (0.5)	580 (3.5)	62***
6 Irregular Alternation Noun	30	503 (0.7)	549 (1.5)	46***
7 Phonological Overlap	20	581 (6.5)	571 (3.5)	-10

*** denotes p<0.01; Reaction Times are in ms; Error rates in percentages (in parentheses).

An overall ANOVA with Prime (2 levels), Condition (7 levels) and Version (2 levels) was run, separately for subjects (F1) and items (F2), and revealed that there was a facilitatory effect of Prime F1(1, 40)=160.22, p<0.001, F2(1, 153)=200.94, p<0.001. There was a main effect of Condition F1(6, 240)=35.52, p<0.001, F2(6, 153)=3.94, p<0.01, and a two-way interaction of Condition and Prime F1(6, 240)=160.22, p<0.001, F2(6, 153)=8.67, p<0.001.

Subsequently an analysis of the simple effects of Prime at each level of the Condition was run. There was a consistent facilitatory effect of Prime at all levels of Condition with the exception of the Phonological Overlap Condition (p<0.001 throughout). To explore whether there were any differences in the magnitude of priming between no alternation, regular alternation and irregular alternation, planned comparisons were run separately for verbs and nouns. Regarding verbs, there was no significant difference in the magnitude of priming between No Alternation and Regular Alternation (F1<1, F2<1), No Alternation and Irregular Alternation, (F1<1, F2<1), and Regular Alternation and Irregular Alternation, F1(1, 40)=2.866, p=0.098, F2(1, 46)=1.31, p=0.258. The results for the nouns paralleled those of the verbs. There was no significant difference between the magnitude of priming for No Alternation and Regular Alternation, (F1<1, F2<1), No Alternation and Irregular Alternation, [F1(1,40)=1.281, p=0.264, F2<1] and Regular Alternation and Irregular Alternation, F1(1, 40)=1.208, p=0.278, F2<1.

Discussion

Significant priming was found for regulars as well as for irregulars, and no differences were found in the magnitude of priming between all verb conditions compared together, and all noun conditions compared together. Although there was a slight numerical decline in the amount of priming for the irregular alternations, this was not statistically significant in any analyses.

These results suggest, first, that the representation and processing of verb and noun forms is comparable in Polish. The only difference here is the significantly larger amount of priming for verbs overall compared with nouns. A possible explanation for this is that nouns in the oblique cases (all noun primes had this characteristic) are less effective primes than conjugated verbs (all the verb primes were conjugated forms). Nouns in the oblique case typically occur in a specific prepositional context, and they may be more difficult to process out of context, in contrast to conjugated verb forms, which can frequently occur without further context.

More generally, there is again no evidence here that the processing of Polish regular and irregular verbs and nouns invokes distinct underlying processing. This finding groups Polish data together with the data on Italian and French, but not with the English and German results. However, before proceeding further, we need to put these results on firmer ground.

The absence of priming for the pairs with pure phonological overlap indicated that the effects cannot be attributed just to phonological overlap. We cannot, however, exclude an account purely in semantic terms, since all of the verb and noun test pairs were strongly related not only morphologically but also semantically. It is possible, for example, that the preserved priming for the irregular alternants reflects a strong semantic input, compensating for reduced morphological priming. To address this concern, we ran a subset of the items from Experiment 1 (the verb materials) in a second experiment designed to separate morphological and semantic effects.

Experiment 2

This experiment uses the delayed repetition auditory-auditory priming task. In this task, where several items intervene between prime and target, we generally see no effects of pure semantic relatedness but robust effects of morphological relatedness (e.g., Marslen-Wilson & Tyler,

[4] DMASTR/VMASTR software was developed by Ken and Jonathan Forster at the University of Arizona, Tucson, U. S. A.

1998). If the priming effects for the alternation conditions are primarily morphological in character, then these should survive the change in task.

Materials

Because of the requirements of the task, the inclusion of all the materials from Experiment 1 would have made the experiment infeasibly large. We therefore used only the verb materials, which can be linked most directly to the research in other languages.

108 prime-target pairs were selected for 5 experimental conditions. Three of these were the Verb conditions from Experiment 1, with 20 pairs in the No Alternation condition, 24 in the Regular Alternation condition, and 24 in the Irregular Alternation condition. A further 20 pairs were selected from the Phonological Overlap condition (***kot***/*let*/***kot*** 'cutlet/cat'). The fifth, new condition consisted of 20 pairs of words that were Semantically but not Morphologically Related [+Sem, -Morph] (*banan/kokos*, 'banana/coconut'). This was to check whether purely semantic priming could be observed.

Procedure

Standard delayed auditory-auditory priming was used. The subjects heard binaurally a string of words, one every 3 seconds, which were a mixture of primes, controls, targets and fillers. Their task was to make a lexical decision by pressing an appropriate button on a response box to every heard item. The task was designed in such a way that primes and targets were separated by 12 intervening items (approximately 35 seconds). The experiment was run in Kraków using DMASTR/VMASTR software. The same experimental equipment as in Experiment 1 was used.

Results

4 participants from version 1 and 3 from version 2 were discarded from the analysis on the same criteria as in Experiment 1. Additionally 1 participant from version 1 and 1 from version 2 were excluded, because of technical problems. A total of 19 subjects per version was entered into the analysis. Further details on participants were the same as in Experiment 1. Two experimental items were removed from the analysis, because of high error percentages. A total of 106 items were entered into the analysis. (See Table 2 for the details of the descriptive statistics).

The analyses are based on the Target reaction times only. The inversely transformed data were analysed in a repeated measures ANOVA. The overall analysis for all 5 conditions revealed that there was a main effect of Prime, $F1(1, 36)= 40.14$, $p<0.001$, $F2(1, 96)=16.17$, $p<0.001$. There was also a main effect of Condition, $F1(4, 144)=67.80$, $p<0.001$, $F2(4, 96)=4.24$, $p<0.01$ and a two way interaction of Condition and Prime $F1(4, 144)=7.26$, $p<0.001$, $F2(4, 96)=3.50$, $p<0.05$.

Subsequently, the simple effects of Prime on each level of the Condition were investigated. There was significant priming in all the verb conditions as predicted: No Alternation Verb: $F1(1, 36)=11.05$, $p<0.01$, $F2(1, 16)=5.69$, $p<0.05$; Regular Alternation Verb: $F1(1, 36)=25.97$, $p<0.001$, $F2(1, 22)=12.69$, $p<0.01$; Irregular Alternation Verb: $F1(1, 36)=28.99$, $p<0.001$, $F2(1, 22)=9.56$, $p<0.01$. No significant priming was found either in the Phonological Overlap condition [$F1(1, 36)=1.41$, $p=0.242$, $F2<1$], or in the Semantically Related and Morphologically Unrelated condition [$F1(1, 36)=1.83$, $p=0.184$, $F2<1$].

To explore whether there were differences in the magnitude of priming between the three verb conditions the appropriate planned comparisons were made. There were no significant differences in the magnitude of priming in any of the comparisons between the No Alternation, Regular Alternation, or Irregular Alternation conditions ($F1<1$, $F2<1$ throughout).

Table 2. Priming effects and error rates in Experiment 2.

Condition	N	Prime (Mean RT)	Control (Mean RT)	Priming
1 No Alternation Verb	20	718 (0.6)	748 (0.9)	30*
2 Regular Alternation Verb	24	743 (1.1)	781 (1.8)	39**
3 Irregular Alternation Verb	24	753 (3.7)	785 (3.7)	32**
4 Phonological Overlap	20	816 (8.9)	803 (7.4)	-14
5 [+Sem, -Morph]	20	810 (2.6)	819 (1.8)	9

* denotes $p<0.05$; ** denotes $p<0.01$; Reaction Times are in ms; Error rates in percentages (in parentheses).

Discussion

The results indicate that the priming effect observed in all the verb conditions is morphological in nature and not semantic. As in Experiment 1, the effects are equally strong across the alternation sets. There is no trace of a semantic effect under these testing conditions, but there is robust priming between all morphologically related pairs, indicating that both prime and target map onto the same underlying morpheme at the level of the lexical entry. The absence of significant priming for the Phonological Overlap condition confirms that any facilitatory priming here cannot be attributed to the pure phonological overlap between primes and targets.

General Discussion

The question asked at the beginning of this paper was whether a dual or single mechanism can best account for the results from Polish. The data we report, with no difference in the magnitude of priming for regulars and irregulars, seems to group with earlier findings on Italian and French (Meunier & Marslen-Wilson, 2000; Orsolini & Marslen-Wilson, 1997), and indicates that a uniform set of processing procedures and representations are applied to Polish regular and irregular verbs and nouns.

We suggest that the explanation for these properties of Polish, and its similarities with French and Italian, lies in the fact that every verb and noun in Polish functions within similar inflectional paradigms which requires suffixation. All verbs and nouns, despite having regular or irregular vocalic or consonantal alternations, are inflected using con-

catenative processes which link verb roots to a series of inflectional suffixes. This is in contrast to English, where the regularity/irregularity distinction is confounded with a contrast in type of morphological process. The regular past tense inflection involves concatenative suffixing morphology, whereas the irregular forms have no overt inflectional structure, and have to be both stored and processed as unanalysable full forms. The sequence *jumped* can be broken down into the pair {jump} + {-ed}, but no such analysis can be applied to forms like *bought* or *gave*.

The consequences of this, in English, is that regular and irregular inflected forms do partially involve separable underlying cognitive and neural systems, with the regular inflected forms requiring the involvement of specialised systems supporting processes of morphophonological assembly and disassembly. These systems, that can be selectively damaged following stroke and other injuries to the brain, are not required for the access and processing of the irregular forms, which are not phonologically decomposable (Marslen-Wilson & Tyler, 1998). The same distinction does not apply, of course, to Polish (or French and Italian) irregulars, all of which are morphophonologically complex, and which invoke the same range of processing mechanisms as the regular forms.

These considerations suggest that further progress in elucidating the properties of the mechanism underlying the processing of regular and irregular forms will require more attention to the neural underpinnings of these mechanisms. A start has been made in this direction in the study of English and German inflection. For instance, Marslen-Wilson, Csibra, Ford, Hatzakis, Gaskell and Johnson (2000) examined the processing of English regular and irregular past tenses using an immediate cross-modal priming experiment during which ERPs were recorded. The results revealed differences in the pattern of scalp activity for regulars and irregulars and provide support for the claim that partially different mechanisms underly the processing of each type of material. Two other ERP studies reported by Clahsen (1999) on the representation and processing of German regular and irregular plurals and participles, using a violation paradigm, claim that regularisations elicit signals which are characteristic for violations of a morpho-syntactic rule, whereas irregularisations elicited signals which are typical of anomalous words and can be regarded as support for a distinction between rule-based and lexically based inflectional processes (Pinker, 1999).

Thus, if Polish regular and irregular nouns and verbs are indeed processed by a uniform underlying mechanism, as suggested by the data presented in this paper, then one would not predict significant differences in ERP recordings for the regulars and irregulars, nor in neuro-imaging studies using techniques such as fMRI, allowing a greater degree of spatial localisation. But whatever the outcome, input from studies of this sort are likely to be an essential component of any future resolution of the kinds of questions raised here.

Abstract

The goal of this paper is to replicate and extend the connectionist model presented by Mareschal and French (1997) as an account of 'the particularities of […] infant memory and categorization'. With infants, the sequential presentation of cats followed by dogs yields an expected increase in infants' looking time, whereas the reversed presentation order does not. This intriguing asymmetry of infants' category formation, first reported by Quinn, Eimas, and Rosenkrantz (1993), was simulated by Mareschal et al.'s simple connectionist network. In addition, the authors proposed that this asymmetric categorization is a natural byproduct of the 'asymmetric overlaps of the visual feature distributions' of cats and dogs. Using a simple feedforward backpropagation network, we successfully replicated this asymmetric categorization effect, as well as a reported asymmetric exclusivity effect in the two categories, and an asymmetric interference effect of learning dogs on the memory for cats, but not of learning cats on the memory for dogs. We furthermore investigated the authors' explanation of the asymmetric effects, firstly, by systematically varying the overall similarity between learned items and interfering items, and secondly, by adding a binary feature to the input set, namely the animal cry (barking vs. mewing). The results of the present modeling underscore the authors' explanation of the observed effects in infants' memory and categorization, but also suggest lines of further experimental research susceptible to undermine the proposed connectionist account.

Introduction

In this paper, we report on a replication and two extensions of Mareschal and French's (1997) simple connectionist model that accounts fairly well for unexpected findings observed in spontaneous category formation in young infants (e.g., Quinn, Eimas, & Rosenkrantz, 1993) and in infant memory. Indeed, Mareschal et al. focused their modeling efforts on three target behaviors of very young infants concerning their categorization and memory, namely: (a) the ability to categorize complex visual stimuli, (b) the asymmetric effect in early categorization, and (c) interference effects in early memory.

The empirical data Mareschal et al. modeled show that infants, aged 3 to 4 months, are able to accurately categorize cats and dogs, and that they form an exclusive category of cats (thus excluding novel dogs) but an inclusive category of dogs (thus novel cats may well fall into the category of dogs) (Quinn et al., 1993). Furthermore, infants are known to present catastrophic forgetting of previously learned stimuli when shown certain other intervening material (e.g., Cohen & Gelber, 1975). This interference effect decreases precisely when infants' categorization abilities increase (Quinn & Eimas, 1996). Infant memory and categorization can thus be thought to be closely linked to each other and to depend on the same basic mechanisms.

Indeed, the connectionist account given for the observed asymmetric effects in categorization and for the interference effects in memory is based on the same reasoning. The asymmetry in category formation arises from the unequal overlap of the visual features distribution and not just the variance of the distribution itself. In other words, the values of the cat features fall within those of the dog values. Hence, based merely on the statistical structure of the input features, infants (and neural networks) form a category of dogs including cats, whereas they form a category of cats excluding (some) dogs[1]. The correlational structure extracting mechanism is precisely what accounts for the observed asymmetric effects of unequally exclusive (or inclusive) cat and dog categorizations. Catastrophic forgetting, on the other hand, can be understood as the deleterious effect of representing, within the same connections, stimuli whose features are very differently distributed. This, consequently, "washes out" the relevant knowledge previously stored in the network. However learning items whose features lie within the same range as those learned previously should not create very different internal representations - and may hence even consist in "learning more of the same". Based on this connectionist account of the relationship between infant categorization and memory, Mareschal et al. successfully produced the conjectured asymmetry in catastrophic interference consistent with the asymmetry observed in category elaboration (i.e., dogs interfered with previously learned cats, whereas cats did not interfere with learned dogs).

[1] Indeed, some dogs "look" like cats, since that they fall into the range of the cat distribution for some features. We will come back to this later.

In the following we, first of all, report on a conceptual replication of Mareschal et al.'s modeling results, concerning the development of categories, the asymmetry in category exclusivity, and the asymmetry in interference effects. Next, we show that the results of a cluster analysis performed on the input data and on the hidden units activation patterns (after learning of all items had occurred) suggest that the asymmetry in category exclusivity closely depends on the particular items used for "cross-category compatibility"[2] testing. Then, we explain how we tested Mareschal et al.'s connectionist account of asymmetry in category exclusivity and in interference effects, based on two systematic manipulations of the overlap in feature distributions of cat and dog categories. The first variation of overlap was produced by carefully choosing the items presented for training and those for interfering. The second variation of overlap was produced by the introduction of a supplementary (binary) input feature that unambiguously, taken individually, separates cats from dogs. Finally, we propose lines of further experimental research that might undermine the connectionist account embraced here.

The Model

We made the same assumptions as Mareschal et al. about the mapping between experimental results found in infants with the technique of preferential looking times and modeling results. The increase of error in the model's output is indeed assumed to be related to increased infant attention. The results reported below are based on the performance of a standard 10-8-10 feedforward backpropagation network, as well as that of a standard 11-8-11 network when the supplementary input feature was added. For both models, learning rate and momentum were both set to 0.9. The Fahlmann offset used in the original paper was not used in our model. Networks learned the data for a maximum of 250 epochs or until all output bits were within 0.2 of their targets. Results are averaged over 50 replications. Weights were updated after each stimulus presentation. Further details about changes in procedure compared to Mareschal et al.'s model are given in the results section below.

The Data

The data were identical to those used by Mareschal et al. A description of their origin and their characteristics can be found in their paper. In the following paragraphs, we report a cluster Analyses performed on the input data (and on the activation patterns of the trained network's hidden units) that will provide some insight into the inherent structure of the input data and its implication on modeling results. They will as well allow us to justify the proposed extensions of Mareschal et al.'s neural network simulations.

Cluster Analysis

On the basis of the clusters of correlated values of the input data, cats and dogs cannot be clearly separated into two mutually exclusive categories (see figure 1). Likewise, the connectionist model's internal representations (as reflected by the activation pattern of its hidden units after training on the whole set of stimuli) do not reflect clear-cut groupings of just dogs or just cats (see figure 2). Indeed, some cats, respectively some dogs, are more prototypical in terms of their overall feature similarity with the other members of their category.

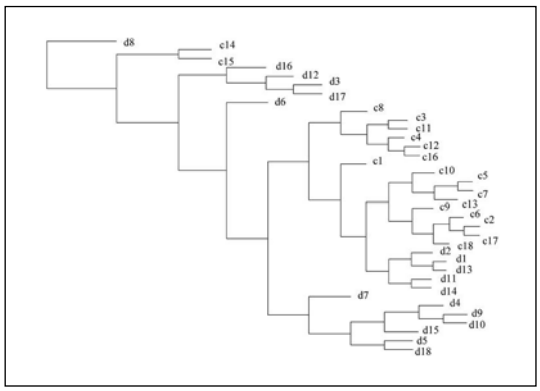

Figure 1. Cluster analysis performed on the input data patterns for cats (c1-c18) and dogs (d1-d18). Distances and cluster structure in this graph correspond to the overall similarity structure of the input patterns.

Moreover, and this is most crucial for Mareschal et al.'s proposed account of infant memory and categorization, nearly all cats (except 2 out of 18) fall into the "family" of "dog-cat"s[3], whereas, only 5 dogs (out of 18) clearly fall into the group which the majority of cats belong to. The clustering of cats and dogs into different subgroups suggests that the observed category exclusivity effects, as well as interference effects, should not occur for all combinations of learned and novel items (respectively, learned, interfering and novel/same-category items). Based on these results we predicted, precisely, that the closer items are in terms of cluster analysis distance, the smaller interference and cross-category exclusion effects should be.

[2] Cross-category compatibility refers to the question whether a novel exemplar is "accepted" as a member of the opposite category or not.

[3] "Dog-cat"s corresponds to a regrouping of clusters containing cats and dogs.

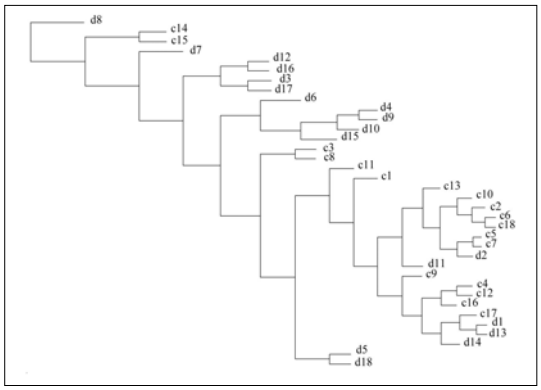

Figure 2. Cluster analysis performed on the activation patterns of the network's hidden units for cats (c1-c18) and dogs (d1-d18). Distances and cluster structure in this graph correspond to the overall similarity structure of the network's internal representations of the input patterns.

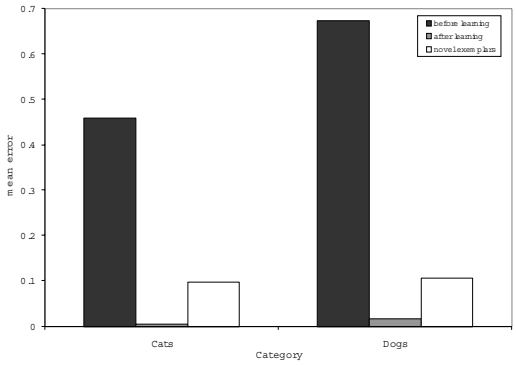

Figure 3. Mean error on the network's output when (a) presented with exemplars before learning, (b) presented with trained exemplars after learning, and (c) presented with untrained exemplars after learning.

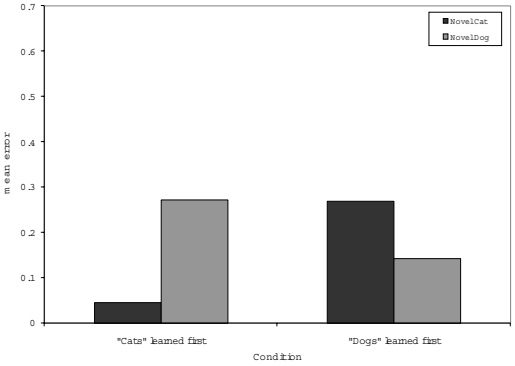

Figure 4. Asymmetric exclusivity of the cats and dogs categories. When trained first on cats, an untrained dog results in a larger increase of error than an untrained cat, but when trained on dogs, an untrained cat only produces a small increase in error as compared to an untrained dog.

Results

In the following section, we will briefly report the basic replication results since they nearly reflect the findings of Mareschal et al., and then describe our new results with their model.

The Development of Cat and Dog Categories

We obtained results comparable to those described in Mareschal et al. Networks do form a category of both cats and dogs. Figure 3 shows the initial mean error score, the mean error after training on the first 12 items of each category[4], and the mean error score (after learning) for the 6 remaining exemplars of the corresponding category (same-category testing). Needless to say that networks develop a faithful internal representation of both cats and dogs, and that they nevertheless recognize novel items as unfamiliar (small increase in error compared to the learned items). It is worth noting however that the initial error scores are slightly different between dogs and cats. Relative to those of cats, the features of dogs are more variable. Thus the mean error on dogs without training tends to be bigger than on cats. This confirms Mareschal et al.'s data analysis in terms of means and variances of the feature distributions of cats and dogs.

The Exclusivity of Cat and Dog Categories

Figure 4 shows the mean error on output of networks trained on 17 (out of 18) cats when they are presented with either the single remaining cat or with any of the dogs (18 out of 18), as well as with the corresponding opposite configuration (dogs learned first and then tested on novel dogs, respectively novel cats).

We used this training regime, instead of training the networks on 12 out of 18 items and then testing it on 4 cats, in order to get a reasonable number of different controlled combinations of training and testing items. All cats, respectively dogs, appear once as the novel item which the network has to categorize based on its nearly perfect "knowledge" of the same or opposite category. Our results show that, on average, dogs are less likely to be accepted as members of the cat category, than vice-versa. Indeed, a novel cat presented to a network that has learned dogs is less likely to produce a big increase in error, than a dog when presented to a network that was trained on cats. Based on the results of the cluster analysis, we suggest that the exclusion of the various cross-category items (but also of very atypical same-category items) somehow depends on their similarity with the core representation the network has developed during training.

[4] We suppose that this selection is pseudo-random, since we did not give the stimuli set a particular a priori order.

The Asymmetric Interference Effect

In this section we examine the effect of learning items of a second category on the networks ability to correctly "accept" novel items as belonging to the category it was trained on in the first time. The network, for instance, was trained on 12 cats, then tested on the remaining (novel) cats, then trained on 4 dogs, and finally re-tested on the novel cats. The difference in error scores on the novel cats before and after learning the 4 dogs is called interference effect, interference of dogs on the memory for cats. The same reasoning holds for the opposite case, memory for dogs interfered by training on cats. The interference effect of dogs on cats was easily replicated, by pseudo-randomly (see above) choosing cats to learn and dogs to interfere with the memory for cats. However, in contrast to Mareschal et al., we did observe a considerable interference effect of learning cats upon the memory for dogs.

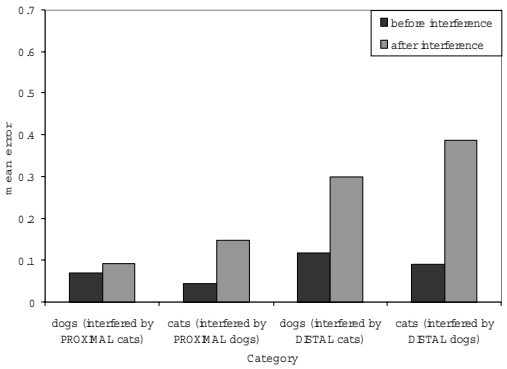

Figure 5. Network performance with untrained exemplars before and after learning an interfering category as a function of overall similarity between trained items and interfering items (distal vs. proximal).

See figure 5 for the results on the network's performance with novel items before and after learning items of the opposite category. We thus observed catastrophic interference in both cases, when not controlling for the similarity between training, testing and interfering. In figure 5, "distal" refers to items that are very dissimilar to the target category based on the cluster analysis. We thus analyzed the similarity between training and interfering items, we had pseudo-randomly chosen, and furthermore carefully selected packages of items in order to produce the "desired" results, based on the distance between items estimated by cluster analysis. The results of the simulations conducted on these items is reported in the following paragraph.

The Effect of Similarity between Learned and Interfering Items

We trained the network with various combinations of category learning items and interfering items from the other category. The choices of the items were motivated by the results of the cluster analysis performed on the input data. This enabled us to distinguish between groups of stimuli that are more or less "similar" to each other. We predicted that interference depends upon the overall feature similarity (i.e., overlap of feature distributions) between the central tendencies of these two groups, the bigger the similarity, the smaller the interference should be and vice-versa. We were, by this subterfuge, able to qualitatively reproduce Mareschal et al.'s asymmetry in interference effects by showing that, under selected conditions, dogs are not interfered by cats (see figure 5, dogs interfered by proximal cats). We were also able to show that results contrary to those reported in Mareschal et al. could be found. If cats learned in the first place, were "interfered" by very similar dogs, and the test items (i.e., novel cats) were chosen as close to the (two) learned set(s), then interference was minimal and relatively close to that observed in the case of dogs "not-interfered" by (similar) cats. Our results show that the results found by Mareschal et al. need not be the only possible ones. Furthermore, we could not manage to replicate the reported "average"[5] absence of interference of learning cats on the memory for dogs. Still, consistent with their connectionist account of infant category and memory our results are conclusive regarding the influence of overall feature similarity on the exclusivity and interference effect, though locally and not really globally. We could indeed show that overall similarity of items used for training and those used for interference could be used to predict interference of learning a second category on the memory for a first category. What we could not show was that this really is true for cats and dogs, on average, taken as categories. We remain agnostic to the very reasons of our failure to reproduce the absence of interference of cats on the memory for dogs when exemplars of both categories were randomly chosen. If the account given by Mareschal et al. is as general as they presume, a claim to which we subscribe in principle, then it should show up more consistently and more reliably with nearly any random selection of cats and dogs. Although we stay puzzled concerning the precise reasons of our failure to replicate, we have some hints on potential explanations. In fact, we wonder whether the rather small increase in error on dogs after interference by cats is consistent with the nevertheless not so small increase in error found with novel cats when dogs have been learned first. If it is true that, on average, learning cats does not have a deleterious influence on the memory for dogs, then why does presenting cat after training on dogs produce an increase in error compared to

[5] Since the authors did not precisely mention how they chose their items for training and interfering, we assume that the reported asymmetry in interference effects must be supposed to reflect average results, which is quite consistent with their account of the category exclusivity effects.

presenting a dog? After all, if learning cats is truly somewhat equivalent to learning more of the dog category[6], then why does testing on novel cats not produce less error then testing on novel dogs? We think that this prediction might be consistent with the connectionist account proposed by Mareschal et al., solely based on the asymmetry of overlap of feature distributions. Since nearly all cats belong to a narrow range of distribution embraced by the distribution of the dog category, dogs are more likely, on the average, to fall outside this narrow range, within which the "prototypical" dog also falls and which is precisely what the network's internal representation should reflect. Comparing cats and dogs to this "prototypical" dog should show that cats are situated closer to it in nearly all considered feature distributions, thus producing less error than dogs (which are more likely than cats to be different from this prototype).

The Effect of Induced Changes in the Inherent Structure of the Stimuli

We conducted the same simulations as before, except that networks were trained on inputs that included the animal cry (barking vs. mewing) as an eleventh characteristic variable. A cluster analysis (shown in figure 6) performed on these input data shows that this manipulation manifestly segregates dogs and cats into two next-to-perfectly distinct categories. The increase in distinctiveness of cats and dogs produced by the addition of the binary variable should eliminate (or at least considerably reduce), we hypothesized, the asymmetry of the category exclusivity, as well as the asymmetry of cross-category interference effects.

The results shown in figures 7 and 8 confirm our predictions based on the account given by Mareschal et al. In other words, cats no longer could be part of the dog category, and learning cats considerably interfered with the memory for the dog category. The inherent correlational structure of the input data thus has an important effect on networks categorization and memory. Note that the networks successfully formed a category of cats and dogs just like when the animal cry was not added to the stimuli features.

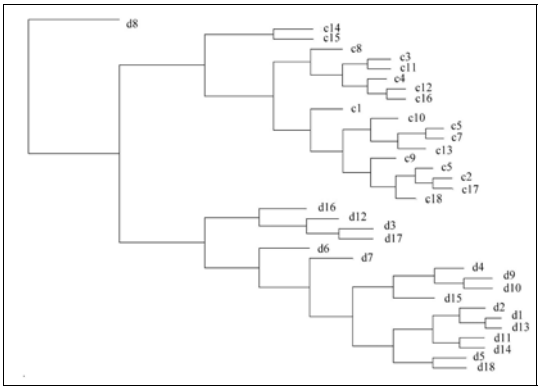

Figure 6. cluster analysis performed on the input data patterns for cats (c1-c18) and dogs (d1-d18) after addition of the "animal cry" feature. Distances and cluster structure in this graph correspond to the overall similarity structure of the modified input patterns.

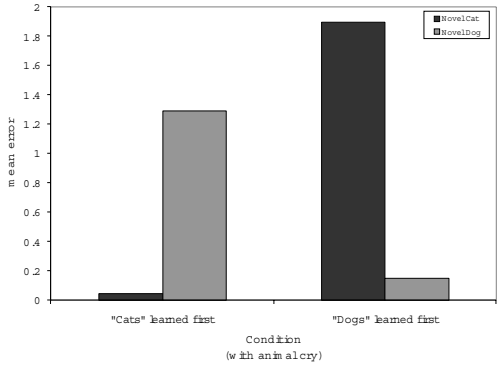

Figure 7. Symmetric exclusivity of the cats and dogs categories, when "animal cry" is added to the input features.

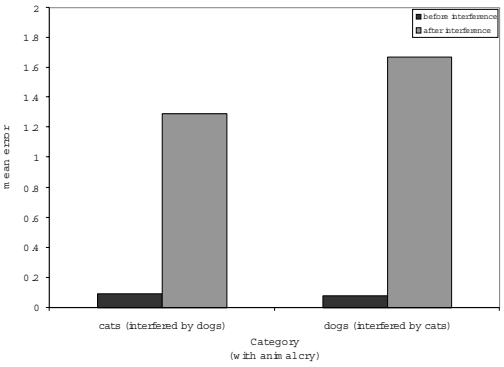

Figure 8. Network performance with untrained exemplars before and after learning an interfering category, when "animal cry" is added to the stimulus features.

[6] This is of course only true in some sense, since the dog category is clearly characterized by greater feature variance.

Discussion

Connectionist autoassociator networks, like young infants, form categorical representations of cats and dogs. The categories developed show asymmetric exclusivity, closely related to the unequal distribution of features in the stimuli shown. Most of the cats could be classified as dogs, but most dogs are not plausible cats. The model also suggests the presence of asymmetric interference effects of sequential learning of cats and dogs. Such effects have recently (Mareschal, French, & Quinn, draft) been observed in infants. Supported by empirical works on infants, the model thus pleads for a close link between the mechanisms underlying infant visual memory and categorization. In fact, Mareschal et al. (1997) claim that some kind of associative, data driven mechanism underlies early visual memory and categorization. The present paper underscores this claim, by showing that explicit manipulations of the correlational structure of the data input influences the networks performance. Connectionist models, by making clear assumptions about the input data, can thus be helpful in predicting which stimulus features are likely to be taken into account by infants. Indeed, experimental works (Spencer, Quinn, Johnson, & Karmiloff-Smith, 1997) have shown that infants typically rely 'on head/face information to categorically differentiate between cats and dogs, under conditions of short exposure duration'. This empirical result is consistent with the connectionist model presented here, since face visual features (viz. nose length and nose width) are the most informative features about the cat/dog distinction. In addition, based on Mareschal et al.'s (1997) connectionist account, it seems reasonable to predict that presenting pictures of cats and dogs in association with the corresponding animal cry should produce the same results in infants than in networks, namely mutual and symmetric category exclusivity and symmetric interference effects. Based on simulation results, we also predict a close parallelism between infants' and connectionist models' performances in memory and categorization task in terms of the similarity of particular stimuli (and combinations of stimuli). Truly, the model incorrectly excludes certain stimuli and not others, thus infants should present the same behavior pattern with precisely those stimuli in question. Likewise, if the model, for certain items but not others, does not present the discussed asymmetry in interference effects then infant's behavior should qualitatively reflect the same catastrophic forgetting. We thus suggest an item based analysis of networks' and infants' memory and categorization performances. Finally, we would like to recall that, by construction, connections networks' performance depends upon the very selection of certain stimulus features and not other. Thus, if networks produce categorization and memory effects similar to those of infants, then the selection of the particular features is given support. Nevertheless, it must be experimentally shown that infants actually rely on those features and not others. Still, connectionist models provide good predictions about which stimulus features are most likely to participate in infant categorization and memory.

Abstract

A variety of experimental results have suggested that motor systems can participate in what were thought to be purely perceptual tasks. Extending previous work in the stimulus-response compatibility paradigm, we show that a representation of a visual stimulus accessed from memory can activate potential motor interactions. Other research has shown that mental images and mental models can have analogue or spatial characteristics. In our second experiment, we present evidence that such representations, generated purely from linguistic descriptions, can also activate motor affordances. Results are discussed within the context of the embodiment of *conceptual*, as well as perceptual, processes

Introduction

One can often observe people who, having lost the set of keys they held a moment ago, mentally retrace their steps, miming their previous interactions with objects and places that might now be a hiding place. Similarly, when imagining the rearrangement of a room, people often move their hands as if picking up and moving furniture. The gestures that embellish discourse are also made by people who are on the telephone, and even by the congenitally blind (Iverson & Goldin-Meadow, 1998).

Hand waving examples such as these offer glimpses of the relationship between 'higher' cognitive functions such as language and imagination, and the seemingly more mundane perceptual and motor systems that carry out our daily chores. Increasingly, it is suggested that these motor systems have an important contribution to cognition.

This zeitgeist of 'embodiment' has been described as 'a seismic event … taking place in cognitive science' (Newton, 1998) and a 'perennial recycling of behaviourist ideology' (Pylyshyn, 2000). In general, proponents of an embodied perspective reject the idea of cognition as wholly the processing of abstract, or amodal, symbolic representations. They emphasise the ways in which the representational and processing burden of cognition can be offloaded on the external world and the motor and perceptual systems that interact with it (Barsalou, 1999a; Clark, 1997; Lakoff 1999)

There is a growing weight of behavioural and brain imaging work that implicates motor systems in perceptual judgements. Observers often interpret visual stimuli in terms of the physically plausible motions it would take to produce them (eg Shiffar & Freyd, 1993). Bargh, Chen and Burrows (1995) present intriguing evidence that even sophisticated social constructs are imbued with motoric representations, to the degree that activating a stereotype will automatically cause motor behaviour typical of that social group.

In some cases, brain imaging techniques have shown the direct involvement of motor areas in 'motor perception' (Stevens, Fonlupt, Shiffrar & Decety, 2000). The existence of 'mirror neurons' also indicates that visual and motor systems share neural circuitry (Gallese, Fadiga, Fogassi & Rizzolatti, 1996). Behavioural experiments by Wohlschläger and Wohlschläger (1998) demonstrated that when subjects mentally rotated a 3D object, performance was slowed if the response used a rotational motor action that was in the opposite direction to the mental rotation. De'Sperati and Stucci (2000) argued that the motor system acts to simulate rotations: in their studies, subjects could more easily judge the rotation of a screwdriver if it was pictured in an orientation easily graspable by their dominant hand. This work is supported by studies that find activation of motor areas during mental rotation tasks (eg. Richter, Somorjai, Summers, Jarmasz, Menon, Gati, Georgopoulos, Tegeler, Ugurbil & Kim, 2000)

Recent research in the stimulus-response compatibility paradigm has found further evidence of the intrusion (or participation) of task-irrelevant motor representations during a perceptual judgement (e.g. Craighero, Fadiga, Rizzolatti & Umilta, 1998). In experiment 1 of Tucker and Ellis (1998) (henceforth T&E) subjects made an orientation judgement (right-side-up/upside-down) about pictures of household objects such as a coffee mug. Each object had an affordance - a handle - on the right or the left side. It was found that subjects were faster when they responded using the hand that was on the same side as the affordance. Later work (Ellis & Tucker, 2000) found a similar compatibility effect when subjects signalled a judgement about an object with a motor action (precision pinch/power grasp) that was appropriate or inappropriate for that object.

This work demonstrates a tight coupling between visual and motor systems: the perception of a graspable object immediately actives a potential motor interaction with that object, even though the affordance is irrelevant to the perceptual judgement. Yet is this just evidence of a rapid link, a transient information hook-up, between visual and motor systems, or is it indicative or a more long term

relationship, whereby the representation of objects is not merely visual, or an amodal list features, but has a motor component that is just as much part of the object bundle.

In Barsalou's (1999a) Perceptual Symbol Systems theory, motor activations such as those revealed in T&E's work should become part of the long term 'simulator' or concept of an object. It has been shown that there are strong associations between object-action pairs (Klatzky, Pelligrino, McClosky & Lederman, 1993) and that object recognition and object grasping utilise overlapping neural networks (Faillenot, Toni, Decety, Gregoire & Jeannerod, 1997). It would be of further interest to show that simply activating a representation of an object causes activation of potential motor interactions. In the first experiment presented here, we extend the results of T&E to show an effect of response compatibility when subjects are recalling a visual image from short term memory.

A considerable body of research demonstrates that conceptual processing has some of the hallmarks of perceptual processing (cf. Barsalou, 1999a). For example, the 'scanning' of mental images mimics the time course of scanning a real image; if a certain location in a mental model is activated, the nearby locations are primed (Bower & Morrow, 1990). If, as the work above suggests, motor activation is often part of perceptual processing, then, we reasoned, perhaps it will be part of conceptual processing as well. The second experiment investigates the role of motor systems in a typical conceptual task – listening to a story.

Experiment 1

We have seen that the presentation of an object's image can activate a potential motor interaction that causally effects a motor response to that stimulus. In this experiment, we would like to see if affordances can be stored in, or reactivated by, short term visual memory.

Method

Subjects 40 undergraduate students of Cornell University participated in exchange for extra credit. All subjects were right handed

Stimuli We compiled 198 images of household objects by using a digital camera and searching public domain image databases. Each picture was in full colour, with a resolution of 500 x 400 pixels. 154 of these were filler images of objects with no obvious affordance, or with an affordance that could be accessed by both the left and right hand equally. We obtained 22 images of objects that had a clear affordance on one side; each of these was mirror reversed. Some stimuli were taken, with kind permission, from Carlson-Radvansky, Covey and Lattanzi (1999). 40 sound files were recorded by an experimenter: the names of the 22 afforded objects, and the names of 18 objects that did not appear in the stimuli set.

Design Each subject was randomly assigned to a response mapping condition. In Left condition, subjects responded 'yes' by pressing the 'S' key and 'no' by the 'K' key. In the Right condition this mapping was reversed.

A schematic of each trial is given in Figure 1. Each trial began with the subjects being reminded of their response mapping. They then pressed the space bar to initiate the trial. Subjects were given a countdown from 3, and then saw 8 images in rapid succession. Each presentation lasted for 200ms. After a 1000ms pause, subjects heard the name of an object. They responded as quickly as possible whether the object was present in the set of 8. No feedback was given.

There were 40 trials. In 18 filler trials, the named object was not present. In the remaining 22 trials, an afforded

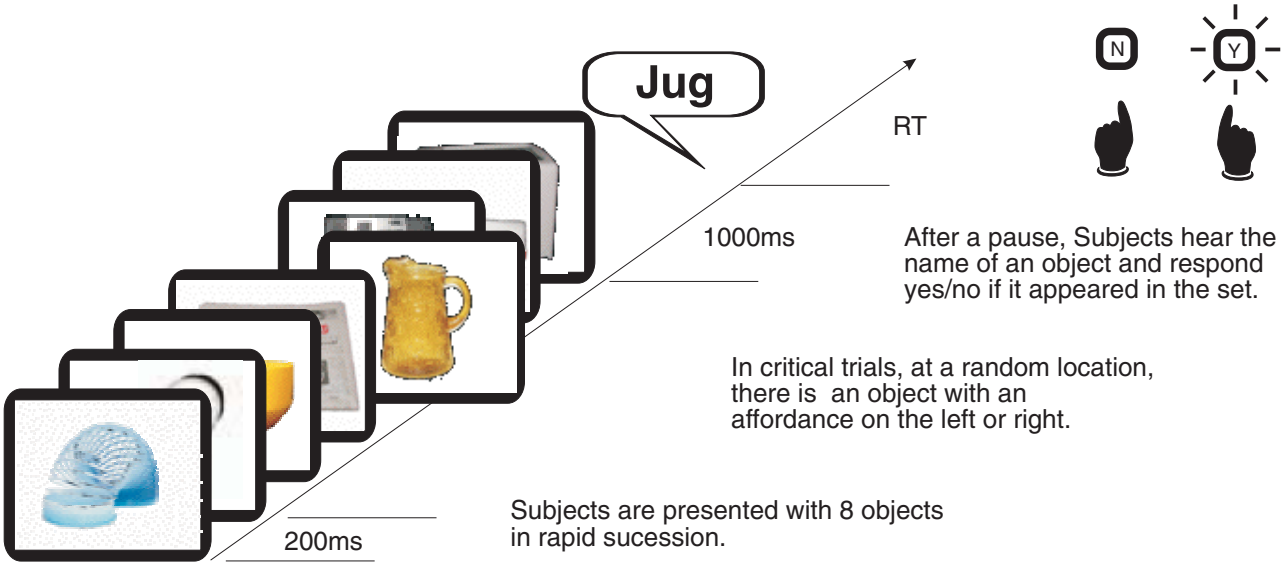

Figure 1: Schematic of Experiment 1.

object was present at a random location, and subsequently named. Half of these objects had an affordance on the left and half on the right, counterbalanced across subjects. The order of the trials and was fully randomised.

Subjects were asked beforehand not to try and name the objects as they appeared. The use of very short presentation times was designed to discourage this verbal labelling strategy. After the experiment., subjects were debriefed and asked to what degree they were able to comply with these instructions.

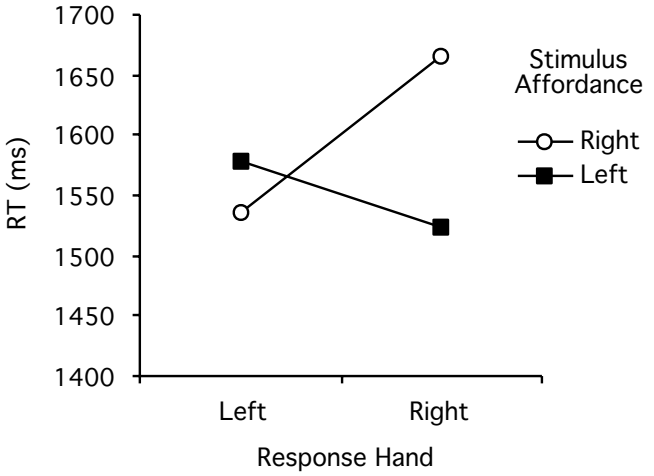

Figure 2 Mean RTs for correctly answered, critical trials, Exp.1

Results In the critical trials, the correct answer was always 'yes'. Accuracy on these trials was 74%. For the remaining analyses, we discarded trials with incorrect responses, and trials with an RT longer than 2.5 standard deviations from the mean (0.006% of the data). Figure 2 shows the trimmed data set.

Subjects making their 'yes' response with the left hand (1551ms) were marginally faster than the those using the right (1601ms), although this effect of response mapping did not approach significance ($F(1,38)=0.20$, $p>.6$). Responses were made slightly quicker when the named object had an affordance on the left (1556ms) versus the right (1598ms), but again this effect did not approach significance ($F(1,38)=1.72$, $p>.19$).

Yet as Figure 2 shows, there was a robust interaction between the stimulus and response conditions that was significant ($F(1,38)=8.22$, $p<.01$). When the hand making the response was on the same side as the affordance of the named object (compatible trials), the mean RT was 1611ms; when the response and object affordance were opposite sides (incompatible trials) the mean RT was almost 90ms faster at 1524ms.

Discussion

Like T&E, we have found an interaction between stimulus affordance orientation and response hand. Yet our results have some interesting differences. First, we have found an incompatibility effect, such that subjects are facilitated when making a judgement using the hand on the *opposite* side to the stimulus affordance. Second, our subjects have response times of about 1500ms, whereas T&E's subjects responded in roughly 700ms. This can be explained by the relative difficulty of the two tasks: our subjects also made about five times as many errors as T&E's.

We suggest that it is primarily this second factor that helps explain the difference in the direction of compatibility. Work by Stoet and Hommel (1999; 2000) shows an interesting time course to the activation and binding of stimulus and response features. These authors use the framework of the Theory of Event Coding, which holds that perception and actions are coded in a common medium. They showed that up until a certain time, stimulus features can be activated such that they facilitate compatible or overlapping responses. However, when the features are activated for a longer time period, they can become bound into an "event file". Once bound, those features are less available for coding compatible responses, and hence an incompatibility effect is found.

This explanation would suggest that if we simply made our visual memory task easier, and hence shortened RTs to the level of T&E's, then we would find a compatibility effect. Our preliminary experiments in this direction are encouraging.

Experiment 2

We have found evidence for an effect of compatibility between a motor response and the affordance of a visual stimulus under conditions where subjects are recalling the relevant object from memory over the course of several seconds. We have seen that there are interesting suggestions form other work that, (a) the direction of the effect hinges upon the time course of feature activation, and (b) these visuo-motor feature codes may be inherent to the representation of functional objects.

If it is the case the motor activation can occur with - perhaps be part of - the activation of object representations, then it should be possible to generate stimulus response compatibility effects from non-visual, verbal descriptions. The difficulty is how to make subjects imagine an afforded object in a particular orientation. Of course, if subjects heard, 'A jug with a handle on the left', then it could be argued that any spatial compatibility effects would be generated by the word 'left' rather than anything related to a motor component of the representation of 'jug.

We attempted to solve this problem by constructing rich scene descriptions. Subjects listened to these stories and then made a yes/no key press in response to a question. The critical trials contained sentences in which the location and orientation of an afforded object was implied by reference to other objects. As in experiment 1, for critical trials this question pertained to the afforded object, and the correct answer was 'yes'. This design allowed us to investigate whether the imaginary orientation of object - indirectly and

verbally described - could interact with the hand used to make a key press.

Pilot work with these stories suggested that subjects made their responses between about 400 and 1800ms – roughly the spanning the RTs of T&E's subjects and our own in Experiment 1. Therefore, we decided to probe the time course of any feature activation by splitting the data at the median RT. We hypothesised that responses below this time would follow a S-R compatibility pattern similar to T&E's, whereas response over the median would have an incompatibility effect resembling Experiment 1.

Method

Subjects 110 right handed Cornell undergraduates participated in this experiment in exchange for course credit. None of the subjects had previously run in Experiment 1.

Stimuli 24 short scene descriptions and questions were written and recorded by the experimenter. The present tense was used throughout. Half of these stories were used as filler items, and the question related to the property of some object or person in the story. The other half of the stories were used as critical trials. Each of these included a description an object with an affordance, and specified the orientation of that object by reference to surrounding items.

First, there was a sentence or two conveying the background scene; in this case, a breakfast table. Two items, one on either side of the scene, were then described. We termed these the 'anchor' objects. In Figure 3 these are a bowl of cornflakes and an egg cup. Then, a third object was mentioned. This was the critical item, an object with an affordance, and was located between the two anchors. Then two phrases specified the orientation of the critical item. They linked a feature or affordance of the critical object with each of the anchors. In the Figure 3 example, the milk jug handle is next to the egg cup, and the spout is pointing towards the bowl. A sentence or two ended the scene description with some further background information. The question was some form of, 'In the center of the [scene] was there a [afforded object]?' The answer to this question on critical trials was, of course, 'yes'.

Figure 3 shows the structure of an example critical trial. This structure allowed us to counterbalance two factors between subjects. Firstly, we varied the left/right positions of the two anchor objects, and hence the afforded object's orientation. Secondly, we switched the order of the two phrases linking afforded object features to anchor objects. This meant that between subjects, we could counterbalance whether a right sided or left sided object was referred to last. Hence any response biases could not be accounted for in terms of simple recency effects.

Design Each subject was randomly assigned to a response mapping condition, as in Experiment 1. Before each trial, subjects were reminded of the response keys to use. There were 24 trials. Each began with a short scene description, about 30 seconds in duration, played over a set

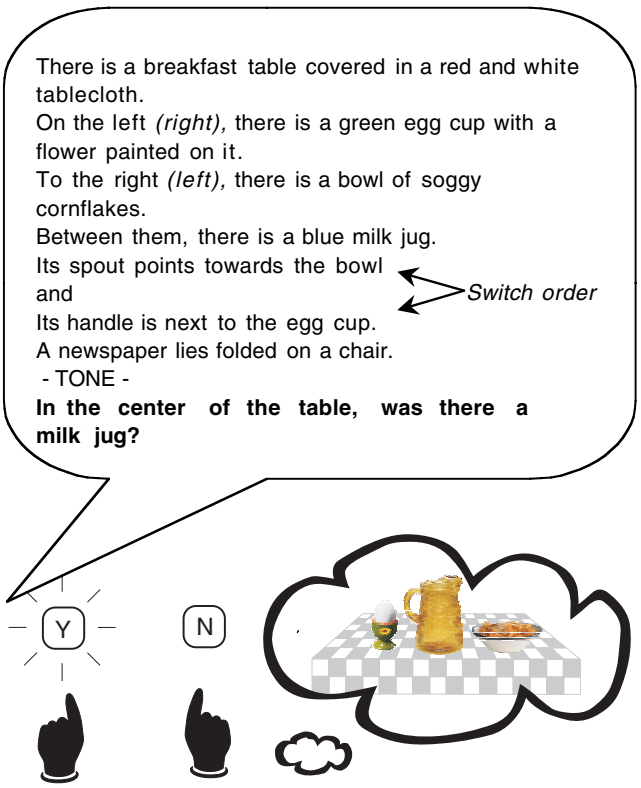

Figure 3: Schematic of a critical item, Exp. 2.

of headphones. At the end of each description, subjects heard a one second tone and then a question concerning the previous information. They were instructed to give their response as quickly and as accurately as possible. Although subjects could take as long as they wanted, if their response time exceeded 5 seconds, that trial was not used in further analysis. We were primarily interested in how subjects represented and manipulated information in order to answer the question, not whether or not they could remember the description verbatim. The cut off point was set on the basis of pilot data to exclude trials in which subjects were struggling to remember details.

Results

The accuracy rate on critical trials was 84.5%. As in Experiment 1, only correct answers to critical trials were analysed. RTs more than 2.5 standard deviations from the mean were excluded from the analysis (4.8% of the data).

The mean RT was 1180ms. The subjects making right handed responses (1158ms) were slightly faster than those using the left hand (1201ms), but this effect did not approach significance ($F(1,108)=0.32$, $p>.5$). In addition, neither the effect of stimulus affordance ($F(1,108)=0.48$, $p>.4$), nor the hand x stimulus interaction ($F(1,108)=0.06$, $p>.8$) approached significance.

To test our hypothesis concerning the time course of stimulus response compatibility effects, we split the trials at the median RT (1020ms) into late and early groups. In order to carry out ANOVAs, we had to remove subjects who did not contribute to both cells. There remained 82 subjects in

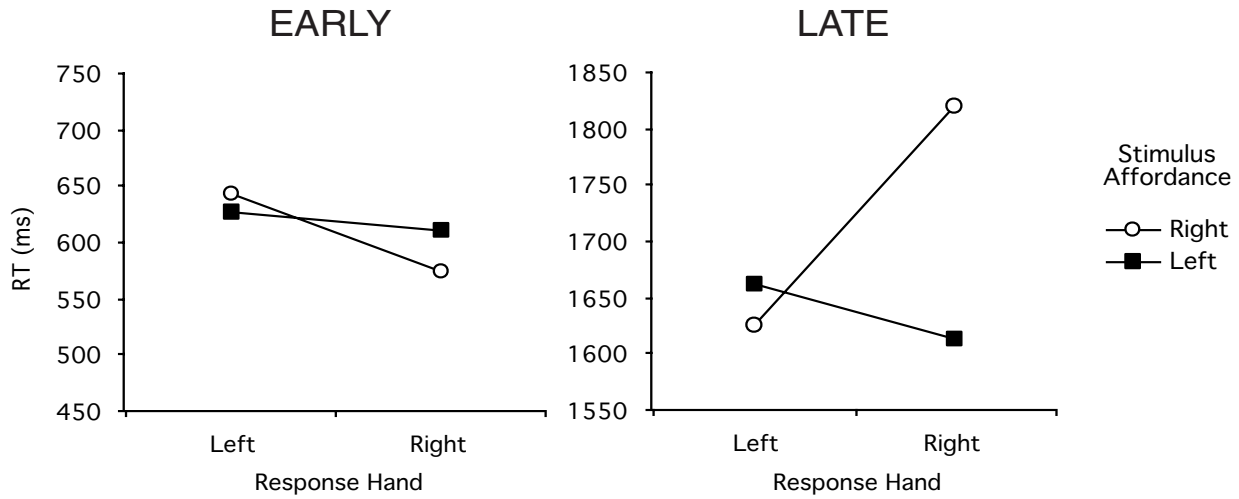

Figure 4: RTs of Experiment 2, split at the median of 1020ms.

the early response condition, and 90 in the late. Their results are shown in Figure 4.

In both groups the main effects of response hand (early, $F(1,80)=2.33$, $p>.1$; late, $F(1,88)=1.12$, $p>.29$). and stimulus affordance (early, $F(1,80)=0.30$, $p>.5$; late, $F(1,88)=0.32$, $p>0.18$) did not approach significance. There was a significant interaction between hand and stimulus in the late group; $F(1,88)=4.38$, $p<.04$. This interaction was not significant in the early responses; $F(1,80)=0.30$, $p>.5$.

Thus, the significant hand X stimulus interaction in the late responses clearly shows an S-R *incompatibility* effect for responses that take place after 1020 ms. In contrast, the early responses show a numerically inverted, albeit nonsignficant, interaction - suggesting an S-R *compatibility* effect for responses that take place before 1021 ms. It is noteworthy that the magnitude of the S-R compatibility advantage for these early responses (20-30 ms) is numerically comparable to that found by T&E.

Finally, in order to get some quantitative indication of whether the interactions taking place in the two time periods are indeed different from one another, we conducted a three-way ANOVA that included early vs. late group as a factor. (Strictly speaking, it is improper treat this factor, which is derived from a dependent variable, as an independent variable. However, the test of a three-way interaction should be sensitive to the relative reaction times across conditions rather than the raw reaction times, and therefore should not be unfairly affected by this procedural irregularity.) As it was necessary to exclude participants who did not contribute to all cells of the design -- many participants were always fast or always slow -- the three-way ANOVA was conducted on the remaining 61 subjects. As predicted, a reliable three-way interaction was obtained where the early reaction times showed a pattern consistent with an S-R compatibility effect and the late reaction times showed a pattern consistent with an S-R incompatibility effect; $F1(1,59)=4.995$, $p<.05$.

Discussion

As hypothesized, the early and late responses show opposite stimulus-response compatibility effects, offering support for the feature activation integration model of Stoet and Hommel (1999). Moreover, we have shown that even in the prime 'disembodied' activity of language comprehension, subjects employ motor representations to construct a mental model, much as Stein's (1994) METATOTO robot created internal maps out of its motor interactions. Thus we have found empirical evidence in support of Bryant's (1998) claim - 'the internal worlds we create do not form maps of external space per se, but of perceptual and behavioral affordances within space.'

General Discussion

Research within the stimulus-response compatibility paradigm has shown that there is a tight coupling between perception and action; indeed, their function is so intimate that it suggests a 'common coding' of perceptual and motor features (Hommel, Müsseler, Aschersleben & Prinz, 2001).

The current experiments reveal one way in which conceptual processes intersect with this tight perception-action arc. Object representations, whether they are memories of a visual stimulus, or part of a mental model generated from a linguistic description, contain motor representations. These results show how motor systems take can take part in 'higher' cognitive functions.

Previous work in our laboratory has shown how *oculo*motor systems participate in the comprehension of spatially extended narratives (Spivey, Tyler, Richardson & Young, 2000), and the spatial indexing of linguistic information (Richardson & Spivey, 2000). Gold and Shadlen (2000) found that in the monkey cortex, competing patterns of activation in populations of the *motor control* neurons will themselves instantiate a 'decision' to saccade. These cases of motor activation occurring as part of a cognitive process are complimented by examples of

linguistic representations intruding upon motor processes. Gentilucci, Benuzzi, Bertolani, Daprati, and Gangitano (2000) showed how automatically activated linguistic representations can intrude upon motor processes. They found that words such as 'near' and 'far' taped on a small wooden bar systematically modulated the kinematics of subjects' reaching behaviour. Moreover, the grammatical class of words, adjectives or adverbs, differentially affected motor control. The results presented in this paper show that the motor system can be modulated not just by spatially extended words, but also by descriptions of afforded objects.

Barsalou (1999b) observed that language is often framed as a means for archiving knowledge. In contrast, he argued for a conception of language comprehension as a 'preparation for situated action'. The involvement of motor representations in memory and mental models we have shown here suggests that language is aptly embodied for this function.

"Language is Spatial": Experimental Evidence for Image Schemas of Concrete and Abstract Verbs

Abstract

Cognitive linguistics and experimental psychology have produced tantalizing hints that a substantial portion of language is encoded in the mind in the form of spatial representations that are grounded in perception and action. Researchers represent these spatial aspects using "image schemas" that depict verbs of motion or spatial prepositions via a 2-D layout of generic icons. In two experiments, we tested naïve subjects' intuitions about such image schemas for concrete action verbs as well as abstract action verbs and psychological predicates. A substantial agreement across subjects was observed in both a forced choice task and a free form computer-based drawing task, for both concrete verbs and abstract verbs. In addition to providing support for the generality of image schemas, the data provide a set of norms for future online studies of spatial representations underlying real-time language processing.

Introduction

Many theorists have argued for a spatial component to language. The arguments are commonly set against an amodal view of representation which defines items in some formal symbolic system. The motivations for proposing an alternative to the symbolic approach range from difficulties in implementing a symbolic system (Barsalou, 1999), commonalties between 'parsing' in the visual system and in language (Landau & Jackendoff, 1993), capturing subtle asymmetries and nuances of linguistic representation in a spatial, schematic way (Langacker, 1987; Talmy, 1983), and a more general account of the mind as an embodied, experiential system (Lakoff, 1987).

If we accept the idea that there is a spatial or perceptual basis to the representation of linguistic items, it would be reasonable to assume that there is some commonality between these representations across different speakers, since by and large we communicate successfully. Therefore, we might expect that there would be a consensus among subjects when we ask them to draw simple diagrams representing words. Theorists such as Langacker (1987) have produced large bodies of diagrammatic linguistic representations, arguing that they are constrained by linguistic observations and intuitions in the same way that 'well formedness' judgements inform more traditional linguistic theories. However, it remains to be seen whether naïve subjects share these intuitions and forms of representation. Therefore, in the same way that psycholinguists use norming studies to support claims of preference for certain grammatical structures, we propose to survey a large number of subjects and see if there is a consensus amongst their spatial representations of words.

Recent work has also documented the mapping between spatial linguistic terms and the mental representation of space (eg Hayward & Tarr, 1995; Carlson-Radvansky, Covey & Lattanzi, 1999; Schober, 1995). Although there are consistencies in the ways in which spatial language is produced and comprehended (eg Hayward & Tarr, 1995), the exact mapping appears to be modulated by such factors as visual context (Spivey-Knowlton, Tanenhaus, Eberhard & Sedivy, 1998), the common ground between conversants (Schober, 1995) and the functional attributes of the objects being described (Carlson-Radvansky et al., 1999).

When language refers directly to explicit spatial properties, locations, and relationships in the world, it is quite natural to expect those linguistic representations to have at least some degree of overlap in their format. Spatial language terms appear to be grounded, at least somewhat, in perceptual (rather than amodal) formats of representation. However, an important component of the work presented herein involves testing for this representational format in an arena of language that does *not* exhibit any literal spatial properties: abstract verbs (such as 'respect' and 'succeed'). Much work in cognitive linguistics has in fact argued that many linguistic and conceptual representations (even abstract ones) are based on metaphorical connections to spatially laid out "image schemas" (Gibbs, 1996; Lakoff, 1987; Langacker, 1987; Talmy, 1983). This work suggests that if consistency across subjects is observed for spatial depictions of *concrete* verbs, then one should also expect such consistency for *abstract* verbs. Experimental evidence for this kind of broad consensus among speakers would extend the "language is spatial" hypothesis beyond spatial terms, and make some experimentally supported, albeit preliminary, claims about abstract language as well.

There are various old and new results suggesting that there is some consistency among speakers in the *visual imagery* associated with certain ideas and concepts. For example, Scheerer and Lyons (1957) asked subjects to

match the referents ‘gold’, ‘silver’, and ‘iron’ with three drawings which had previously been produced by other naive subjects. At least one set of these drawings (which resembled sine, saw tooth, and square waves, respectively), were correctly matched by 85% of the subjects. Lakoff (1987) offers anecdotal evidence that when asked to describe their image of an idiom such as 'keeping at arms length' people have a considerable degree of commonality in their responses, including details such as the angle of the protagonist's hand. Similarly, Gibbs, Strom and Spivey-Knowlton (1997) carried out empirical work querying subjects about their mental images of proverbs such as 'a rolling stone gathers no moss' and found a surprising degree of agreement – even about fine details such as the stone bouncing slightly as it rolled. Experimental work has shown that the listing the features of a concept involves something akin to visually inspecting its properties (cf Barsalou, 1999).

This approach extends beyond the simple visual properties of a concept, towards more schematic or spatial representations. Barsalou’s (1999) perceptual symbol system theory endorses the view held by several theorists (e.g. Lakoff, 1987; Gibbs, 1996) that to some degree abstract concepts are represented by a metaphoric relation to more concrete domains. For example, it is argued that the concept of ‘anger’ draws on a concrete representation of ‘liquid in a container under pressure’. There is some debate over how central these metaphorical aspects are to the representation of abstract concepts. But for the representation of time, at least, there is strong experimental evidence that subjects’ reasoning is structured by a metaphorical relation to space.

Boroditsky (1999) observed that English speakers tend to use horizontal spatial metaphors when talking about time, whereas Mandarin speakers use both horizontal and vertical. In a reaction time study, speakers from both languages were asked true/false questions about time (e.g. ‘March comes earlier than April’) It was found that Mandarin speakers responded faster when they had been presented with vertical rather than horizontal spatial primes, and the reverse was true for English speakers. The result is particularly impressive since both groups carried out the experiment in English. Boroditsky (2000) identified two schemas that are used in both spatial and temporal domains: ego moving and time/object moving. She found that the use of one type of schema in the spatial domain, would prime a judgement of the same schema in a temporal domain.

In this paper, we empirically test the claim that between subjects there is a coherence to the imagistic aspects of their linguistic representations. To this end we will address two questions – *Do subjects agree with each other about the spatial component of different verbs?* And, *Across a forced choice and an open ended response task, are the same spatial representations being accessed?* It would be of further interest if the subjects’ diagrams bore resemblance to those proposed by theorists such as Langacker (1987). However, as with more standard norming studies, the real value of the data will be in allowing us to generate prototypical representations that could be used as stimuli for studies of online language comprehension.

Experiment 1

Methods

Subjects 173 Cornell undergraduates participated in exchange for course credit.

Design We selected 30 verbs to fill out a concreteness by spatial layout, 2x3 factor design. Using the MRC psycholinguistic database, we divided the words into high and low concreteness. These two concreteness groups were each divided into 3 groups based on the expected primary axes of their image schemas (vertical, horizontal, and neutral), based on our survey of the cognitive grammar literature. This 2x3 factor design was filled with a list of 30 verbs. Each was placed in the past tense in the form of a simple rebus sentence, with circle and square symbols representing agents and patients.

The subjects were presented with a single page, containing a list of the verbs and four pictures, labelled A to D. Each one contained a circle and a square aligned along a vertical or horizontal axis, connected by an arrow pointing up, down, left or right. Since we didn't expect any interesting item variation between left or right placement of the circle or square, the horizontal schemas differed only in the direction of the arrow.

For each sentence, subjects were asked to select one of the four sparse images that best depicted the event described by the sentence (Figure 1)

The items were randomised in three different orders, and crossed with two different orderings of the images. The six lists were then distributed randomly to subjects.

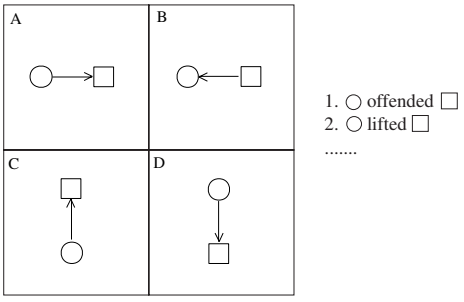

Figure 1: Example of the questionnaire in Experiment 1.

Results

Subjects’ responses are summarised in Table 2. The most frequently chosen image column is in bold for each verb. On average, for any given verb, the particular image orientation that was most popular was chosen by 63% of the subjects. The second most popular was chosen by 21%, the third by

10% and the fourth by 5%. This suggests a substantial degree of agreement between subjects.

To test our predictions concerning the primary axes of the verbs' image schemas, we converted the forced choice data into axis angles. The left and right image schemas were assigned an angle of 0, and the up and down image schemas a value of 90. See Table 2.

A two-way ANOVA by-items analysis revealed a significant main effect of expected axis ($F(2,24)=30.30$, $p<0.0001$), and the effect of concreteness did not approach significance ($F(1,24)=1.84$, $p>0.18$). There was, however, a significant interaction ($F(2,24)=5.28$, $p<0.02$), indicating that the effect of expected axis was more dramatic for concrete verbs than for abstract verbs. Planned comparisons revealed that, even among the abstract verbs, the mean axis angle of the expected-horizontal verbs was lower than that of the neutral verbs and the mean axis angle of the vertical verbs was greater than that of the neutral verbs (all *p*s<.05).

Discussion

It appears that there is a considerable degree of agreement between subjects. This consistency was seen in both concrete verbs of motion, eg 'lifted', and abstract verbs, such as 'respected'. Yet it could be argued that this coherence mainly reflects the artificial and limited nature of the forced choice ask, rather than a commonality of deeper significance between subjects' representations. In our next experiment, we allowed subjects to create their own image schemas in an open response task.

Experiment 2

In this experiment, we asked subjects to create their own representation of the sentences using a simple computer based drawing environment.

Method

Subjects Twenty-four Cornell University undergraduates participated in exchange for course credit. None of these subjects had participated in Experiment 1.

Design Subjects were presented at random with a sentence from Experiment 1. They were given as much time as they required to draw a schematic representation of the sentence. When they had finished, they clicked a done button and were given the next sentence.

The drawing environment is shown in Figure 2. Subjects could drag the shapes on to central canvas. Any number of shapes could be used, and they could be repositioned. Subjects could also use up to 3 arrows. By holding down modifier keys, the arrows could be re-sized and rotated.

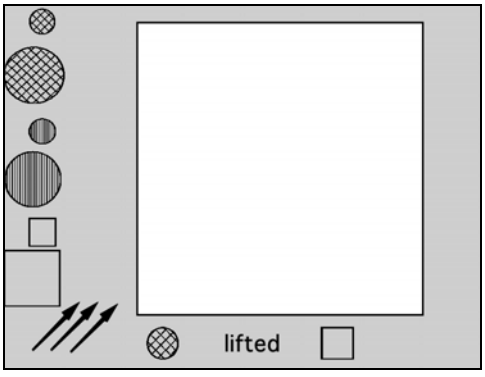

Figure 2: Screen shot from Experiment 2.

Results

Subjects spent approximately a minute completing each drawing. Some subjects produced quite sparse, schematic representations; others attempted more complex depictions. Figures 3 and 4 show a random selection of drawings of the concrete verb 'argued with' and the more abstract verb 'respected'.

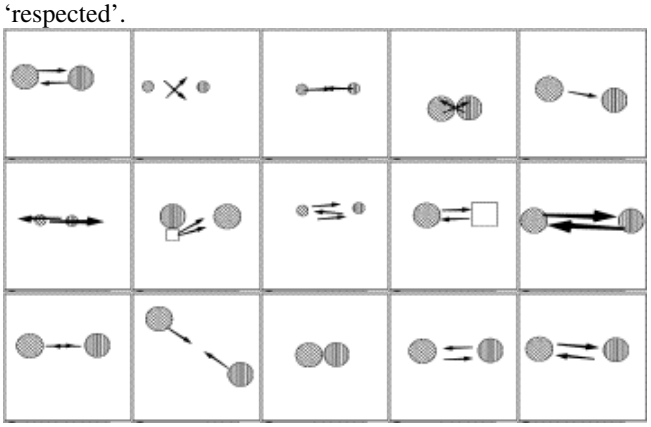

Figure 3: Example depictions of "ARGUED WITH".

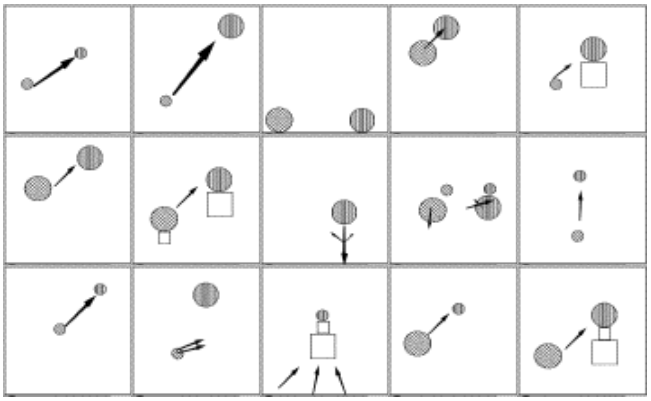

Figure 4: Example depictions of "RESPECTED".

The majority of subjects appeared to represent the verbs schematically using quite sparse images. However, there were a few subjects who, despite the limitations of the drawing toolbox, attempted to *pictorially* represent the verbs. For example, in the third and fourth figures in the second row of Figure 4, we can see that the subjects have drawn humanoid figures, using the arrows as arms. Indeed, since they were the only items that could be rotated and resized, the arrows were often used as generic lines forming a pictorial drawing. For this reason, we decided to ignore the arrows in our analysis, and focus on the relative positions of objects.

Using the coordinates of objects in the drawing, we defined the 'aspect angle', as a value between 0 and 90 which reflects the horizontal versus vertical extent of each drawing. If one imagines a box drawn around the center points of all objects in a picture, the aspect angle is the angle of a diagonal line connecting the lower-left and upper-right corners of the box. If the objects are aligned on a horizontal axis, the aspect angle would be 0; on a vertical axis, 90.

Note that the aspect angle collapses left-right and top-bottom mirror reflections of a drawing. We decided to use this measure since we were primarily interested in the horizontal versus vertical aspect of each drawing. In addition, the initial starting orientation of the arrows (Figure 2) might bias subject towards a right rather than left, and an upwards rather than downwards layout in their drawings: this bias would be avoided in calculating the aspect angle. Figure 5 graphically represents the aspect angle data in what we have termed a 'radar' plot. Each verb's mean aspect angle (solid line) is shown together with its standard error (shaded fan area), and included is the mean axis angle of that verb in the forced choice task of Experiment 1 (dashed line). The means for each condition are shown in the final column of Figure 5.

These results were subjected to a ANOVA items analysis. The only significant effect was of expected axis ($F(2,24)=6.69, p<0.005$). The mean aspect angle for the horizontal group was 21˚, neutral 36˚ and vertical 45˚.

Discussion

Despite the free form nature of the task, it seems that there was a reasonably high degree of agreement between subjects. The mean standard error for all verbs was 6.5 degrees. Previous work has found that subjects consistently place the flow of action from left to right when depicting events (Chatterjee, 2001), but our subjects employed contrasting horizontal and vertical image schemas as well. Moreover, there is considerable consistency between the drawings and the results of the forced choice task. We observed a significant correlation between the mean aspect angles for the verbs in the two tasks (R= 0.71).

General Discussion

We have presented data that suggest there is an impressive degree of coherence in the spatial, schematic components of some linguistic representations. Two different tasks attempted to tap these representations. A forced choice task with very sparse images appeared to produce comparable results to a creative, open response task. In this sense, the data suggest a positive answer to two of our opening questions - Do subjects agree with each other? and Do the two tasks assess the same underlying representations?

We would also argue that our third question - *Do naive subjects agree with trained linguistic intuitions?* – can be given a qualified 'yes'. In both experiments, the expected axis had a significant effect on the orientation of subjects' responses. Figure 5 reveals some informative cases where our expectations were defeated by subjects. For example, in our neutral condition, both 'perched' and 'rested' were consistently given a vertical aspect angle by subjects in both tasks. This observation highlights the importance of using normative methodologies to accompany traditional linguistic methodologies.

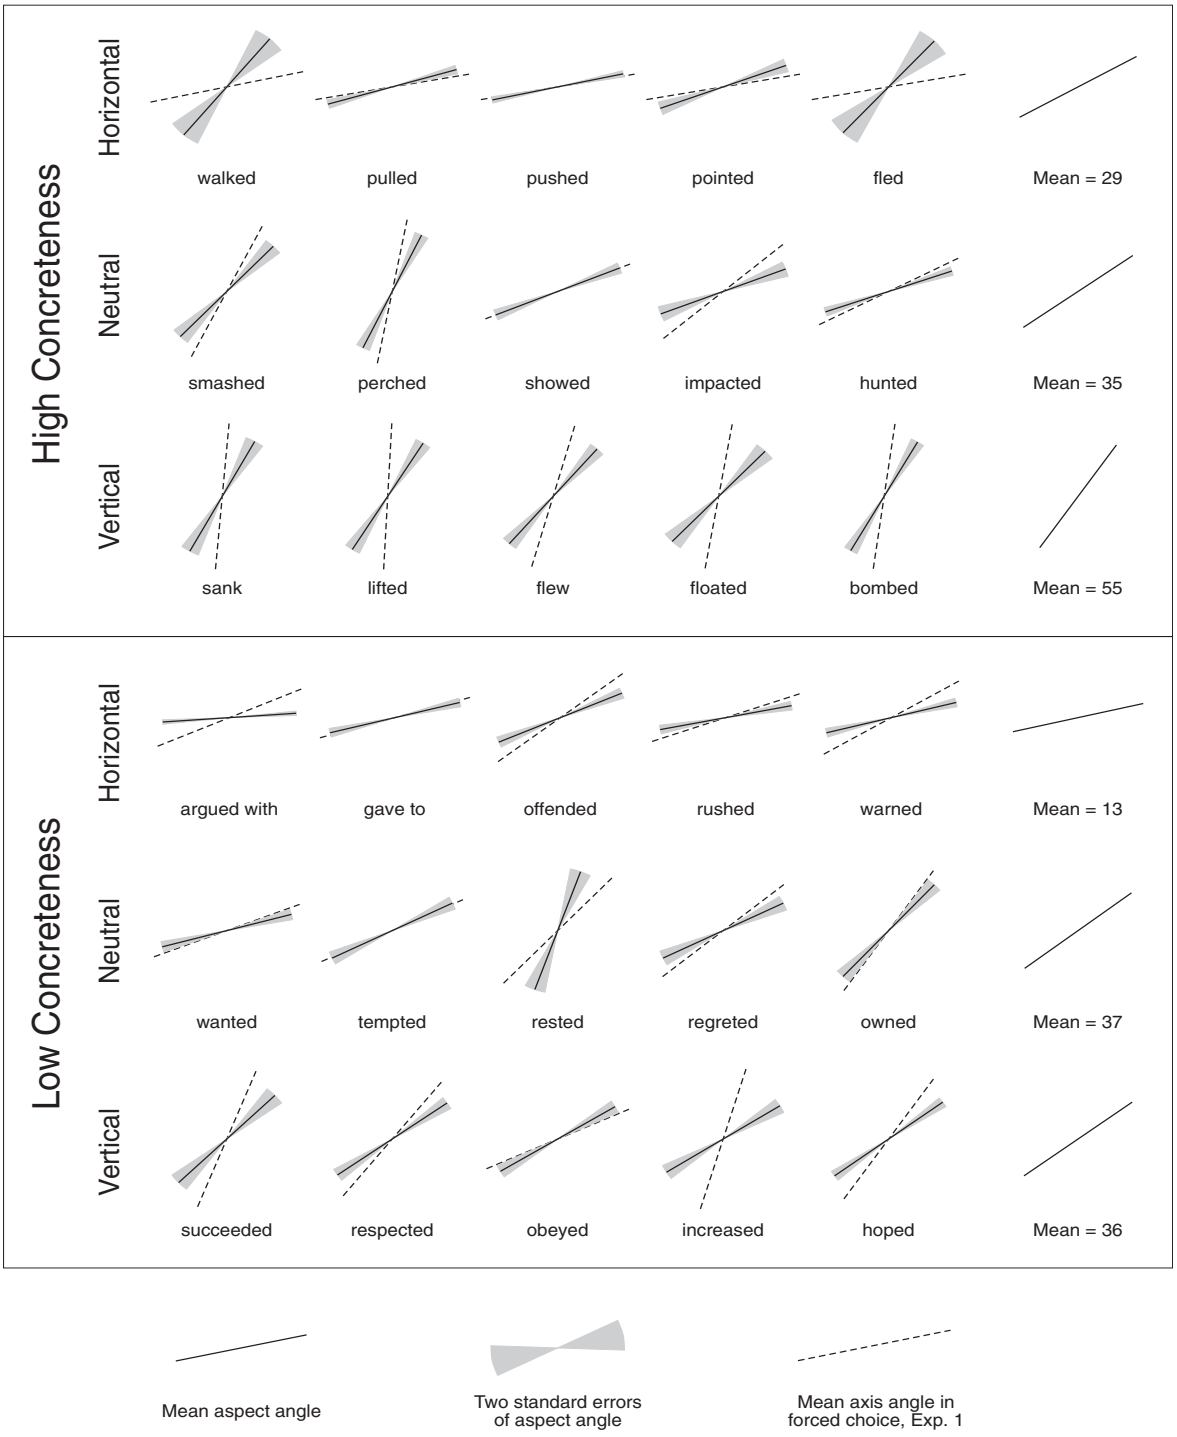

Figure 5: 'Radar' plots of mean aspect angles in subjects' drawings, Exp.2

Although these norming studies demonstrate considerable (and perhaps surprising) agreement between the intuitions of cognitive linguists and naïve subjects, we would argue that the true value of these results is in the predictions they generate for real-time language processing. Just as offline word similarity ratings predict online performance in word priming tasks, we hope that our offline data will predict effects of spatial priming for online language comprehension. In this way, we can further test whether the spatial formats of linguistic representation suggested by these results are indeed fundamental components of language processing in natural situations, and not just artefacts of contemplative metalinguistic intuitions induced only by unusual offline tasks.

There are theoretical grounds for proposing such experiments. For example, in Barsalou's (1999) perceptual symbols systems, a simulator "controls attention across the simulation" (p.604). If our experiments have successfully tapped the spatial element of such simulators, concepts, or image schemas, then we would expect linguistic processing to modulate spatial attention in some manner. For example, if it is the case that the representation of certain words have a spatial element with some degree of verticality, then perhaps priming subjects with a vertical image schema such as those used in Experiment 1 would facilitate a lexical decision task for words such as 'respect' and 'succeed'.

In addition to more standard psycholinguistic paradigms, we hope to use eye movement data to investigate the spatial component of linguistic processing. It has been well demonstrated that mental imagery and mental models exhibit properties of an analog spatial layout (eg Denis & Cocude, 1992; Bower & Morrow, 1990). Work in our laboratory has demonstrated that this spatial component is evidenced in subjects' eye movements. When passively listening to a scene description and staring at a blank wall, subjects tend to make eye movements that correspond to the direction of the events described (Spivey, Tyler, Richardson & Young, 2000).

Similarly, Kaden, Wapner and Werner (1955) showed that visually perceived eye level is influenced by the spatial components of words. Subjects sat in a dark room and saw luminescent words at their objective eye level. Subjects then had the words moved up or down, until they were at the subjective eye level. Words with an upward connotation ('climbing', 'raising') had to be placed lower to be perceived as being at eye level, whereas words with a downward component ('falling', 'plunging') had to be placed above the objective eye level.

We hope that these image schema norms will allow us to measure spatial effects at a finer grain of representation than previous eye movement studies. Given that corresponding eye movements are made during an explicitly spatial description, perhaps they will also be made during an implicitly spatial description (due to metaphorical connections to image schemas). For example, we might find a bias towards vertical eye movements when listening to a description of John's respect for Mary.

Many of these findings are, or will be, surprising. If the purpose of communication is to *guide attention* and *coordinate action*, one should expect visuo-spatial information to play a causal role in linguistic processing. Future work will determine how strong a role.

Abstract

Cheng and Holyoak, and many others in psychology and cognitive science, subscribe to the view that humans have little context-independent deductive capacity, and that they can't acquire such a capacity through instruction in formal logic. This position is based, in no small part, upon C&H's well-known investigation of the efficacy of an undergraduate course in logic in improving performance on problems related to Wason's Selection Task, in which they found the benefit of such training to be minimal (Cheng, Holyoak, Nisbett, & Oliver, 1986). We believe, based on the encouraging results of a new study involving a similar pre-test/post-test design on a logic class at RPI, that the results obtained in the Cheng & Holyoak study serve to highlight problems with the way logic has historically been taught (related to techniques unavailable or impractical before the advent of heavy computer saturation in higher education), rather than to suggest that humans are unable to learn to reason. This prompted the reevaluation of conclusions based on C&H's research, requiring a new theory of meta-reasoning, Mental MetaLogic.

Introduction

The backlash against Piaget's claims (e.g., see the claims in Inhelder and Piaget, 1958) that humans naturally acquire competence in (elementary extensional) logic has "ruled the roost" in the psychology of reasoning for some time. Recently there has been some thought that perhaps the inherent irrationality of the species has been exaggerated (see Bringsjord, Noel, & Bringsjord, 1998; Evans & Over, 1996; Rips, 1994). This article is targeted specifically at the claims made by Cheng et. al. (1986) that not only are humans inherently bad at logic, but we are unable through training in formal logic to learn how to reason in abstract, context-independent fashion. One of the experiments they report, experiment 2, involves a pre-test/post-test design in which students in a logic class are tested on their understanding of how the conditional works in examples—the improvement they report is minimal. Using the same design, but a different instructional method, our results indicated a significantly greater improvement.

The three major reasons put forth in this presentation that the logic class at RPI differed from those in previous studies is that it taught disproofs, diagrammatic techniques, and, "Rigorous and general-purpose procedures for formalizing natural language logic problems in first-order logic so that they can then be solved by automated theorem provers". (For more on this last technique, see Bringsjord & Ferrucci, 2000.) Briefly, disproofs are proofs that one sentence does not follow from a set (possibly empty) of givens. Put another way, they are proofs that, given whatever premises one has, it is not possible to prove the goal, nor is it possible to prove the negation of the goal. The software used in the course, HYPERPROOF (Barwise

and Etchemendy, 1994), allows students to see how sentential information in first-order logic interacts with a toy world which acts as the domain of discourse (were it not for the existence of this world, it would not be possible to perform disproofs in a way remotely similar to that used in the RPI course) through experimentation and practice problems. Because of this, our students learn the meanings of the sentences in a much more understandable fashion while retaining the abstractness and universality of formal logic—these are the diagrammatic techniques. Finally, one of the most challenging tasks involved in solving many of the problems presented by psychologists of reasoning is finding the intended content in the words presented. The translation procedures mentioned above allow students to make fewer errors on these sorts of tasks. The virtues of these advances are discussed in some detail in Bringsjord, Noel, & Bringsjord (1998), with additional data presented in Bringsjord & Rinella (1999).

To demonstrate the abovementioned diagrammatic techniques from HYPERPROOF, which may be unfamiliar to many readers, consider figure 1:

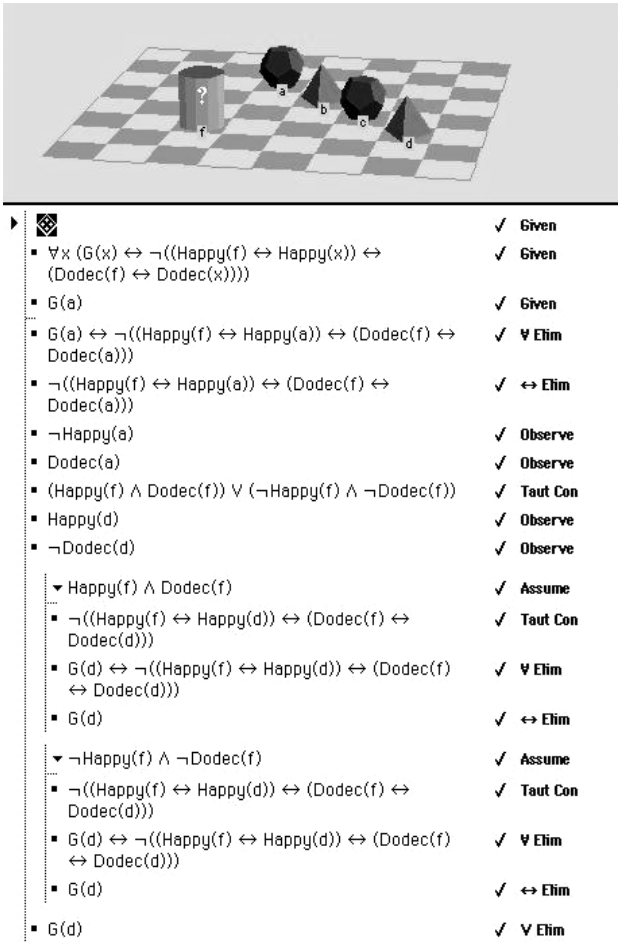

Figure 1:The THOG Problem

The HYPERPROOF window consists of two major areas: on top, there is the toy world, which shows the locations and properties of a small number of objects (in this case, five); on the bottom, sentential logic inferences proceed toward the goal. This particular example is a formalization of the THOG problem, a common problem used in the psychology of reasoning. The first given sentence claims that an object has the property G if and only if it has either the emotional state (happy or unhappy) or the shape (dodecahedron or tetrahedron) of the object f, but not both. Since we don't know f's shape (HYPERPROOF hides shape when it is not know by placing a cylindrical box over the object, which is why f appears to be a cylinder) or emotional state, we need the information in the second given, that object a has property G, to determine which of the other objects has property G. The proof proceeds by first manipulating the givens to extract the information that object a has either the emotional state or shape of f, but not both. Unlike regular sentential logic, we are then able to observe from the world the status of a, noting that it is unhappy and a dodecahedron (in some problems, it is actually necessary to use information from the sentential section to add information to the world, often allowing the user to detect an object's location, shape, or size, so this information moves up to the world as well as down to the sentences). From this, we infer that f must be either a happy dodecahedron or an unhappy object of a different shape. Finally, we show that, in either of these instances, object d also has property G, and conclude by stating that d must have G. Students using this system have the advantage that they are able to see what the sentences mean—rather than proceeding merely by manipulating the symbols of the sentences according to rules they have learned by rote, they begin to understand how different configurations of objects alter the effects of different sentences.

Method

We gave students enrolled in Rensselaer Polytechnic Institute's Introduction to Logic class in the Fall term of 1998 a pre-test including Wason's Selection Task as problem one, the THOG problem as problem two, and five other problems from previous work by psychologists of reasoning or from experience with tests of logic encountered by students in other contexts (e.g., two of the problems were straightforward adaptations of problems the Board of Regents of New York State say every New York high school students should be able to solve; Verzoni & Swan, 1995). A similar test, mathematically matched for problem type and difficulty, was given as a post-test appended to the final exam. Though there is insufficient space here to present them, the complete pre-test and post-test are available online:

http://www.rpi.edu/~faheyj2/SB/INTLOG/pre-test.f98.pdf, http://www.rpi.edu/~faheyj2/SB/INTLOG/post-test.f98.pdf. An example pair of THOG-like problems follows. In both cases, of course, students had to provide correct justifications.

> **2**
> Suppose that there are four possible kinds of objects:
>
> - an unhappy dodecahedron
> - a happy dodecahedron
> - an unhappy cube
> - a happy cube
>
> Suppose as well that I have written down on a hidden piece of paper one of the attitudes (unhappy or happy) and one of the shapes (dodecahedron or cube). Now read the following rule carefully:
>
> - An object is a GOKE if and only if it has either the attitude I have written down, or the shape I have written down, but not both.
>
> I will tell you that the unhappy dodecahedron is a GOKE. Which of the other objects, if any, is a GOKE?

The analogous problem on the post-test was the following:

> **2**
> Suppose that there are four possible kinds of objects:
>
> - an smart tetrahedron
> - a stupid tetrahedron
> - a smart cube
> - a stupid cube
>
> Suppose as well that I have written down on a hidden piece of paper one of the mental attributes (smart/stupid) and one of the shapes (tetrahedron/cube). Now read the following rule carefully:
>
> - An object is a LOKE if and only if it has neither the mental attribute I have written down, nor the shape I have written down.
>
> I will tell you that the stupid tetrahedron is a LOKE. Which of the other objects, if any, is a LOKE?

Note that a direct, unreflective transfer of reasoning brought to bear on the first of these problems to the second won't yield a solution to the second. This pair of problems (and this holds true for each pair on our pre-test/post-test combination) will not "match" at the surface level in English, nor at such a level in the propositional calculus. However, we needed pairs of problems that, at the level of proof or disproof, could be said to be very similar, formally speaking. Without such mathematical similarity we wouldn't be able to justifiably say that the problems, from the standpoint of formal deduction, are essentially the same. Figure 1 above presents a proof-theoretic solution to the first of the THOG-like problems—it is at this level of detail that difficulty must be matched without allowing the same argument form to work a second time.

Subjects who took only one of the two tests were discarded, to ensure that every participant had exposure to the entire course, leaving exactly 100 participants. After the first test, we abandoned asking the subjects whether they had seen the question before. There were two reasons for this: prior experience did not correlate with success on the questions, and the problems on the post-test were so similar in theme and difficulty that it was very likely that their experience with the pre-test would generate false positive responses. We also of course asked for justifications for their answers, hoping that out of the data we would be able to divine an appropriate scheme for categorizing the unstructured and heterogeneous responses we were likely to get.

As a preface to the first test, we gathered some biographical information, including the sex of the participants, the location of their high school, and previous logic experience. Since New York's Board of Regents has decreed that students must learn logic in their math courses, we hypothesized that attending high school in New York state would increase performance on tests of reasoning. We also hypothesized that previous experience in logic would increase scores on the pre-test, but that this effect would be reduced or eliminated by the post-test.

Results & Discussion

As expected, the averages on the pre-test were significantly lower than on the post-test, 3.89 correct compared to 5.11 correct. A paired-samples t-test reported an extremely low (t = -8.393) probability of no effect, suggesting that taking the logic class did improve students' ability to reason logically. Full results for each of the questions appear in table 1, below:

Table 1: Individual Question Results

	Test 1	Test 2	t	Significance
Question 1	29	84	-9.563	0.000
Question 2	72	83	-2.076	0.040

Question 3	77	94	-3.597	0.001
Question 4	55	80	-4.639	0.000
Question 5	90	98	-2.934	0.004
Question 6	7	58	-9.768	0.000
Question 7	59	14	7.595	0.000

Though the improvement was significant at the .01 level for each of the first six questions except question two (which had a problem with a ceiling effect, but was still significant at the .05 level), there were three questions that particularly attracted our attention. Questions one and six showed extremely low initial rates of success, but great improvement—this suggests that these question types may be particularly amenable to improvement by instruction in formal logic. Question seven totally reversed our expectations—students did markedly worse on the post-test.

Individual Question Findings

The first result of some import is the comparison of Wason's Selection Task and its analogue (in each case, question one) on the post-test. These problems were chosen to test the ability of students to comprehend the use of the conditional in a context-free setting. The difficulty our subjects had on the pre-test with this problem very much agrees with the performance of Cheng & Holyoak's participants on their pre-test (1985). From this poor performance, and the lack of improvement, Cheng & Holyoak concluded that people are not good at using the conditional in a context-independent manner. On the pre-test, the problem looked like this:

> **1**
> Suppose that I have a pack of cards each of which has a letter written on one side and a number written on the other side. Suppose in addition that I claim the following rule is true:
>
> - If a card has a vowel on one side, then it has an even number on the other side.
>
> Imagine that I now show you four cards from the pack:
>
> >
>
> Which card or cards should you turn over in order to decide whether the rule is true or false?

The analogous problem (from Verzoni & Swan, 1995) on the post-test follows:

> **1**
> Suppose that you are doing an experiment for a biology expedition. You learn before starting on this expedition that insects can be one of two kinds, a spade fly or a bevel wasp, and that insect color is either black or green. Your task is to study insects in order to find out if a certain rule is false. The rule is:
>
> - If an insect is a spade fly, then it is black.
>
> You see an insect that is green. Which of the following would be true about the insect if it violates the rule?
>
> **a** The insect is a spade fly.
> **b** The insect is a bevel wasp
> **c** The type of insect does not matter.

Because these are the problems which are identical in underlying form to those used by Cheng et. al. in the aforementioned 1986 study, we were quite pleased to discover that our methods had induced an improvement from 29 correct responses to 84 correct responses, an extremely impressive improvement. This confirms our initial hypothesis, and allows our results to very directly be compared with previous work.

The second question which drew our attention because of the extremely poor (well below chance) performance on the pre-test. Since this was the question relating to *reductio ad absurdum,* or proof by contradiction, which is an integral part of the work our students do with HYPERPROOF during the semester. Such a proof, from the standpoint of the psychology of reasoning (which focuses on untrained reasoning), is exotic, but from the standpoint of mathematics and mathematical logic, it's thoroughly routine, and is therefore part and parcel of an introductory course of the type we offered. The full text of this question from the pre-test follows:

> **6**
> We will use lower-case Roman letters *a, b, c, …* to represent propositions. Let the symbol '¬' stand for 'it is not the case that.' Let the symbol '∨' stand for 'or.' Let the symbol '→' stand for 'if-then', so that $p \rightarrow q$ means 'if p then q.'
> Given the statements
> $\neg\neg c$
> $c \rightarrow a$
> $\neg a \vee b$
> $b \rightarrow d$
> $\neg(d \vee e)$
> which one of the following statements must also be true? (Check the correct answer.)
>
> $\neg c$

e
h
¬*a*
all of the above

Once again, of course, we gave a corresponding problem on the post-test. Alert readers will have realized that the answer to **6** is "all of the above," which of course means that *h* must be true given the quintet. The reason for this, of course, is that the quintet is inconsistent, and therefore a straightforward proof for *h* (or any other propositional variable) can be easily given.

The final question of particular interest was question seven, the results from which seemed to suggest that our course had made students worse at reasoning of this type. It involved fairly complex reasoning on statements which were presented in English, thus requiring more effort to extract meaning. Looking for an explanation, we noticed that the following sentence appeared in the pre-test version of this question (from Smullyan, 1982), "'At least one of them did [tell the truth],' replied the Dormouse, who then fell asleep for the rest of the trial." The question from the post-test, which was intended to be analogous, included the following sentence, which was supposed to play the same role, "'Well, one of them did [tell the truth],' replied Devin, who then fainted and remained unconscious for the remainder of the investigation." This difference seemed potentially problematic.

On further investigation, we noticed that many of the justifications on the second problem suggested that subjects were having problems interpreting this statement by Dr. Devin, "Well, one of them did." This can be (and was) interpreted in two common ways, as, "One and only one of them did," or as, "At least one of them did." If these are both appealing interpretations, as they seemed to be for many of the participants, there is no entirely logical way to figure out the answer. A very small number of particularly clever subjects assumed that there would be enough information given in the question to figure out the right answer, and realized that one of the interpretations, that only one of them told the truth, did not fulfill this requirement. These students then rejected this option and solved the problem. However, doing all of that, which seems to be the only way other than guessing that subjects were able to correctly answer the problem, is far more difficult than interpreting the analogous statement in the missing jam problem, which was made by the Dormouse, in response to questioning about whether the Mad Hatter and March Hare had spoken the truth: "At least one of them did." Since this is clearly much more explicit, we have considered the seventh questions on the two tests to be sufficiently different that they are no longer appropriate for comparison. Unfortunately, it was not possible to counter-balance the pre-test and post-test, because of the high degree of availability of students to each other; to make both sets of questions available in this way would have introduced an unacceptably strong confound.

Demographic Data

Without the last question on each test, averages dropped to 3.30 correct on the pre-test and 4.97 on the post-test. This improved the value of the t-statistic to t= -13.653. This indicates even more clearly that subjects did in fact improve their ability to succeed on tests of reasoning due to the instruction in logic, and that the improvement was of a fairly substantial magnitude.

Interpreting the justifications turned out to be fairly problematic. Our initial attempt was a fairly subjective rating system based on the opinions of a competent logician, but there is a potentially very important confound in this method, which is that a correct answer is much more likely to suggest to a reader that the subject knew what s/he was doing, even if this is somewhat underdetermined by the written justification. Since we are most interested in the correlation between justification quality and success rate, this rating system was unacceptable. However, the information from the justifications did turn out to be useful in checking to make sure that the questions were interpreted as we intended, and further exploration may reveal a more objective way to code this data such that it may be made more useful.

Point-biserial correlations (appropriate for categorical data of this type, rather than more common values) were calculated between sex, high school attendance in New York state/elsewhere, and previous logic experience and the two test averages, and similar Pearson correlations calculated within those two groups of factors. Nothing significant came out of sex. Surprisingly, we did not observe a significant correlation between high school state and performance on either test. Previous logic experience did correlate positively with performance on the pre-test, but not on the post-test, as expected, with Pearson correlations of .246 (significant at the 0.05 level) and -.021, respectively. This indicates that the course did make up for any disadvantage less experienced students may have had coming in, and also suggests that performance on the pre-test was actually higher than it ought to have been, because we assumed that incoming students would not have been formally trained in logic. Since only one-tenth of the subjects were so trained, and sometimes in courses that dealt only tangentially with logic, we suspect this effect was negligible.

Unsurprisingly, none of sex, high school state, and previous logic experience correlated with each other. Also unremarkable was the highly significant correlation of .465 found between the pre-test and post-test scores—subjects with higher initial ability are likely to have higher ability after the end of the course.

Conclusions

The proposition that humans are unable to learn to reason better through instruction in formal logic seems to be disconfirmed by these data. This naturally does not mean that pragmatic effects hold no power over our attempts to use what deductive competence we have developed, nor does it suggest that all tests of reasoning will show improvement following an arbitrarily-selected course in logic. However, Cheng and Holyoak's proposed pragmatic reasoning schema theory (see Cheng et. al., 1986; Cheng and Holyoak, 1985; and Holyoak and Cheng, 1995) needs revision to remain a plausible candidate explanation of human reasoning. Yang and Bringsjord (2001, 2001) have suggested an alternative theory of human and, by extension, machine reasoning, viz., Mental Metalogic (MML), which allows pragmatic reasoning schemas to continue to play a role in human cognition, but not alone. In MML, mental models and mental logic exist side-by-side with such schemas, and a higher-level choice mechanism selects the most appropriate form of reasoning for the task at hand. In this regard, it's important to note that MML draws from a part of mathematical logic hitherto untapped in cognitive science: metatheory.

Recent advances in the teaching of logic (particularly HYPERPROOF) were utilized in the course used in the study, and this may help explain the differences in the results seen by Cheng and company, and those found in our study (for a mathematical analysis of HYPERPROOF in the context of "heterogeneous" reasoning consistent with Mental MetaLogic, see Barwise & Etchemendy 1995). In addition to the technological sophistication and concomitant improvement in available techniques, our interest in matters related to the psychology of reasoning may help to explain these results. In the class at RPI, students were encouraged to think about problems from the standpoint of metatheory: to ponder the way that they might approach logic problems (e.g., from the standpoint of searching for proofs *a la* mental logic, or from the standpoint of disproofs and mental models.) We routinely presented several options and contrasted their power, and also studied the reasoning process itself. The increased introspection about the reasoning process that this may have produced in our students is another factor which distinguishes the RPI logic class from previous subjects of similar experiments.

We believe that the reason standard logic instruction has not improved performance on tests of the sort given by proponents of the pragmatic reasoning schema theory may be related to the importance of one or more of the factors we have mentioned, which are historically missing in most classes. If this is correct, contra Cheng and Holyoak, it is not the level of abstraction that keeps logic instruction from being efficacious in improving reasoning. With the right theoretical perspective (MML), and pedagogical techniques which recognize the efficacy of non-pragmatic reasoning associated with that perspective, students can easily carry out difficult context-independent deduction suggestive of that of a professional logician or mathematician.

Using cognitive models to guide instructional design: The case of fraction division

Bethany Rittle-Johnson (br2e@andrew.cmu.edu)
Kenneth R. Koedinger (koedinger@cmu.edu)
Human-Computer Interaction Institute, Carnegie Mellon University

Abstract

Cognitive modeling can be used to compare alternative instructional strategies and to guide the design of curriculum materials. We modeled two alternative strategies for fraction division, and the models led to specific empirical predictions of the benefits and drawbacks of each strategy. These insights provided concrete suggestions for developing lessons on fraction division, including a new potential strategy that combines the benefits of the two strategies. This on-going work illustrates the potential of cognitive modeling for informing the design of better mathematics curricula.

Background

Although U.S. students are fairly proficient at performing routine calculations, they lack a conceptual understanding of mathematics and have difficulty solving non-routine problems (Lindquist, 1989; Jakwerth, 1999). These findings have spurred many educators to call for an increasing focus on building understanding and problem solving skill in mathematics instruction. The National Council for Teachers of Mathematics (NCTM) standards state the overarching learning goal as: "Students must learn mathematics with understanding, actively building new knowledge from experience and prior knowledge," (p. 16, NCTM, 2000). The standards proposed by NCTM, and curriculum and evaluations based on them, have met with opposition from advocates of "back-to-basics" approach (Mathematically Correct, 2000). Mathematicians, politicians, teachers and parents have raised concerns that students are not learning their arithmetic facts and basic computational skills and are lobbying to abandon these reform efforts. Further, many teachers have been resistant to changing their teaching practices and doubt the benefits of reform-based curricula.

Although there is agreement on the need to improve the mathematics curriculum in the U.S., there is considerable disagreement on how the curriculum should be changed. Controversy over how to teach fraction division helps to illustrate this fundamental conflict over whether the curriculum should focus on gaining conceptual understanding or on proficiency in retrieving facts and executing computational procedures. To solve fraction division problems, students are traditionally taught the computational procedure of inverting the divisor and changing the operation to multiplication (invert-and-multiply strategy). As an alternative, the NCTM 2000 standards proposed a picture division strategy where students draw a picture of the starting amount, repeatedly "cut off" groups of the size specified by the divisor and count the resulting number of groups. For example, to solve six divided by 3/4, students could draw a line six units long, divide each unit into fourths, and then start at six and mark off groups of three fourths to find how many 3/4 are in six. According to the standards: "Lacking an understanding of the underlying rationale [for invert and multiply], many students are therefore unable to repair their errors and clear up their confusions about division of fractions.. Carefully sequenced experiences with [picture division] problems such as these can help students build an understanding of division of fractions." (p. 218 NCTM, 2000).

In principle, an ideal approach to informing the debate on how best to teach a particular mathematical topic is to conduct a multi-year, multi-site experimental study comparing a reform-based approach with a back-to-basics approach. In addition to the practical limitations of this approach, an empirical evaluation does not explain the reasons for the results or offer insights into how to apply these results to other topics.

We have begun to explore the role of cognitive models in helping to inform this debate. Developing cognitive models offers four key advantages. First, developing cognitive models requires precise and unambiguous specification of problem representations and action sequences and allows for detailed comparisons of problem solving strategies. Second, the specificity of the models leads to generation of specific hypotheses that can be tested through smaller, focused, empirical studies. Third, cognitive models can be used to understand and explain empirical results, allowing researchers to understand the mechanisms underlying the differences and to extrapolate the findings to other domains. Finally, inspection and evaluation of these models yield concrete suggestions for better content and methods of teaching a particular topic.

To illustrate the potential of cognitive modeling for informing the current debate in mathematics instruction, we describe our use of cognitive modeling to guide the design of lessons on fraction division (as part of a middle-school math curriculum we are developing). Rational number concepts and procedures are a cornerstone of middle-school mathematics, but U.S. students perform poorly on a range of rational number problems, including fraction division problems. (e.g. Lindquist, 1989; Lesh & Landau, 1983). Fraction division is a representative topic in mathematics for which the standards-based and back-to-basic movements have proposed alternative strategies.

In the current paper, we present cognitive models of both fraction division strategies, outline predictions for learning

and transfer that are revealed by the models, and offer preliminary implications of the models for instructional design, including a new strategy for fraction division that was suggested by this work.

Cognitive Models

Our cognitive models are based on ACT-R theory, which breaks knowledge into two main categories – a declarative knowledge base of facts and a procedural knowledge base of production rules (Anderson, 1993). Declarative knowledge includes both prior domain knowledge and representation of the current problem situation. A production rule is a simple IF-THEN statement that manipulates declarative knowledge, and a series of production rules model actions for solving a problem.

Model of Picture Division Strategy

We collected informal verbal protocols from five sixth-grade students while they solved basic fraction division problems such as 15 ÷ 1 1/2. The students had received no formal instruction on fraction division. One student spontaneously used a picture division strategy, and the other students were provided with a picture and encouraged to try using the strategy.

The combination of the task analysis and students' think alouds revealed 4 main sub-goals for implementing this strategy: 1) identify the values in the problems and draw the appropriate picture, 2) mark the picture into the appropriate size groups, 3) count the number of groups, and 4) convert the remainder (if there is one) to a fractional value. These four sub-goals translate into 13 key steps or actions that the problem solver must take (see Table 1; a dotted line designates the beginning of a new sub-goal). These actions were instantiated as productions in an intelligent tutoring system that is based on ACT-R theory (Anderson, Corbett, Koedinger & Pelletier, 1995).

Table 1: Cognitive model of picture division strategy

Productions	Student Example
1. Identify-starting-amount	Here's her 8 foot long board
2. Draw-whole-starting-amount	[draws line with 8 sections]
OR	
3. Draw-mixed-starting-amount	
4. Identify-size-of-groups	And she wants each one [shelf] to be a half,
5. Identify-value-of-divisions	So, I'd split each one in half
6. Draw-divisions	[marks each whole in half]
7. Identify-step-size	[group size = 1; skip to 9]
8. Mark-first-group	
9. Mark-next-group	
10. Finished-marking-groups	
11. Count-whole-groups	And then that's how many shelves. [counts] 16.
12. Identify-remaining-divisions	NA
13. Step-size-as-denominator-of-remainder	NA

Note: Extra productions would be needed to solve problems where the denominators of the dividend and divisor are different and one is not a multiple of the other (e.g. 3/5 ÷ 1/3).

Table 2: Example declarative knowledge chunk: Representation of 2/3

```
QUANTITY 2/3>
  isa number
  whole          0
  top-number     2
  bottom-number 3
  parts-per-whole 3  ;;Picture Division strategy only
  needed-parts    2  ;;Picture Division strategy only
```

The productions in the picture division model rely on meaningful representation of problem information in declarative memory. First, selection of this strategy comes from representing the meaning of division as finding the number of groups of a given size in the starting amount. Second, the productions rely on a quantity-based representation of fractions. Students need to represent fractions as parts of a whole (e.g. 2/3 is two out of three equal size parts) rather than only as a visual arrangement of numbers (e.g. 2 is the top number and 3 is the bottom number). Table 2 provides a sample declarative chunk used in representing the problem.

Model of Invert-and-Multiply-Strategy

The invert-and-multiply strategy can be broken into 4 main sub-goals: 1) identify the dividend and the divisor, 2) if needed, convert whole numbers and mixed numbers to fractions, 3) invert the divisor and multiply the two fractions, and 4) if needed, simplify the answer by

Table 3: Cognitive model for invert-and-multiply strategy

Productions	Student Example
1. Identify-dividend	12
2. Identify-divisor	1 1/2
3. Whole-dividend-to-fraction	12/1
4. Identify-mixed-dividend	NA
5. Identify-mixed-divisor	
6. Mixed-to-fraction	1 1/2 is 3/2
7. Invert-divisor	So, make it 12/1 * 2/3
8. Multiply-top-&-btm-#s	Equals 24/3
9. Improper-to-mixed	That is 8
10. ID-whole-#-answer	[Done]
11. ID-if-quotient-is-reducible	NA
12. Reduce Fraction	NA

converting an improper fraction to a mixed number and/or by putting the fraction in simplest terms. These four sub-goals translate into 11 key steps or actions that the problem solver must take (see Table 3; dotted lines designate the beginning of a new sub-goal).

The declarative knowledge used by the invert-and-multiply strategy differs from that used by the picture division strategy. In the invert and multiply strategy, division is represented as performing actions on numbers. Fractions are represented as a visual arrangement of digits, and quantity-based knowledge is not used (see Table 2).

Empirical Support for Our Models

We designed a brief intervention to validate and refine our cognitive models. The students had already been taught the invert-and-multiply strategy, and we gave them a brief lesson on the picture division strategy. Thirty-two ninth-grade students from two math classes for below-average math students participated in the study.

On the first day of our study, students received a 10-minute lesson on fraction division from their classroom teacher. The teacher discussed how to solve two types of fraction division problems using each strategy. Instruction on the picture division strategy focused on forming a quantity-based representation of the problem without detailed instruction on the actions (productions) for implementing the strategy. The teacher then reviewed the steps for using the invert-and-multiply. After this brief lesson, students were randomly assigned to use one of the two strategies to solve a set of problems. Students solved two problems using the assigned strategy and received feedback and help in finding the correct answer if needed. Students then solved a set of 10 problems without feedback or help – 4 instructed problems (problems with whole numbers and/or unit fractions), 5 transfer problems (problems with non-unit fractions and with mixed numbers), and a fraction multiplication problem. Students had approximately 20 minutes to solve the problems, and their compliance with the strategy instructions was high. In the invert-and-multiply group, there was no trace of students using a pictorial strategy, and in the picture division group, a picture was drawn on 83% of attempted problems. Four days later, students were asked to solve a parallel set of 10 problems using any strategy they wanted.

Students had difficulty learning the picture division strategy from our brief lesson. On Day 1, they solved 60% of the instructed problem types correctly, but only 9% of the transfer problems correctly. Many students got stuck and did not finish the assessment; students only attempted 57% of the problems (compared to students attempting 96% of problems in the invert-and-multiply group).

Not surprisingly, students who were assigned to use the familiar invert-and-multiply strategy solved more problems correctly on Day 1, compared to the Picture Division group (49% vs. 28% correct; $F(1,30) = 16.96$, $p < .01$). They solved 89% of the instructed problem types correctly, but only 31% of the transfer problems correctly (although they had previously received instruction on these problem types as well.) Student had particular difficulty when the problems involved mixed numbers. Only half of the students solved at least one problem of this type correctly.

When students were free to choose any strategy on Day 2, students used the more familiar and well practiced invert-and –multiply strategy on a majority of problems (M = 62% of trials with a mean accuracy of 60%). The picture division strategy was used on 10% of problems, and only by students who were assigned this strategy on Day 1.

To help explain the difficulties of each strategy, students' incorrect solutions were classified using the productions in the relevant cognitive model. We distinguished between failing to initiate a production and implementing a production incorrectly (an error). The ease of coding student solutions is an additional benefit of developing cognitive models. We report solution data from Day 1, but a similar pattern arises on Day 2.

Tables 4 and 5 show the distribution of failures and errors over the productions for each strategy. On the picture division strategy, students often did not know how to start the problem. When students attempted the problem, they often did not succeed on the first sub-goal – identifying values and setting up the picture. There were a surprising number of errors in identifying the dividend and in drawing the divisions correctly (e.g. students added 3 extra divisions per whole for 1/3, thus making fourths). Students' errors on identify-parts-per-whole varied by problem type, suggesting that an additional production was needed in our model. When the dividend was a fraction, students sometimes divided the fractional amount, rather than the whole, into the specified number of parts (e.g. for 1/2 ÷ 1/10, dividing the half into 10 sections). Students need an extra production for mapping the parts-per-whole to the parts-per-fraction (e.g. if 10 division in one whole, half as many (5) in 1/2). We have very little data on the difficulty of productions that occur later in the sequence because students often abandoned this strategy.

Students using the invert-and-multiply strategy were much more likely to attempt to solve a problem, and the majority of mistakes arose from failing to or incorrectly converting mixed numbers to fractions. However, this error did not cause students to abandon the strategy. Rather, students made illegitimate adaptations to the strategy, such as inverting the fractional portion of the divisor and then multiplying the whole number portions and the fraction portions separately (e.g. 8 2/3 ÷ 2 1/3 = 8 2/3 * 2 3/1 = 16 6/3). Further, students' errors on the fraction multiplication problem suggested that the conditions for firing the invert-divisor production were overly general for many students. Half of the students in the invert and multiply group inverted the second fraction before multiplying.

Table 4: Classification of students' incorrect solutions using the picture division strategy on day 1

Action/Production	No. of Errors	No. of Failures
<Start Problem>	NA	64
ID /Draw-whole-starting-amt	6	1
ID /Draw-mixed-starting-amt	7	-
Identify-size-of-groups	-	-
Identify-value-of-divisions	6	11
Draw-divisions	10	-
Identify-step-size	7	1
Mark-first-group	-	-
Mark-next-group	1	-
Finished-marking-groups	-	-
Count-whole-groups	2	1
Identify-remaining-divisions	NA	NA
Step-size-as-denominator-of-remainder	NA	NA

Table 5: Classification of students' incorrect solutions using the invert and multiply strategy on day 1

Action/Production	No. of Errors	No. of Failures
<Start problem>	NA	8
ID Dividend	-	-
ID Divisor	-	-
Whole-to-fraction	-	-
ID-mixed-dividend & Mixed-to-fraction	13	15
ID-mixed-divisor & Mixed-to-fraction	4	9
Invert-divisor	2	9
Multiply-top-&-btm-#s	4	8
Improper-to-mixed	3	9
ID-if-common-factor	NA	NA
Reduce Fraction	NA	NA

Implications of the results for the cognitive models

The empirical results revealed a necessary refinement to the picture division model and validated the other productions in the two models. Students' errors when using the picture division strategy indicated that an additional production was needed when the dividend was a fraction. Otherwise, the models captured students' behaviors quite well.

The empirical results also provide information on common buggy rules and on the frequency of correct productions "failing to fire". Students' buggy rules will be modeled as production rules, allowing us to identify the source of the differences in the correct and incorrect productions. This information can be used to target instruction at addressing or preventing these errors.

These results also highlight the importance of the declarative knowledge structures. The ninth-grade students in this study did not seem to form quantity-based representations of fractions or to represent division as finding the number of groups of a certain size in the starting amount. Without these declarative knowledge structures, students had great difficulty implementing the initial productions for the picture division strategy. In contrast, the invert-and-multiply strategy only relies on a superficial representation of division and of the position of the digits in fractions, although a quantity-based representation of the values could be used to recognize errors in its execution (e.g. that multiplying the whole numbers will lead to too large of an answer). After more than 5 years of instruction on the division operator and on fractions, these students did not seem to be forming meaningful representations of either.

Predictions from the models

Cognitive models of the picture division and invert-and-multiply strategies can lead to comparative predictions for 1) difficulty of learning each strategy, 2) efficiency of using each strategy once learned, 3) generality of each strategy to the range of fraction division problems, 4) retention of the strategies, and 5) transfer.

First, the ease of learning the two strategies depends on students' prior knowledge. In particular, learning difficulty should be predicted by two factors – how students represent fractions and division and how well they know symbol manipulation rules for working with fractions. If students form quantity-based representations of fractions and attach meaning to the division operation, learning the picture division strategy should be relatively straightforward since a majority of the productions are based on familiar and well practiced knowledge (e.g. marking sections and counting). However, if students only represent fractions as visual arrangements of digits and division as manipulating symbols, this representation is not compatible with the strategy, so the strategy will be difficult to learn. The invert-and-multiply is not dependent on a quantity-based representation of fractions. In contrast, the ease of learning this strategy depends on how well students already know productions for converting whole and mixed numbers to fractions and for converting improper fractions to mixed numbers.

Second, our models support the predictions that the two strategies will not be equally efficient once they are mastered. Although the total number of productions to learn is similar in the two strategies (13 vs. 12), the number of production firings is often higher for the picture division strategy because some productions must fire many times. For example, to solve $6 \div 3/4$, the draw-divisions production fires 18 times and the mark-next-group production fires 6 times. Thus, to solve this problem, the picture division strategy has 32 production firings whereas the invert-and-multiply strategy has 6 production firings. On a majority of problems, the invert-and-multiply strategy is more efficient than the picture division strategy once the strategy is mastered.

Third, the ease of applying the two strategies to the full range of fraction division problems is not equivalent. Once the full set of productions is mastered for the invert-and-

multiply strategy, it can be applied to any fraction division problem. In contrast, the picture division strategy becomes very cumbersome if the dividend is large, the denominator of the divisor is large, or if the denominators of the dividend and divisor are not "friendly" (i.e. one denominator is not a factor of the other, such as 3 and 5). The first two constraints require an unmanageable number of firings of the draw-divisions and mark-next-group productions. The third constraint requires a new set of productions for finding equivalent fractions with a common denominator, thus necessitating extra productions that are not well grounded in the situation. Overall, the picture division and invert-and-multiply strategy can both be used to solve a majority of fraction division problems, but the invert-and-multiply strategy has the advantage of more uniform difficulty on all types of problems.

The fourth prediction concerns the retention of the two strategies and confers an advantage to the picture division strategy. In ACT-R, recall is based on spreading activation, so knowledge that is connected to a richer network of knowledge chunks is easier to recall (Anderson, 1993). The picture division strategy utilizes rich knowledge representations of quantities and operations, so this network of relations should facilitate recall. In contrast, the invert-and-multiply strategy utilizes sparse, visual-based representations that are not connected to a rich knowledge base, so this strategy should be harder to recall after a delay. Our results indicate that students have difficulty correctly retrieving all of the relevant productions for invert-and-multiply. In addition, both level-of-processing and dual-code theories of memory (Craik & Lockhart, 1972; Paivio, 1971) suggest that the richer problem representations utilized by the picture division strategy should lead to better recall of this strategy, compared to the invert-and-multiply strategy. Thus, we predict that recall of the picture division strategy will be more robust.

Fifth, the models lead to very different transfer predictions. Inspection of the models indicates no overlap in the productions that are used by each strategy, so learning one strategy will not aid learning of the other. The two strategies also transfer differently to other topics. When knowledge chunks are activated, their memory trace is strengthened (Anderson, 1993), so quantity-based representations of fractions and a meaning-based representation of division are strengthened (and possibly refined) when students use the picture division strategy. Thus, learning the picture division strategy should facilitate performance on tasks utilizing these representations. Representing fractions as part-whole quantities provides a powerful declarative knowledge structure for choosing and implementing a variety of strategies for tasks such as comparing magnitudes, estimating, or adding and subtracting fractions. The picture division strategy should also transfer to decimal division since it strengthens a meaningful representation of division and many of the productions can be used to solve division problems with decimals. In contrast, the invert-and-multiply strategy should facilitate performance on problems involving other fraction operations or algebraic simplification. This strategy strengthens productions that are also used for adding, subtracting and multiplying fractions, such as converting improper fractions to mixed numbers, reducing fractions, and multiplying fractions (although students may over-generalize the strategy and also invert the second fraction when multiplying fractions). Productions from this strategy can also be applied to simplifying algebraic expressions. Overall, the two strategies should aid performance on very different types of transfer problems.

Developing cognitive models of the two strategies leads to precise predictions of the benefits and drawbacks to each strategy. The picture division strategy should be easy to learn if students have quantity-based representations of fractions, should be recalled after a delay, and should transfer to tasks such as comparing fractions and dividing by a decimal. In contrast, the invert-and-multiply strategy should be easy to learn if students already know productions for manipulating fractions, should be efficient and broadly applicable once mastered, and should transfer to other fraction operations and to algebra.

Implications for Instructional Design

Comparing the benefits and drawbacks of each strategy allows for an informed decision on whether and how to teach each strategy. Neither of the strategies was strong along all five dimensions that we considered (difficulty of learning, efficiency, generality, retention and transfer). Instead, there were trade-offs for learning each strategy.

How the fraction division problems are represented in declarative memory helps to explain the benefits and drawbacks to each strategy. The picture division strategy supports a quantity-based representation of fractions as a specified number of parts of a whole. Quantity-based representations provide a unified representation that can be used when solving a large variety of rational number problems, such as modeling, estimating, comparing, and doing arithmetic with fractions. Thus, retention of the strategy should be high. In contrast, the invert-and-multiply strategy relies on a visual, position-based representation, and this representation requires different, special-purpose productions to solve a similar variety of rational number problems, and retention of the productions would be relatively low. However, these specialized productions lead to more efficient performance.

Ideally, instruction could bridge from the more meaningful and grounded strategy of picture division to the more abstract and efficient strategy of invert and multiply, while maintaining high retention. Unfortunately, there is no overlap in the problem representations or the productions used by these two strategies, making it difficult to build from one to the next. Because of this limitation, we developed a third strategy, labeled the common denominator strategy, which builds off the picture division strategy and leads to an efficient and general method for dividing fractions. Because this strategy builds on the picture

division strategy, we first discuss suggestions for teaching the picture division strategy and then outline a model of this new strategy.

The cognitive model suggests a careful sequence of lessons for teaching the picture division strategy. Students should first learn to represent fractions as part-whole quantities. Next, students should be taught to use the picture division strategy on problems that rely on the fewest number of productions - dividing a whole number by a unit fraction. After students have learned this minimum set of five productions, they will need help identifying the group size of non-unit fractions and mixed numbers, identifying the number of smaller divisions in bigger divisions if both numbers contain fractions, and converting remainders to fractional values when needed.

After students have experience with the picture division strategy, the common denominator strategy can be introduced as a more general and efficient strategy. Initially, the common denominator strategy can be tightly grounded by the picture division strategy, and then it can be abstracted to a more efficient algorithm. Both the grounded and abstract versions of the common denominator strategy are illustrated in Table 6. The strategy has five main sub-goals: 1) identify the initial values, 2) find the total number of divisions in the starting amount (which may involve finding a common denominator for the dividend and divisor), 3) identify the size of each group (with this common denominator), 4) divide the total number of division by the group size, 5) simplify the answer. After identifying the initial values, students must figure out the total number of divisions in the starting amount, which is analogous to marking the divisions and counting the total number of divisions. To identify the group size, students must make sure the divisor is a fraction that has the same number of parts-per-whole (denominator) as the dividend. Next, the number of groups is found by dividing the total number of divisions by the group size (i.e. dividing the two numerators), which is analogous to marking the groups on the picture and counting the number of groups. This leads to an answer in appropriate fractional form, although the answer may need to be converted from an improper fraction to a mixed numbers. After linking this strategy to the picture division strategy, a more formal, symbol-based strategy can be abstracted, which relies on converting whole and mixed numbers to fractions and finding fractions with a common denominator and then dividing the numerators and denominators. This strategy retains the quantity-based representations of the picture division strategy while being more efficient and general than this strategy. We have used these analyses to design a set of lessons on fraction division that integrate all three strategies, and we are piloting these lessons with sixth grade students who have no prior experience with fraction division.

Table 6: Example of common denominator strategy for solving 1 1/2 ÷ 3/4

Grounded approach:
Because 1/2 = 2/4, and 1 whole = 4 fourths, 1 1/2 = 6/4.
now have: 6/4 ÷ 3/4
In 6/4, there are 2 groups of 3/4, so the answer is 2.
Abstract approach:
Equivalent fractions: 1/2 = 2/4
Mixed to fraction: have 1 2/4: 1 * 4 = 4; 4 + 2 = 6, so 6/4
Now have 6/4 ÷ 3/4
6 ÷ 3 = 2; 4 ÷ 4 = 1
Answer is 2/1, and because any number divided by 1 is that number, the answer is 2.

In summary, cognitive modeling is a promising tool for evaluating alternative strategies and techniques that can be leveraged in the development of better curriculum material and instructional approaches.

Acknowledgments

This work was supported by NIMH/NRSA training grant 5 T32 MH19983-02 and by a grant from Carnegie Learning. We would like to thank Jay Raspat and his students at North Hills Junior High for participating in the empirical study and Juan Casares, Aaron Powers and Willie Wheeler for their help with the cognitive model for the picture division strategy.

Abstract

Several studies have reported an advantage in lexical decision for words with multiple meanings. More recently, Rodd, Gaskell, and Marslen-Wilson (in press) have reported a more complex pattern of ambiguity effects. While there is a processing advantage for words that have many highly related word senses (e.g., *twist*), there is a disadvantage for words that have more than one meaning (e.g., *bark*). Here we show that these two apparently opposite effects of ambiguity can both emerge from the competition to activate a coherent semantic representation in an attractor network. Ambiguity between unrelated meanings delays recognition because of interference between the two possible stable patterns of semantic activation, that correspond to separate attractor basins. In contrast, the patterns of semantic activation that correspond to different senses of the same word meaning all lie within a single attractor basin, and the semantic flexibility associated with these words results in a widening of the attractor basin, thus produces a processing advantage relative to unambiguous words.

The Ambiguity Disadvantage and Sense Benefit

Models of word recognition often make the simplifying assumption that each word in the language has a single, well-defined meaning. However, many words refer to more than one concept. For example, *bark* can refer either to a part of a tree, or to the sound made by a dog. Other words, such as *twist*, have a range of systematically related dictionary definitions including to *make into a coil or spiral*, *to operate by turning*, *to alter the shape of*, *to misconstrue the meaning of*, *to wrench or sprain*, and *to squirm or writhe*. To understand such words, we select the appropriate interpretation, normally on the basis of the context in which the word occurs. In this paper we review the literature on how semantic ambiguity affects the recognition of single words, and report a series of network simulations that examine the implications of these results for models of word recognition

Several studies in the literature report faster lexical decision times for ambiguous words, compared with unambiguous words (Azuma & Van Orden, 1997; Borowsky & Masson, 1996; Millis & Button, 1989). There have been various explanations for why it might be easier to recognise words with multiple meanings. Typically it is assumed that ambiguous words benefit from having more than one competitor in the race for recognition. More recently, this view that there is a simple advantage for semantic ambiguity has been challenged. Rodd et al. (in press) argue that a distinction should be made between the accidental ambiguity of words like *bark* which, by chance, have two unrelated meanings, and the systematic ambiguity of words that have multiple senses. For example, although there are important differences between what it means to *twist an ankle* compared with to *twist the truth*, these different senses of the word *twist* are closely related to each other, both etymologically and semantically. This relationship is quite unlike the ambiguity for a word like *bark*.

All standard dictionaries respect this distinction between word meanings and word senses; lexicographers routinely decide whether different usages of the same spelling should correspond to different lexical entries or different senses within a single entry. However, although this distinction appears easy to formulate, people will sometimes disagree about whether two usages of a word are sufficiently related that they should be taken as senses of a single meaning rather than different meanings. However, even if there is not always clear distinction between these two different types of ambiguity, it is important to remember that words that are described as ambiguous can vary on a continuum between these two extremes.

Rodd et al. (in press) support the psychological importance of this distinction in a set of lexical decision experiments which show that while multiple related word senses do produce a processing advantage, multiple unrelated meanings delay recognition. Here we report a series of simulations which investigate whether these two apparently opposite effects of ambiguity can both emerge from the competition to produce a coherent distributed semantic representation within an attractor network.

Semantic Competition Models of the Ambiguity Advantage

Joordens and Besner (1994) and Borowsky and Masson (1996) have tried to model effects of ambiguity using a two-layer Hopfield network (Hopfield, 1982) to learn the mapping between orthography and semantics. The models show an advantage for words that are ambiguous between unrelated meanings. The authors argue that this advantage arises because, when the orthography of a word is presented to the network, the initial state of the semantic units is randomly determined. The network must move from this state to a valid finishing state corresponding to the meaning of the word. For ambiguous words there are multiple valid finishing state, and on average, the initial state of the network will be closer to one of these states than for an unambiguous word, where there is only one valid finishing state. However, as discussed above, it is now apparent that ambiguity between unrelated meanings produces an disadvantage, so that there is a discrepancy between the data and the behaviour of these models.

One limitation of these models is that their performance on

the task was surprisingly poor. Joordens and Besner (1994) report an error rate of 74%. These errors often result from the network settling into blend states, which are a mixture of the word's meanings. Gaskell and Marslen-Wilson (1999) have shown that blends between unrelated semantic representations can be relatively meaningless, and may be closer to a different word in the lexicon than to either of the components of the blend. In the Borowsky and Masson (1996) study, these blend states are not considered to be errors; the authors argue that to perform lexical decision it is not necessary to resolve the ambiguity successfully in order for there to be sufficient familiarity to make a successful lexical decision. Although this approach may be appropriate for modelling the specific task of lexical decision, this would severely limit the model in being extended to be a more general model of word recognition. It is the case that, given an ambiguous word in isolation, we are able to retrieve one of its meanings. In contrast, the model would predict that without a contextual bias to direct us to one of the meanings we would get stuck in a blend state that may be quite unlike either of the meanings.

It is possible that the observed ambiguity advantage may be an artefact of this tendency to settle into blend states. Indeed, Joordens and Besner (1994) report that as the size of their network is increased, and performance improves, the ambiguity advantage is eliminated. However, even in these larger networks, the problem of blend states is still present; Joordens and Besner (1994), report a maximum performance level of 48.8% for ambiguous words. In the following simulation, we attempt to improve the overall performance of the network, and investigate how ambiguity affects performance in a network that is able to successfully retrieve the meanings of ambiguous words.

Simulation 1: The Ambiguity Disadvantage

Introduction

While Hopfield networks are known to have limited capacity, the networks discussed above are performing well below the theoretical capacity limit. Hopfield (1982, pg 2556) stated that *"About 0.15 N states can be simultaneously remembered before error in recall is severe"*, where N is the number of units in the network. Therefore the Joordens and Besner (1994) network should be able to learn 45 patterns, and yet the network cannot reliably learn 4 words. This poor performance is because the patterns corresponding to the different meanings of ambiguous words share the orthographic part of their pattern. Hopfield (1982) noted that these networks have a particular difficulty with correlated patterns. Therefore, the simple Hebbian learning rule, which captures the correlational structure of the training set, may not be suitable for learning ambiguous words.

Simulation 1 uses instead the least mean-square error-correcting learning algorithm, which adjusts the weights between units to reduce any error in the activation patterns produced by the current sets of weights. This may therefore alleviate the problem of blend states, as the learning algorithm will change the weights such that these states are not stable.[1]

[1] Kawamoto, Farrar, and Kello (1994) used this algorithm to learn ambiguous words, but they do not report error rates.

Method

Network Architecture The network has 300 units: 100 (orthographic) input units and 200 (semantic) output units. The network is fully connected; each unit is connected to all other units. All units are bipolar; they are either on $[+1]$ or off $[-1]$.

Learning Algorithm All connection strengths were initially set to 0. During each learning trial, the network was presented with a single training pattern, and an error-correcting learning algorithm was used to change the connection strengths. The change in connection strength from a given unit i to a unit j is given by

$$\Delta w_{ij} = x_i(x_j - \sum_k w_{kj}x_k)/3n, \quad i \neq j, \tag{1}$$

where x_i is the activation of unit i and n is the number of units in the network. The learning rate parameter, $1/3$, was selected to provide good performance after a relatively small amount of training.

Training Unambiguous word representations were created by randomly assigning values of $+1$ and -1 to each of the 100 input and 200 output units, such that half the units in each part of the network were assigned $+1$, and the other half -1. For the ambiguous words, a single, randomly generated input pattern was paired with two different output patterns.

In the Joordens and Besner (1994) simulations, the network was trained on only one unambiguous word and one ambiguous word. Here the training set varies between 1 and 16 pairs of ambiguous and unambiguous words, (i.e., 2 to 32 words or 3 to 48 unique semantic patterns). The number of times that each word was presented to the network was varied between 2 and 64 times. The unambiguous and ambiguous words were matched for overall frequency of the orthographic pattern. For each combination of training set size and length of training, the network was trained, and its performance was tested on 200 independent passes; for each pass, a different, independently generated set of training items was used.

Testing Each input pattern was presented to the network, and the output units were all set randomly to $[+1]$ or $[-1]$. Retrieval of the semantic patterns was the result of an asynchronous updating procedure. A unit was selected at random, and its activation was updated by summing the weighted input to that unit. If this input was greater than zero, then the unit was set to $+1$, otherwise the unit was set to -1. This updating continued until a sequence of 1500 updates produced no change in the state of any unit. The network was considered to have settled correctly only if the activation of all its units was correct when it reached a stable state.

Results

For the unambiguous words, the network settled into the correct semantic pattern for over 99.8% of the words, for all the levels of training and set sizes. For the ambiguous words, performance was more variable. The percentage of trials on which the network settled into a correct training pattern for these words is shown in Figure 1 for different amounts of training, and for different sizes of the training set. Importantly, under some conditions, the network was able to settle

correctly into the semantic pattern corresponding to one of the word's two meanings on 98% of the trials. Therefore, the LMS error-correcting algorithm performed substantially better than the Hopfield algorithm on this task.

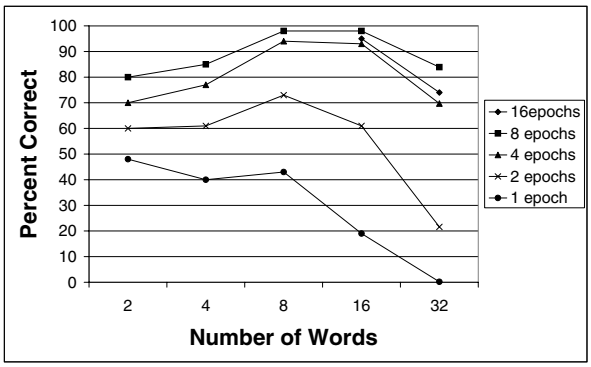

Figure 1: Simulation 1, Performance for Ambiguous Words

Despite this improvement, the ambiguous words were still difficult to learn, compared with the unambiguous words. For the unambiguous words, the network always reached near-perfect performance, having been presented with the training set only once. For the ambiguous words, only when the training set had been presented to the network four times, did performance ever rise above 90%. The number of cycles taken by the network to settle was also generally greater for the ambiguous words than for the unambiguous words. Table 1 shows the difference between the settling times for the two types of words; positive numbers indicate faster settling for the unambiguous words. For the smallest training-set size, the difference between the two types of words was small and variable, but for larger training sets, a consistent ambiguity disadvantage emerges. Crucially, for all the networks where performance on the ambiguous words was greater than 90%, there was a significant ambiguity disadvantage (all significant using the Bonferroni correction for multiple comparisons).

Table 1: Simulation 1, Percentage Benefit in Settling Times for Unambiguous Words

Training	2 Words	4 Words	8 Words	16 Words	32 Words
2	-1	4	38	87	-
4	0	6	23	65	105
8	-1	3	16*	41*	94
16	2	5	11*	25*	64
32	-2	3	12*	32*	57
64	-1	4	11*	32*	49

Notes. * performance on ambiguous words exceeded 90%,

The change in the performance as a function of the size of the training set was somewhat surprising. At all levels of training, the network settled more quickly when it had been trained on fewer patterns. However, the effect of training-set size on error rates for the ambiguous words is more complex (see Figure 1). It is not altogether clear why the network performs so poorly for a very small training sets. It is possible that the increased error produced by the other words in the training set results in the error-correcting learning algorithm operating more effectively; alternatively, the number of spurious stable attractors may increase for small training sets because of the small number of learned attractor basins.

There is an interesting effect of training on performance: initially, training improves performance, in terms of both error rates, and settling times. However, for some training-set sizes, performance reduces if the training set is presented more than 16 times. This suggests that over-learning of the training set produces poor performance for the test items (in which only a subset of the training features are activated).

Discussion

This simulation shows that the introduction of an error-correcting learning algorithm improved performance on the ambiguous words to a level where it is reasonable to investigate the effects of ambiguity on performance. In all conditions where performance exceeded 90%, there was a significant *disadvantage* for the ambiguous words in terms of the number of cycles taken for the network to settle.

Therefore, this simulation suggests that the ambiguity advantage found by Joordens and Besner (1994) is atypical for a network of this type. When performance is improved such that the network reliably settles into a stable semantic representation that corresponds to one of the word's meanings, the interference between the multiple patterns of ambiguous words delays their recognition, relative to unambiguous words. Therefore, a simple semantic competition network of this type can simulate the ambiguity disadvantage seen by Rodd et al. (in press). The question that remains is whether this type of network can also produce the benefit for words with multiple, related word senses.

Simulation 2: Word Senses as Random Noise

Introduction

We have now shown that semantic competition between word meanings delays the settling of the network for ambiguous words, relative to unambiguous words. How then are we to explain the advantage reported by Rodd et al. (in press) for words with multiple senses? One difference between these two forms of ambiguity is the degree of semantic overlap between the alternative semantic patterns. However, although an increase in the similarity of the two meanings of an ambiguous words may reduce the level of semantic competition (and therefore the ambiguity disadvantage), this can only improve performance to the level of the unambiguous words; it cannot produce a benefit.[2]

In this simulation, we explore the hypothesis that the variation in the meanings of words such as *twist* and *flash*, which are listed as having many word senses, should be viewed not in terms of ambiguity, but in terms of flexibility. We assume that the multiple senses of these words are not distinct, but that their meaning is flexible or vague, such that it has a slightly different interpretation in different contexts. In particular, we assume that these words can be represented as having a single base pattern that represents the core meaning of the word. Then, every time this pattern is presented to the

[2]This has been confirmed in a set of simulations identical to Simulation 1 except that the semantic relationship between the meanings of the words was systematically varied (Rodd, 2000).

network, random noise is added to this base pattern, such that each time the network sees the word, it is slightly different from other instances of the word.

Although this idea that words with many senses should be characterized as words whose meanings are flexible about a core meaning does not reflect how these words are listed in dictionaries, there is support for this idea that the classification of the meanings of such words into distinct senses is artificial. For example, Sowa (1993) states that "for polysemous words, different dictionaries usually list different numbers of meanings, with each meaning blurring into the next".

The reason that we might expect this characterization of word senses to produce the processing benefit seen in the human data is that, as we saw in Simulation 1, if an identical pattern is repeatedly presented to the network, it can develop a very deep attractor basin that can be difficult for the network to settle into when it is given only the orthographic input. It is possible that adding a small amount of noise to the network might prevent this over-learning, and might allow the network to develop broader attractor basins, that are easier for the network to enter.

Method

Network Architecture, Learning Algorithm and Processing The architecture and learning algorithm used in this simulation were identical to those used in Simulation 1. However, to reduce the length and variability of the settling times, a different updating procedure was used. Updating now consisted of a series of update sequences in which all the semantic units were updated once in random order.

Training The networks were each trained on 64 words. Half these words were unambiguous, and were presented to the network in exactly the same form on each presentation. The other words had noise added to them; each time these words were presented to the network, a small number of the semantic units were randomly changed from the original base pattern. The number of units that were changed varied from 1 to 5 across different simulations. The number of times that these words were presented to the network was varied from 16 to 128. For each level of training and noise, 100 networks were trained on independently generated sets of patterns.

Results

For the unambiguous words, the network settled correctly in over 99.5% of trials, in all conditions. For the words that had noise added to them, it is less clear what it means for the network to settle correctly; as the level of noise increased, the percentage of trials on which the network settled into the base pattern decreased. However, those trials on which the network did not settle into the base pattern should not all be considered as errors. If the network settles into a pattern that does not differ from the base pattern by more than the amount of noise that was added to the patterns during training, this can be thought of as the network settling into one of the word's senses rather than the core meaning, and should not be considered to be an error. Using this approach, the percentage correct for these words was always above 99.5%

Table 2 shows settling times for the unambiguous words and the words with the added noise, and the differences between these scores. Positive numbers reflect a disadvantage for the noisy patterns. These data show complex interactions between the effects of noise and training, but crucially, while low levels of noise have no stable influence on performance, as the level of noise increases, a reliable disadvantage for noise emerges. This disadvantage for noise is greatest at low levels of training, and increases with the level of noise.

Table 2: Simulation 2, Cycles to Settle for Unambiguous and Noisy Words

Units Changed		Training Presentations 16	32	64	128
1	Unambiguous	603	617	615	588
1	Noisy	611	622	614	593
1	Difference	+8	+5	-1	+5
3	Unambiguous	587	598	564	515
3	Noisy	617	614	583	539
3	Difference	+30	+16	+19	+24
5	Unambiguous	578	573	536	481
5	Noisy	623	609	568	509
5	Difference	+45	+36	+32	+28

Discussion

Contrary to the idea that noise during training might improve performance, the network was slower to settle into those training patterns that had noise added to them during training, compared with the unambiguous patterns. Therefore, this simulation suggests that even if we characterize the ambiguity between multiple senses as being noise about a base pattern, the ambiguity still produces a processing disadvantage. This is, of course, the reverse of the pattern seen in the human data.

In this simulation, the noise that was added to the semantic representations was random; on each training trial, the activation of a given number of units in the semantic pattern was changed. However, this is not a realistic characterization of how the senses of words differ; it is not the case that a new sense of a word can be created from the core meaning of the word by simply changing arbitrary features. Rather, it is that case that these words have sets of possible semantic features which are sometimes, but not always, present. Therefore, rather than modelling word senses as the addition of random noise, it might be better to assume that each word has a range of possible semantic features, but that not all these features are always turned on. For example, the word *twist* may in some contexts not activate the features relating to pain, but it will never arbitrarily gain a feature such as *has legs*.

To model word senses in this way, we need to move away from semantic representations in which half the units are set to $+1$ and the other half set to -1. Instead, for any given semantic representation, most of the units will be turned off, and only a subset will be turned on. Noise is added such that only those features that should be turned on may be turned off, but there is no arbitrary addition of semantic features.

Simulation 3: Sparse Representations

Method

Network Architecture, Learning Algorithm and Processing The architecture used in this simulation was identical to

that used in Simulations 1 and 2. The training patterns used were sparse, such that only 10% of the units were set to $+1$ and the remainder were set to 0. The change in connection strength from a given unit i to a unit j is given by

$$\Delta w_{ij} = 5x_i(x_j - \sum_k w_{kj}x_k)/n, \quad i \neq j \tag{2}$$

Training As in Simulation 2, the network was trained on 64 words; half of the words had noise added to the semantic representations during training, and the other half did not. Again, the number of units that were changed for the noisy words varied from 1 to 5; however noise was added only to units that were set to $+1$ in the base pattern.

Results

Figure 2 shows the performance of the network at different levels of training and noise.[3] At all levels of noise, performance is better for the words that had noise added during training; the network is able to correctly produce the semantic representations for these words at lower levels of training.

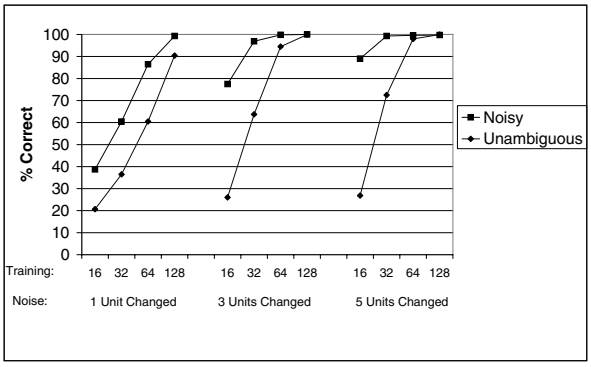

Figure 2: Simulation 3, Error rates

We then looked in detail at the settling behaviour of the network, which was presented with each word 128 times, with a level of noise of 5 units. This network successfully retrieved the meaning in over 99.7% of trials for both types of words. This network settled significantly more quickly for the unambiguous words than for the noisy words; the unambiguous words took on average 407 updates before they were stable, the noisy words took 435 ($t(99) = 8.9, p < .001$). However, a more interesting picture emerges if we look at how the activation of the semantic representations built up over time for this network. Figure 3 shows the total number of semantic units that are switched on at the end of each update of the 200 semantic units. If the network activates 20 units, this corresponds to the activation of a complete semantic pattern. For the noisy words, however, the network tends to activate only a subset of the 20 units; this corresponds to the activation of a sense of the word that does not contain all the possible semantic features for that word.

[3]Unambiguous words are considered to have settled correctly if they settled into the exact training pattern. Noisy words are considered to have settled correctly if they do not differ from their base pattern by more than the amount of noise that was added during training. In a separate analysis, not reported here, this tolerance was also used for the unambiguous patterns; In this analysis, no the error rates differed from those reported here by more than 0.2%.

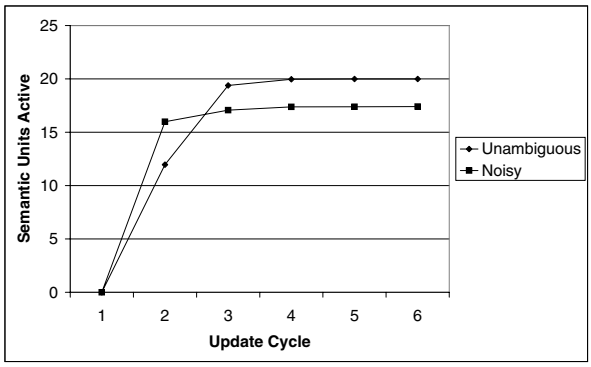

Figure 3: Simulation 3, Activation of Semantic Units

Interestingly, at the end of the first update cycle, the network is significantly more active for the noisy words ($p < .001$). For the unambiguous words, on average 12 units are switched on; for the noisy words, 16 are activated. Therefore, if we assume that lexical decisions are made before the activation of the semantic units has become completely stable, there will be an advantage for the noisy words. It is worth noting that, if this network is presented with a novel word that was not in the training set, the activation of the semantic units very rarely rises above 10. If an activation threshold were set at this level, there would be an advantage for the noisy words.

The later advantage for unambiguous words reflects an assumption built into the training set that the total number of semantic features that are ever activated for words with many senses is equivalent to the total number of features for the unambiguous words. In other words, we have assumed that the individual senses of words with many senses have fewer semantic features than those with only a single sense. This assumption is probably incorrect; it is more likely that words with many senses have a larger set of possible semantic features than words with few senses. It may have been more realistic to assume that the groups of words should be equated on the average number of features that are activated for each individual sense. If this had been the case then the two types of words would settle to the same mean activation level, and the noise advantage would be larger, and extend later in the settling of the network.

Discussion

This simulation shows that if the activation of the semantic features is used as a metric of lexical decision, then there is an advantage for words to which noise is added during training. The advantage is only present early in the settling of the network. This suggests that, as predicted, the noise acts to ensure that the attractor basins are sufficiently wide to allow the activation of the networks to enter the basin quickly. Later in the processing, however, there is a disadvantage for these words; this may be because of competition between multiple stable states (within the large attractor) that correspond to the different senses of the words.[4]

[4]Additional simulations, not reported here, show that the low error rates for ambiguous words and ambiguity disadvantage seen in Simulation 1 is also seen in the rate of activation of semantic units when these sparse representations are used (Rodd, 2000).

Conclusions

The simulations reported here show that networks using the same architecture and learning rule can accommodate the two apparently opposite effects of semantic ambiguity reported by Rodd et al. (in press). While the semantic competition associated with the ambiguity between unrelated meanings delays recognition, the flexibility around the base pattern seen in words with many senses can produce a benefit.

The ambiguity disadvantage shown in Simulation 1 is important because previous simulations of ambiguity effects using networks of this type have shown an ambiguity advantage. We argue that these earlier results were atypical, and relied on using networks that were not able to disambiguate between the different meanings of ambiguous words. Simulations 2 and 3 show that a network of this type can also show a benefit for words whose meanings are flexible between different word senses, but only when their semantic features vary within a limited set of possible features. This limitation fits in with our intuitions about how the semantic representations of words senses vary.

These contrasting effects of ambiguity can best be viewed in terms of the attractor structure of the network. The delay in activating the meaning of an ambiguous word is due to competition between the two stable attractors that correspond to the two different meanings of the word. The initial state of the semantic units produced by the orthographic input will correspond to an unstable blend of the two meanings; the attractor structure of the network will then move the activation of the units away from this blend state towards one of the stable attractors. This disambiguation process takes time, and is responsible for the observed ambiguity disadvantage. In contrast, the different senses of a words all lie within a single attractor basin. Further, the semantic flexibility associated with these words results in a widening of the attractor basin, thus producing a processing advantage relative to unambiguous words. There may, however, be a disadvantage for these words later in processing, due to the existence of multiple stable attractors within the large basin that corresponds to the set of different senses of the word.

In summary, these simulations show that it is possible that the pattern of ambiguity effects reported by Rodd et al. (in press) can be explained in terms of the effects of these two types of ambiguity on the competition to activate a coherent semantic representation within an attractor network. The next stage is to determine whether these explanations are correct.

First, we have assumed that words with many senses should be characterised as words whose meanings are flexible about a core meaning; this assumption must be validated on the basis of detailed analysis of the stimuli used in the experiments. Second, it needs to be confirmed that flexibility is the key property responsible for the sense benefit. As noted by Rodd et al. (in press), words with many senses differ from words with few senses on a range of dimensions, including semantic richness and contextual predictability.

Finally, these simulations investigate two extreme cases of ambiguity; we have compared words with two completely unrelated meanings, with words whose different senses correspond to all the possible combinations of a set of permitted features. This is clearly unrealistic - most words with multiple senses do have some level of structure, and the variation in word senses is often systematic across words. Although the simulations reported here demonstrate important principles about how extreme forms of ambiguity can affect processing, further work needs to be done using more realistic semantic representations. These issues are important if we are to fully understand the implications of ambiguity effects for theories about the representation and access of word meanings.

Abstract

While the effectiveness of one-on-one human tutoring has been well established, a great deal of controversy surrounds the issue of which features of tutorial dialogue separate effective uses of dialogue in tutoring from those that are less effective. In this paper we present a formal comparison of Socratic versus Didactic style tutoring that argues in favor of the Socratic tutoring style.

Introduction

Comparative studies of student learning have already demonstrated that one-on-one human tutoring is more effective than other modes of instruction. Tutoring raises students' proficiency as measured by pre and post-tests by a minimum of 0.40 standard deviations with peer tutors (Cohen et al., 1982), and to up to 2.0 standard deviations with experienced tutors (Bloom, 1984). One prominent component of effective human tutoring is collaborative dialogue between student and tutor (Fox, 1993; Graesser et al., 1995; Merrill et al., 1992). Nevertheless, a great deal of controversy surrounds the issue of which features of tutorial dialogue distinguish effective uses of dialogue in tutoring from those that are less effective.

In this paper we present the results of a formal evaluation of the relative effectiveness of Socratic versus Didactic tutoring in a simulated problem solving environment in the Basic Electricity and Electronics domain. In this study, the Socratic tutoring style is characterized by an emphasis on eliciting information from students through a directed line of reasoning. Thus, the tutor endeavors as much as possible to avoid giving information away. In contrast, in the Didactic tutoring style, the tutor begins extended interactions with students by presenting the student with an explanation of the material the student is meant to learn in the interaction. After the initial explanation, the tutor leads the student through a directed line of reasoning similar to that used in the Socratic condition, except that the questioning plays more of a role of drawing the student's attention to information that the tutor has already explained, rather than eliciting this information from the student. Since drawing the student's attention to the points already articulated by the tutor requires less from the students, the Didactic interactions tended to be significantly shorter than the Socratic interactions. They contained only 70% as many open ended questions and had more of a lecture like flavor than the Socratic interactions.

In a classroom instructional context, it has been well argued that receptive learning, i.e., by means of lectures, can be just as effective as discovery based learning provided that students have the requisite prior knowledge to learn the presented material meaningfully rather than by rote (Ausubel, 1978). However, this view has not been universally accepted by educational psychologists (Piaget, 1973; Vygotsky, 1978). Furthermore, one key difference between tutoring and classroom learning is that there is much more continuity and regularity in classroom learning. In contrast, tutoring is sporadic and decontextualized. Thus, within a classroom setting the teacher is much more familiar with the students' prior knowledge, and is in fact in a position to ensure that students are prepared to learn the material that is presented each day by arranging lessons to build one upon another. We argue that because this is not the case in a tutoring context, it is more critical to draw out the student's thought process in order to tailor the presentation of material to the students' needs.

Previous studies have argued the effectiveness of Socratic and other similar tutoring approaches. Recent research on student self-explanations supports the view that when students explain their thinking out loud it enhances their learning (Chi et al., 1989, Chi et al., 1994, Renkl, submitted). Students learn more effectively when they are given the opportunity to discover knowledge for themselves (Brown and Kane, 1988; Lovett, 1992; Pressley et al., 1992). Collins and Stevens (1982) report that the best teachers tend to use a Socratic tutoring style. A tutoring system based on the Collins and Stevens model (Wong et al., 1998) has received favorable reviews although it has not yet been subjected to a formal comparative evaluation.

Nevertheless, other studies have argued the effectiveness of Didactic style tutoring. In a recent study in which students read previously solved probability problems (Renkl, submitted), an experimental group that had the option to request further tutor explanation performed better than a control group that did not have that option, with an effect size of .5 sigma. Albacete (1999) found that students who received Didactic conceptual minilessons when they made errors learned more than students who received immediate flag feedback and could

request first a pointing hint, then a correct answer. Similarly, McKendree (1990) found that feedback messages with high content caused more learning than feedback messages with low content. Finally, it is reported in (Graesser et al., 1995) that ordinary human tutors seldom use Socratic tutoring, and yet are quite effective.

The results of our formal comparison presented here demonstrate a trend in favor of Socratic style tutoring over Didactic style tutoring.

Experimental Setup

The context of our work is a web-based course on basic electricity and electronics (BE&E). The system was developed with the VIVIDS authoring tool (Munro, 1994) at the Navy Personnel Research and Development Center in San Diego, CA. The original BE&E tutor was designed as a tool for classroom instruction. As we are interested in one-on-one tutoring, we observed how students interacted with the system and with a human tutor in a Wizard-of-Oz setup. The curriculum used in our experiments and prototype system consists of four lessons and six labs covering basic concepts of current, voltage, resistance, power, making measurements with a multimeter, and doing some simple computations and problem solving. Each lesson consists of three sections of between 10 and 25 pages of instructional text and graphical illustrations displayed in a Netscape window, as in Figure 1. After each section, the student was tested with between 3 and 5 multiple choice progress check questions, which act as a springboard for interaction with the tutor to address deficiencies in the student's understanding. After each lesson, the student was presented with one or two labs designed to test and reinforce the concepts introduced in the lesson. The students completed the labs by interacting with a simulated electronics workbench through a point-and-click interface, as in Figure 2.

The 37 subjects who participated in our data collection experiment were University of Pittsburgh undergraduates with little or no prior study of electricity or electronics. Each subject participated in two sessions, each of which lasted between two and two and a half hours. The tutor was a post-doc working at the Learning Research and Development Center at the University of Pittsburgh with some tutoring experience. While the student interacted with the system, the video signal to the student's monitor was split so that a tutor sitting behind a partition could watch the student's progress. The student and tutor had access to a chat interface that allowed them to type messages to each other. Although students sometimes initiated dialogues themselves, the majority of dialogues occurred when the tutor initiated a dialogue because the student either incorrectly answered an important progress check question or showed evidence of not being able to proceed with a lab.

Seventeen of the students participated in a pilot study, which we used to determine how much material on average that students are able to cover in the allotted time (five hours maximum) and which concepts from the domain come up most frequently in the tutoring dialogues.

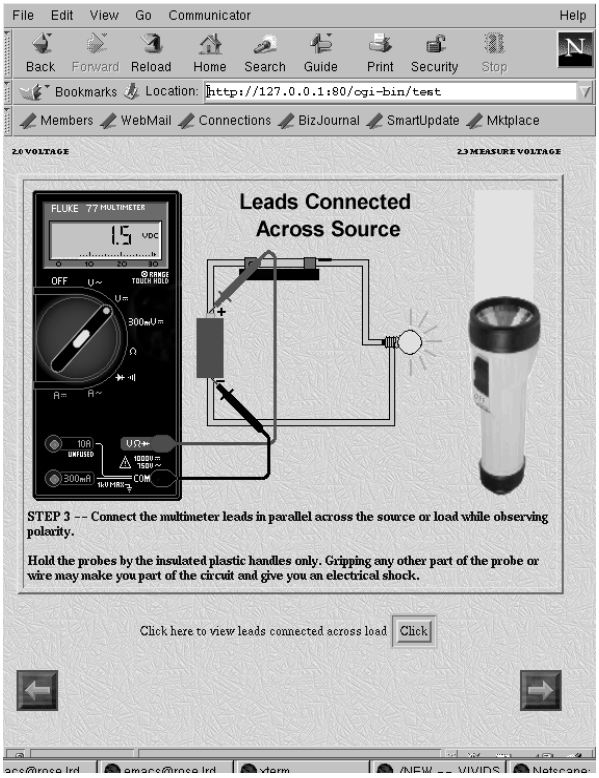

Figure 1: **Netscape Window**

Thus, we designed the pre/post-test for the formal study to focus on these troublesome concepts. We also slightly shortened the lessons by removing some material not essential to learning these concepts (e.g., how to interpret the colored stripes on resistors).

Twenty students took part in the final data collection effort. Each student was randomly assigned to either the Socratic condition or the Didactic condition, described above. Note that the Socratic tutoring style in this study did not typically include heavy use of Socratic irony (i.e., proof by contradiction) as a teaching tool.

Examples of Socratic and Didactic tutoring dialogues from our corpus are displayed in Figures 4 and 5 respectively. Both dialogues occurred during a lab in which the students were expected to find three places in a DC circuit where they could get a non-zero voltage reading. A very typical error students made was to attempt to get a non-zero voltage reading across a closed switch. Both the Socratic and Didactic dialogue examples occurred in response to this error. The important piece of information the tutor wanted to get across to the student in both cases was that it is only possible to get a non-zero voltage reading where there is a difference in charge, and there is no difference in charge across a switch. Notice that in both cases the tutor presented the students with questions to encourage the students to think through the reasoning behind their incorrect action. However, in the Socratic example, the student is doing more of the talking,

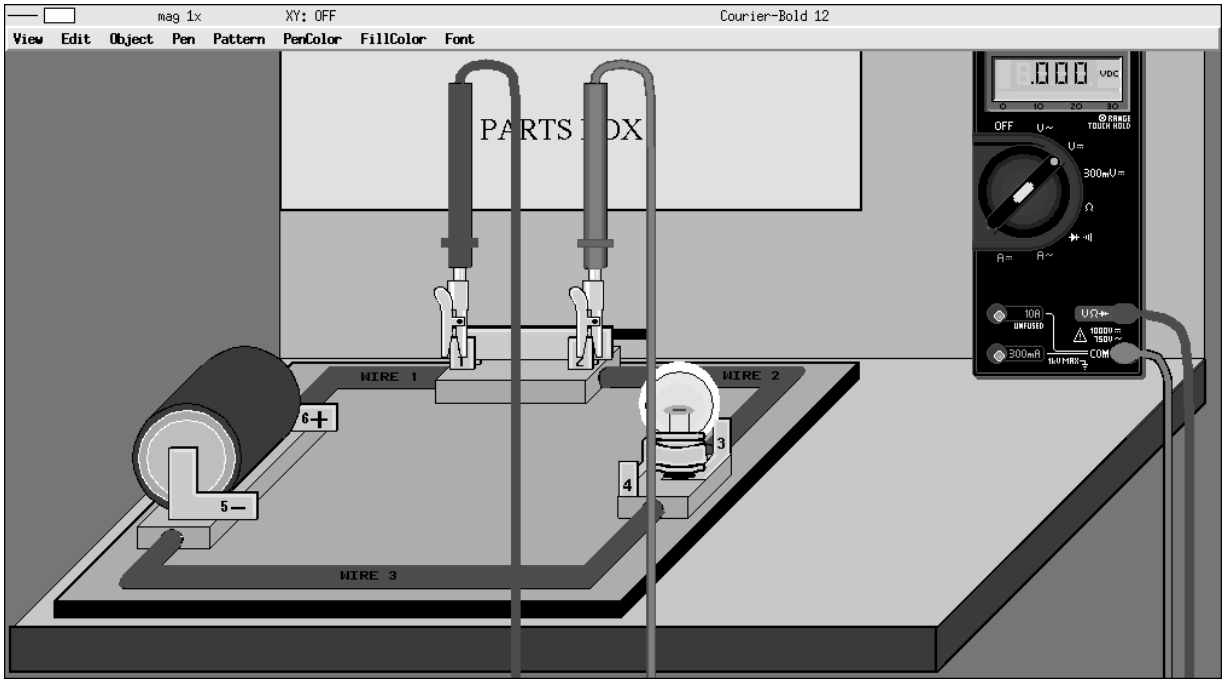

Figure 2: **Simulation Window**

where the Didactic example contains much more lecturing on the tutor's part. In the Didactic example, the tutor explained all that the student needed to know before asking the student any contentful questions. In contrast, in the Socratic example, the tutor asked contentful though questions from the beginning and explained as little as possible. In general, because in the Didactic condition the tutor was able to refer to parts of her own explanation that initiated the dialogue, the Didactic dialogues contained approximately 70% as many open ended questions such as why and how questions. Because in the Socratic condition the students were responsible for articulating as many key concepts as possible themselves, these open ended questions were essential for drawing out the students' reasoning.

Data Analysis

The data collected from the twenty students who participated in the formal study was used in a rule gain analysis to determine the relative effectiveness of the two alternative tutoring strategies. As in (VanLehn et al., 1998), the purpose of our rule gain analysis was to compute a correlation between student learning and the distinctive features of the two alternative tutorial styles. For each student we kept detailed records of their participation in our study as well as other information relevant to evaluating their learning. In particular, we recorded which of the two conditions the student was assigned to, the student's math and verbal SAT scores, the amount of time spent on each lesson and lab, the full text from all tutorial dialogues, and a pre and post-test. The same test was used for the pre-test as for the post-test. Note that students in

```
You can only get a non-zero voltage
reading across a portion of a circuit
where there is a difference in charge
(voltage potential)

There is a difference in voltage
potential across a source

There is a difference in voltage
potential across a load

Sources cause current to move because of
a difference in potential between their
two ends

Loads have a difference in potential
between their two ends because their
resistance causes them to convert
electrical energy into energy of a
different form
```

Figure 3: **Sample Rules for Difference in Voltage Potential**

the Didactic condition spent slightly more time interacting with the tutor and system overall (Socratic students spent an average of 192.68 minutes, SD=37.0; Didactic students spent an average of 198.72 minutes, SD=47.19), however the difference was not significant ($t(18)=.318$, $p=.754$).

For analyzing student learning, we codified the concepts we wanted to teach students into a list of 47 rules. For example, the five rules expressing basic concepts about voltage potential and voltage measurements are

```
Tutor:     So now let's think about the switch.  Is it a source or a load?

Student:   source

Tutor:     Why do you say that?

Student:   when it is turned off, no energy flows

Tutor:     OK, that is true.  But does it actually cause electricity to flow?
           Or is it merely letting what current was produced by the source
           flow through it to the rest of the circuit?

Student:   it does not create energy

Tutor:     Good.  So it is not a source.  Would you say it is a load then?

Student:   no

Tutor:     Good, it is neither a source nor a load.  So does it have a
           difference in charge between its two ends?

Student:   no

Tutor:     Very good.  So then can you measure voltage across a switch?

Student:   no

Tutor:     Right.  So how can you modify the way you have the leads hooked up
           now so that there will be a difference in charge between where the
           two leads are hooked up?

Student:   since i know there is a third place to hook them up, is it possible
           to connect the one to the negative side of the battery and connect
           the other to the positive of the light bulb?

Tutor:     Yes, that would be perfect.  Go ahead and do that.
```

Figure 4: Sample Socratic Dialogue

found in Figure 3. The pre/post test consists of 40 questions that require the students to use the rules either by applying a rule in order to solve a problem, directly articulating a rule, drawing a diagram to illustrate a rule, answering a question about a rule, or recognizing a diagram illustrating a rule. We coded each question in our pre/post test with a list of rules that applied to solving that problem and how those rules applied. For each rule we then developed a formula to assess the student's level of mastery of that rule based on which of the questions where the rule applied the student answered correctly. The formulas designed for computing the mastery score for each rule were based on the assumption that different ways rules apply to questions give different amounts of evidence about how well students have mastered the corresponding rule. For example, directly articulating a rule gives more evidence of student knowledge than answering a multiple choice question. Solving a problem by using a rule gives an even stronger indication. A total mastery score for each student was computed for both the pre and post-test by summing the mastery scores for the 47 individual rules. We also computed a gain score for each student by counting the number of rules for which each student demonstrated a higher mastery score on the post-test as compared with that on the pre-test. For each rule we noted how many students in each condition achieved a higher mastery score for that rule on the post-test as compared to the pre-test.

An ANCOVA with condition as the independent variable, pre-test score as the covariate, and post-test score as the dependent variable confirmed a trend for students in the Socratic condition to learn more (pre-test mean = 10.41, pre-test SD = 7.5, post-test mean = 27.54, post-test SD = 7.28) than students in the Didactic condition (pre-test mean = 14.29, pre-test SD = 53.12, post-test mean = 25.5, post-test SD = 6.31), $F(1, 18) = 3.13$; $p < .1$. Interestingly, despite the fact that the students in the Socratic condition had a lower average pre-test score than the students in the Didactic condition, they achieved a higher average post-test score. The effect size (mean Socratic gain score - mean Didactic gain score / SD Didactic gain score) was 1 sigma. Additionally, for each rule we computed a chi-square to determine whether the number of students who demonstrated learning on that rule in the Socratic condition was significantly higher than the number of students who demonstrated learning on that rule in the Didactic condition. The difference was only significant ($p < .05$) for two rules although for every rule more students in the Socratic condition than in the Didactic condition demonstrated learning. The probability that more students in the Socratic condition would demon-

```
Tutor:      Do you remember in the lesson that it said that every point on a
            conductor is electrically the same?

Student:    yes.

Tutor:      Good.  That means that there is no difference in potential energy
            between one point on the conductor and another point.  So, if both
            leads are attached to the same conductor, there is no difference
            in potential (in other words, no difference in charge) and thus no
            force to measure.  What you need is to have there be a difference
            in potential between where the red lead is attached and where the
            black lead is attached.  This is achieved whenever voltage is
            "created" as in a battery or "used up" as in a light bulb.  So,
            where do you suppose you could attach the leads now to achieve
            that?

Student:    to the light bulb, it seems to be my only source

Tutor:      Right.
```

Figure 5: Sample Didactic Dialogue

strate learning for all 47 rules by chance is very small, specifically $.5^{47}$. We found during our analysis, however, that in spite of having randomly assigned students to conditions, the average SAT score for students in the Socratic condition (1161, SD = 208) was marginally higher than that for students in the Didactic condition (961, SD = 192), F (1, 15) = 4.27, $p < .06$. Finding even a marginal trend with only 20 subjects suggests that the effect may be real even if the statistical power is not sufficient.

A re-analysis in which gain score (post test score minus pretest score) was the dependent variable and SAT score was a covariate was conducted for the 17 participants for whom SAT scores were available. The effect of condition was not significant in this analysis, F (1, 14) = 1.64, p ¿ .20, although the loss of power resulting from the exclusion of three participants from this analysis may have contributed to the lack of statistical significance. Thus, although the trend for greater gains in the Socratic condition was still evident after controlling for SAT scores, we can not conclusively rule out the influence of this possible confound on the results.

Next we checked for an aptitude-treatment interaction by dividing the students into two subsets, with students having above the mean SAT scores in one subset and those with below the mean SAT scores in the other subset. When the ANCOVA was performed on each subset separately, a trend was demonstrated for students in the Socratic condition to perform better within each subset. For above average SAT students, F (1,7) = 1.77, $p < .23$. For below average SAT students, F (1,4) = 5.62, $p < .1$. This seems to be a result of the fact that the below average SAT students tended to have uniformly low pre-test scores and variable post-test scores whereas the above the average SAT students had variable pre-test scores and uniformly high post-test scores.

Discussion and Current Directions

In this paper we present a study in which we explore the relative effectiveness of two alternative tutoring styles, which we have referred to as Socratic versus Didactic. The purpose of our study was to explore alternative methods of encouraging knowledge construction via tutorial dialogue in order to determine how to use dialogue most effectively to this end. The results of our rule gain analysis demonstrate that students in the Socratic condition learned more effectively than students in the Didactic condition, although more data collection is necessary in order to verify the level of statistical significance.

Based on our findings, we are building a dialogue-enhanced version of the original BE&E tutoring system. A small prototype dialogue based version has already been built covering the portion of our curriculum concerned with teaching about measuring voltage in DC circuits (Rosé et al., 1999). Note that in the example Socratic dialogue in Figure 4, the tutor affirmed what was correct in the student's response, that when a circuit is turned off no energy flows, and then addressed specifically what was lacking in the student's explanation. The same ability to evaluate the content of student explanations is required for the tutor to determine when it is no longer beneficial to continue prompting a student with leading questions. This type of sensitivity in tutor response is only possible in an intelligent tutoring system when the system can understand what the student says. Thus, a major focus of our work has been on robust natural language understanding (Rosé, 2000). Our robust core understanding component for English is currently being integrated into three different tutoring systems and is available for use on other projects[1].

Abstract

We present a study on the ability to comprehend conjunction, exclusive disjunction, bi-conditional and conditional. Mental model theory predicts differences in difficulty in dealing with such connectives, and it also predicts that it is easier to envisage situations that comply with an assertion than situations which do not comply. We carried out an experiment on children, adolescents and adults to validate these predictions within a developmental perspective. Participants had to judge some states of affairs as complying or not complying with sentences involving connectives. A further aim of the experiment was to test the power of the theory to account for connectives' comprehension within a pragmatic context. Thus, while half of the participants dealt with an abstract version of the task, the other half coped with a pragmatic version where the sentences were uttered by a character known as sincere in the complying condition and as a liar in the not complying condition. The results of the experiment show that difficulty in comprehension of the different connectives depends on the number of models they require. Also, the results show that it is easier to envisage situations complying with the meaning of a connective than situations which do not comply. The results hold for all groups of participants in both versions of the task. We conclude that mental model theory offers a plausible account of connectives' comprehension, which holds also within the investigated pragmatic context.

1. Introduction

Experimental data show that connectives vary in difficulty of comprehension. Conjunction *and* is handled by 2 years old children (Bloom, Lahey, Hood, Lifter & Fiess, 1980); disjunction *or* is understood after 4 years (Johansson & Sjolin, 1975); bi-conditional *only if then* emerges from 8 years of age but it is not fully mastered until 11;6 years (Staudenmayer & Bourne, 1977); conditional *if then* remains difficult even for 14 year old children, although around 5-6 years there is a clear improvement (Amidon, 1976; Staudenmayer & Bourne, 1977).

The connective interpretation varies from children to adolescents to adults. Conjunction is early understood as implying the co-occurrence of its constituents, even if children sometimes treat it as a disjunction (Johnson-Laird & Barres, 1994). Disjunction is commonly interpreted exclusively, namely as if it would imply a choice between the co-ordinated members and they should not be taken in combination; this kind of interpretation seems the favourite at every age (Staudenmayer & Bourne, 1977). To comprehend conditional relations, individuals have to grasp the possibility of relations between properties that are absent, but implied. The first achievement of this kind is the bi-conditional interpretation. Conditional interpretation is hardly caught even by adolescents and adults, who often interpret it as it would imply its converse, i.e. they usually give a bi-conditional interpretation (Taplin, 1971).

The meaning of the connectives has been mainly a concern of the theories on propositional reasoning, viz. the ability to reason with propositions and connectives. Some of these theories claim that the meaning of the connectives is conveyed by the truth-values they receive in a truth table system. For instance, Piaget and Inhelder (Inhelder & Piaget, 1958; Piaget, 1953) claim that people can construct true and false contingencies of propositions because they posses a mental logic: in their view, some truth functions and a set of transformations would develop by the early teens, so that children would grasp the meaning of the connectives.

Other theorists have proposed that the meaning of the connectives is grasped through natural deduction systems, where rules are claimed to have more psychological plausibility than standard logic (Braine, 1978; 1990; 1998, Braine & Rumain, 1983, Rips, 1990). In their view, the evaluation of contingencies complying with propositions would depend on the internal structure of the proposition itself: each connective would define which inferential rules can be applied and, therefore, how reasoners can envisage the correct contingencies.

In a radically alternative view, Pollard (1981) and Griggs and Cox (1982) claim that the understanding of the meaning of connectives depends on the reasoners' previous experience. In particular, the specific experiences encoded in memory would provide a set of domain dependent rules that reasoners can use in the current situation by analogy.

Cheng, Holyoak and colleagues analyze just the conditional connective and postulate the existence of abstract knowledge structures such as causation, obligation and permission (Cheng & Holyoak, 1985; Cheng, Holyoak, Nisbett & Oliver, 1986). They argue that the meaning of a conditional emerges from the concrete context within which it is introduced. For instance, a permission context would induce the reasoner to think about the possibility in which an action is done provided the precondition is satisfied.

All of the mentioned theories offer an explanation of how people represent the meaning of the connectives, but none of them gives a systematical account of their difference in terms of difficulty of comprehension.

Mental model theory offers such an account. Our investigation into the mental representations of the meaning of the connectives follows the tenets of this theory.

2. Mental Models for Connectives

Mental model theory (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991) claims that the meaning of the connectives is conveyed by mental models. A model is an analogical representation: it does reproduce the structure of the states of affairs perceived or described. For example, the theory claims that the meaning of an indicative conditional such as:

If you eat too many cakes, then you put on weight

is represented by the model representation:

[too many cakes] put on weight
...

Each row in the representation denotes a model of a separate possibility. The first model is explicit and satisfies the antecedent and the consequent, and the second model (dots) is implicit: it allows for the case in which the antecedent is not satisfied.

The construction of models is guided by the Principle of truth and the attempt to maintain as much information implicit as possible. According to the Principle of truth, each model represents only what is true in a particular possibility. Hence, the first model represents the possibility in which the antecedent (and then the consequent) is true. Reasoners do not represent the possibilities in which the antecedent is false. The theory postulates that reasoners make "mental footnotes" to keep track of this information, but that these footnotes are soon likely to be forgotten. To indicate these footnotes we use the square brackets and the dots. The square brackets indicate that the antecedent (i.e. too many cakes) has been exhaustively represented in relation to the occurrence of the consequent (i.e. put on weight), i.e. it can not occur in any other model of the conditional (see Johnson-Laird, Byrne & Schaeken, 1992). The dots denote the wholly implicit models, in which the antecedent is false. Therefore, the fully explicit representation of a conditional calls for three models. In our example:

too many cakes	put on weight
not- too many cakes	put on weight
not- too many cakes	not- put on weight

In essence, mental model theory (MMT hereafter) assumes that human reasoners tend not to represent information explicitly. In fact, the more information that has to be represented explicitly, the greater the load on the working memory, and so the initial models of a proposition represent as much information implicit as possible. Implicit information is not immediately available for processing, but it becomes available when it is made explicit (see e.g. Bara, Bucciarelli, Johnson-Laird & Lombardo, 1994).

The fully explicit models required by each connective and the implicit models which people tend to construct are in Table 1. In fact, constraints of working memory prevents people to imagine all the possible models of a connective, and because truth appears to be highly salient, people represent first what is true.

Table1: Mental models representing the meaning of connectives (fully explicit models).

Connectives	True instances		False instances	
	Implicit models	Explicit models		Explicit models
p *and* q	p q	p q		p ¬q ¬p q ¬p ¬q
p *or else* q	p q	p ¬q ¬p q		p q ¬p ¬q
only if p *then* q	p q …	p q ¬p ¬q		p ¬q ¬p q
if p *then* q	p q …	p q ¬p q ¬p ¬q		p ¬q

The models representing the false instances of a proposition (see Table 1) would be fleshed out afterwards, only if they are needed to make the deduction. Thus, the theory predicts that the mental representation of cases complying with the meaning of a connective (i.e. the true instances) is easier than that of not complying cases (i.e. the false instances). The prediction is confirmed by Barres and Johnson-Laird (1997). They carried out a study where the participants were asked to list the true and the false instances given an assertion, and they found that representing the false instances is more difficult than representing the true ones. Thus, they claim that there is no a direct way to imagine what is false and errors are likely to occur when listing the false instances. For example, given the assertion "A or B, or both", most of their subjects perform correctly, and list the following instances in which the assertion is true:

A

B

A B

Then, in order to infer the false instances, most subjects negate the true ones and list what follows:

not A

not B

not A not B

while we know the only false instance is:

not A not B

The aim of our experiment is to validate the following predictions within a developmental perspective. First, the difficulty of comprehension of the different connectives depends on the number of models they require. Second, in line with the study by Barres and Johnson-Laird (1997), to envisage the false instances of a connective is harder than to envisage the true instances. Also, we derive a corollary prediction from MMT and from the fact that working memory abilities, such as encoding abilities and the time information which can be maintained in memory (Cowan, 1997; Towse, Hitch & Hutton, 1998), are good predictors of the performance of subjects belonging to different age groups. Thus, the ability to deal with the not complying conditions should increase with age; such ability requires keeping in memory the true instances of a connective while deriving the false ones.

We tested these predictions using two different protocols: one in which the connectives are presented within an abstract context and the other in which they occur in a pragmatic context, where they are uttered by a character describing a certain state of affairs. We expect the evaluation of instances complying with the utterance proffered by a sincere character to be easier than the evaluation of instances not complying with the utterance proffered by a liar. This prediction parallels the prediction concerning complying versus not complying conditions in the abstract version of the task. In particular, granted that 7 year olds do possess the ability to think in term of lies, the requested abilities in the two contexts might be the same. Thus, we should detect an analogy between evaluating true instances of a sentence and understanding a person who is telling the truth, and between evaluating false instances of a sentence and understanding a person who is lying. In previous studies, MMT has been proved to account for the ability to comprehend connectives within different contexts, calling for the same basic principles (see, e.g. Bara, Bucciarelli & Lombardo, 2001). As people in everyday life have to deal with *utterances* rather than with abstract *sentences*, MMT for the meaning of connectives has to hold within pragmatic contexts as well as in abstract contexts.

To sum up, our aim is a validation of the following predictions:

i. The difficulty of comprehension of the meaning of the connectives depends on the number of models they require. Thus, we expect to observe the following trend of difficulty, from the easiest to the most difficult connective: conjunction (one model), exclusive disjunction and bi-conditional (two models), conditional (three models).

ii. The evaluation of cases not complying with a connective is more difficult than the evaluation of complying cases (from the Principle of truth). It requires first to represent the states of affairs consistent with the connective, then to negate them. Also, the ability to evaluate instances not complying with a connective would improve with age.

We expect these predictions to hold both in the abstract and in the pragmatic version of the task.

3. Experiment

Method

Participants. We tested a sample of 180 subjects, 60 in each of the following age groups: children from 7 to 7;9 years old, adolescents from 14 to 14;9 years old, adults from 21 to 24;9 years old. They were students from primary schools, high-schools and university residences, who took part in the experiment voluntarily. There was a balanced proportion of males and females in each group of participants.

Design. We devised two protocols: the Abstract Protocol and the Pragmatic Protocol. In the Abstract Protocol propositions were presented within an arbitrary context, whereas in the Pragmatic Protocol the context was provided by a character proffering the utterance. The participants were randomly assigned to one of the two protocols. Thus, half of the participants of each age group dealt with the Abstract Protocol and half with the Pragmatic Protocol.

In either protocol, subjects had to deal with two conditions: «complying» and «not complying». As for the Abstract Protocol, propositions in the complying condition were said to be true, while propositions in the not complying condition were said to be false. As for the Pragmatic Protocol, propositions in the complying condition were uttered by a character said to be sincere, while propositions in the not complying condition were uttered by a character said to be a liar. Each subject dealt with 8 propositions, 4 in the complying condition and 4 in the not complying condition. The order of presentation of propositions within each condition was determined at random.

In either protocol, after reading the proposition, the experimenter showed the subjects a set of 4 cards, each representing a possible state of affairs. For each card the experimenter asked the subject if it satisfied the proposition or not. The cards were presented in a random order.

Materials. In the Abstract Protocol we used the following materials:

- 8 sheets of paper; on each of them it was written a proposition containing one of the following connectives: *and*, *or*, *only if-then*, *if-then*. Each connective occurred in two propositions, but with different content;
- 8 series of cards: each series consisted of 4 cards. Given a proposition «A *connective* B» (for example, «There are an aeroplane *and* a car»), the four cards represented A and B together (aeroplane and car), A alone (aeroplane), B alone (car), and CD, two things different from the ones mentioned in the proposition (for example, train and boat). Four series of cards were used in the complying condition and four series in the not complying condition.

In the Pragmatic Protocol we used the following materials:
- the puppets Minnie and Lucy;
- 8 sheets of paper; on each of them it was written an utterance proffered by a character. Each utterance contained one of the following connectives: *and*, *or*, *only if-then*, *if-then*. Each connective occurred in two utterances, but with different content;
- 8 series of cards: each series consisted of 4 cards, as in the Abstract Protocol. Four series of cards were used in the complying condition and four series in the not complying condition.

Procedure. The participants were tested individually in a quiet room.

Abstract Protocol: complying condition. The participant was told that he will be presented with some true propositions. Then the experimenter showed the sheet of paper with the first proposition and read it. For example:

> «Either there is a parrot, or there is a fish, but not both». I'll show you some cards: you have to choose those satisfying the proposition.

Then, the experimenter showed one of the four cards (for example, the card representing the fish) and asked:

> Does a fish alone[1] satisfy the proposition?

and waited until the participant has judged the card as satisfying or not the proposition. Then, the experimenter showed another card of the set, questioned the participant and so on with the other cards.

The same procedure was followed with the other three propositions of the complying condition.

Abstract Protocol: not complying condition. The participant was told that he will be presented with some false propositions. The procedure was the same as that in the Abstract Protocol, complying condition.

Pragmatic Protocol: complying condition. Participant was introduced to a character, Minnie, said to be sincere and they are told that Minnie will have proffered utterances about some cards she owns. The experimenter began with the first proposition. For example:

> Minnie says «On each of my cards, only if there is a candle, then there is a book». Remember that Minnie always says the truth. I'll show you some cards, and you have to tell me which cards belong to Minnie.

Then, the experimenter showed one of the four cards (for example, the card representing the book) and asked:

> Can a book alone belong to Minnie?

and waited until the participant has judged the card as belong or not to the sincere character. Then, the experimenter showed another card of the set, questioned the participant and so on with the other cards.

The same procedure was followed with the other three propositions of the complying condition.

Pragmatic Protocol: not complying condition. Participant was introduced to a character, Lucy, said to be a liar and they are told that Lucia will have proffered utterances about some cards she owns. The procedure was the same as that in the Pragmatic Protocol, complying condition.

4. Results

The score was computed assigning one mark for each correct response (the choice of a card which would have to be chosen and the non-choice of a card which would have not to be chosen). So, the maximum score participants could obtain in each trial was 4.

i. Trend of difficulty in comprehension of the different connectives.

The trend in difficulty of comprehension of the different connectives is confirmed in the Abstract Protocol (see Table 2).

Table 2: Mean scores obtained by participants in the Abstract Protocol.

Age groups	Connectives			Mean score
	and	*or/only if-then*	*if-then*	
7-7;9	3.28	2.85	1.97	2.70
14-14;9	3.58	3.26	1.88	2.91
21-24;9	3.87	3.33	2.10	3.10
Overall	3.58	3.15	1.98	2.90

Participants find it easier to comprehend the meaning of «*and*» than the meaning of «*or/only if-then*»: the difference is statistically significant in each age group (paired T Test; t value ranging from 2.607 to 9.406, p value ranging from <.001 to p=.007). Also, participants find it easier to comprehend the meaning of the connectives «*or/only if-then*» than the meaning of «*if-then*»: again, the difference is statistically significant in each age group (paired T test; t value ranging from 6.520 to 19.746, p value is always <.001).

[1] The cards are intended to correspond to the instances pq, p not q, not p q and not p not q. Thus, as the participant received pq, p, q and rs, we wanted to clarify that an implicit negation is intended.

Also, the results show that the knowledge of the meaning of the different connectives does increase with age (ANOVA one-way; F= 7.593, p<.001).

The same results hold in the Pragmatic Protocol (see Table 3).

Table 3: Mean scores obtained by participants in the Pragmatic Protocol.

Age groups	Connectives			Mean score
	and	*or/only if-then*	*if-then*	
7-7;9	3.12	2.63	2.02	2.59
14-14;9	3.55	3.18	2.12	2.95
21-24;9	3.37	3.22	2.20	2.93
Overall	3.35	3.01	2.11	2.82

Participants find it easier to deal with «*and*» than with «*or/only if-then*», and the difference is statistically significant in each age group (paired T Test; t value ranging from 3.447 to 3.768, p value ranging from <.001 to p=.005). An exception are adults: their performance with the different connectives is in the predicted direction, however, the difference is not statistically significant (paired T Test; t= 1.260, p=.109). Further, the participants find it easier to deal with the connectives «*or/only if-then*» than with «*if-then*», and the difference is statistically significant in each age group (paired T Test; t value ranging from 4.389 to 12.853, p value is always <.001).

The results show that also within the pragmatic context the knowledge of the meaning of the different connectives does increase with age (ANOVA one-way; F= 7.142, p<.001).

ii. The evaluation of cases complying with a connective is easier than the evaluation of cases not complying.

In the Abstract Protocol the prediction is confirmed (see Table 4).

Table 4: Mean scores obtained by participants in the two conditions of the Abstract Protocol.

Age groups	*Complying*	*Not complying*
7-7;9	2.75	2.53
14-14;9	3.07	2.93
21-24;9	3.24	3.07
Overall	3.02	2.84

All groups of participants performed better in the complying condition than in the not complying condition: the difference is statistically significant in each age group (paired T Test; t value ranging from 1.772 to 3.553, p value ranging from <.002 to <.05).

Also, within the Abstract Protocol the ability to evaluate instances not complying with a connective improve with age, as we predicted (ANOVA one-way; F= 7.249, p<.001).

The same results hold in the Pragmatic Protocol (see Table 5).

Table 5: Mean scores obtained by participants in the two conditions of the Pragmatic Protocol.

Age groups	*Complying*	*Not complying*
7-7;9	2.79	2.40
14-14;9	3.21	2.81
21-24;9	3.08	2.92
Overall	3.03	2.71

All groups of participants performed better in the complying condition than in the not complying condition, and the difference is statistically significant in each age group (paired T Test; t value ranging from 1.746 to 3.972, p value ranging from <.001 to <.05). Also within the Pragmatic Protocol the ability to evaluate instances not complying with a connective improve with age, as we predicted (ANOVA one-way; F= 5.994, p<.004).

Thus, MMT predictions hold both within the Abstract and the Pragmatic Protocol.

5. Conclusions

The aim of the experiment was to test the power of MMT in explaining how people represent the meaning of connectives in their mind. The results of the experiment confirm our predictions.

First, the difficulty in comprehending the meaning of a connective depends on the number of mental models it requires. Our results show the following trend of difficulty among connectives in both the Abstract and the Pragmatic Protocol: conjunction is easier than disjunction and bi-conditional, and the latter are easier than conditional.

Second, MMT predicts that, according to the Principle of truth, evaluating instances of compliance is easier than evaluating instances of non-compliance. Our data confirm such a prediction in both contexts. We have argued, in line with MMT, that the evaluation of instances not consistent with a connective leads subjects to err because they have to imagine first the true instances and then to infer the false ones. The corollary prediction that the ability to evaluate instances of non-compliance does increase with the age is also confirmed.

Our results are consistent with the results obtained by Bucciarelli e Johnson-Laird (2001). They investigate reasoning with conditionals within contexts where subjects have to construct instances complying with an assertion (i.e. instances of truth and obedience) and instances not complying with an assertion (i.e. lie and disobedience). Their results show that, while in a selection task the not complying context improves the performance, in a comprehension task participants are better at constructing cases of compliance than cases of non-compliance.

Our results corroborate MMT's predictions in three different age groups (children, adolescents and adults). These results strengthen the theory, which is powerful enough to predict and explain the development of connectives' comprehension. In particular, MMT explains the different difficulty of connectives, the difference in difficulty of comprehension of the same connective (easier in complying conditions, and more difficult in not complying conditions) and, finally, how people represent the meaning of the connectives both within an abstract context and a pragmatic context.

Abstract

Parallel pattern recognition requires great computational resources. It is desirable from an engineering point of view to achieve good performance with limited resources. For this purpose, we develop a serial model for visual pattern recognition based on the primate selective attention mechanism. The idea in selective attention is that not all parts of an image give us information. If we can attend to only the relevant parts, we can recognize the image more quickly and using less resources. We simulate the primitive, bottom-up attentive level of the human visual system with a saliency scheme, and the more complex, top-down, temporally sequential associative level with observable Markov models. In between, there is an artificial neural network that analyses image parts and generates posterior probabilities as observations to the Markov model. We test our model on a well-studied handwritten numeral recognition problem, and show how various performance related factors can be manipulated. Our results indicate the promise of this approach in complicated vision applications.

Introduction

Primates solve the problem of visual object recognition and scene analysis in a serial fashion with *scanpaths* (Noton & Stark, 1971), which is slower but less costly than parallel recognition (Tsotsos, Culhane, Wai, Lai, Davis, Nuflo, 1995). The idea in selective attention is that not all parts of an image give us information and analysing only the relevant parts of the image in detail is sufficient for recognition and classification.

The biological structure of the eye is such that a high-resolution fovea and its low-resolution periphery provide data for recognition purposes. The fovea is not static, but is moved around the visual field in saccades. These sharp, directed movements of the fovea are not random. The periphery provides low-resolution information, which is processed to reveal salient points as targets for the fovea (Koch & Ullman, 1985), and those are inspected with the fovea. The eye movements are a part of overt attention, as opposed to covert attention which is the process of moving an attentional *'spotlight'* around the perceived image without moving the eye.

In the primate brain, information from the retina is routed through the lateral geniculate nucleus (LGN) to the visual area V1 in the occipital lobe. The *'what'* pathway, also known as the *ventral* pathway for anatomical reasons, goes through V4 and inferotemporal cortex (IT). The *'where'* pathway, or the *dorsal* pathway, goes into the posterior parietal areas (PP) (Ungerleider & Mishkin, 1982). The ventral pathway is crucial for recognition and identification of objects, whereas the dorsal pathway mediates the location of those objects. We should note that although recent findings point towards a distinction between perception and guidance of action (Crick & Koch, 1990) instead of a distinction between different types of perception, the issue is not resolved in favour of a specific theory (Milner & Goodale, 1995).

The serial recognition process gathers two types of information from the image: The contents of the fovea window, and the location to which the fovea is directed. We call these *'what'* and *'where'* information, respectively (Ungerleider & Mishkin, 1982). The object is thus represented as a temporal sequence, where at each time step, the content of the fovea window and the fovea position are observed.

Recurrent multi-layer perceptrons were used to simultaneously learn both the fovea features and the class sequences (Alpaydın, 1996). Other techniques are explored in the literature to apply the idea of selective attention to classification and analysis tasks (Itti, Koch, Niebur, 1998; Rimey & Brown, 1990). Our approach is to combine a feature integration scheme (Treisman & Gelade, 1980) with a Markov model (Rimey & Brown, 1990).

We use handwritten numeral recognition to test our scheme. In our database (UCI Machine Learning Repository, Optdigits Database), there are ten classes (numerals from zero to nine) with 1934 training, 946 writer-dependent cross-validation, 943 writer-dependent and 1797 writer-independent test cases. Each sample is a 32 32 binary image which is normalized to fit the bounding box. There are parallel architectures to solve this problem in the literature (Le Cun, Boser, Denker, Henderson, Howard, Hubbard, Jackel, 1989), and they have good performance, but our aim is to design a scalable system which is applicable to problems where the input data is high-dimensional (e.g. face recognition), or not of fixed size (e.g. recognizing words in cursive handwriting). Implementing a parallel scheme with good performance is not trivial in such cases.

This paper is organized as follows: We first describe our model and its three levels. Then we report our simulation results. In the last section we summarize and indi-

cate future directions.

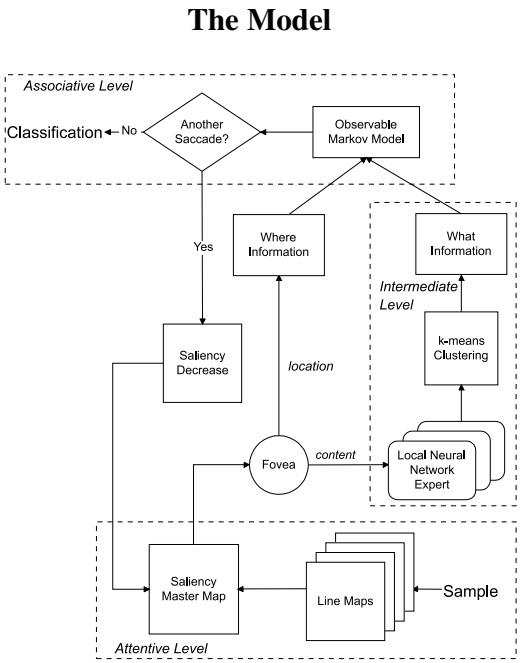

Figure 1: The selective attention model for visual recognition.

The block diagram of the system we propose is given in Fig. 1. It is composed of the *attentive level* that decides on where to look, the *intermediate level* that analyses the content of the fovea, and the *associative level* that integrates the information in time.

Attentive Level

In the first step of the model, the bottom-up part of the visual system is simulated. We work on 12 12 downsampled images to simulate a low-resolution resource. This slightly decreases the classification accuracy, but speeds up the computation considerably. Convolving the digit image with 3 3 line orientation kernels produces four line orientation maps in 0 , 45 , 90 and 135 angles. These are combined in a saliency master map, which indicates the presence of aligned lines on the image.

Line orientations are detected by different primitive mechanisms in the visual cortex, operating in coarse, intermediate and fine scales (Foster & Westland, 1998). We can also talk about simple, complex and hypercomplex cell structures in the visual cortex, that deal with increasing levels of complexity and decreasing levels of resolution. In constructing the saliency map, we use the simplest set of features to decrease the computational cost. Our experiments showed that adding other feature detectors like corner maps, Canny edge detector, and further line orientation maps in higher resolutions increased the classification accuracy only slightly, whereas the increase in the computational cost was significant.

The saliency map indicates the interesting spots on the image. We simulate the fovea by moving a 4 4 window over the 12 12 downsampled image. The saliency values of the visited spots and their periphery are decreased, and these spots are not visited again. This process has a biological counterpart: Once neurons attuned to detect a specific feature fire in the brain, they are temporarily inhibited. Subsequently, subjects respond slower to previously cued locations (Klein, 2000).

Intermediate Level

The simulation of shifts of attention should provide us with *'what'* and *'where'* information, but we want them to be sufficiently quantized to be used in the associative level. We divide the image space into uniform regions, in effect, performing a quantization on the location information. We use a second set of overlappping windows to reduce the effect of window boundaries, as shown in Fig. 2. We obtain a time-ordered sequence of visited regions after the simulation of shifts. This constitutes the *'where'* stream for the particular sample (Fig 3).

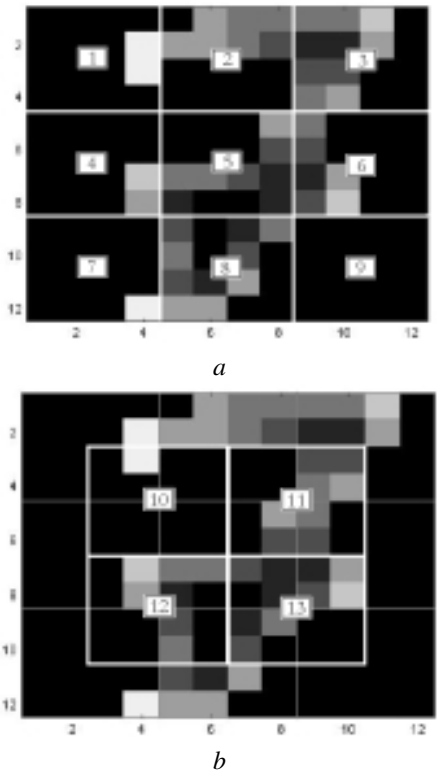

Figure 2: Regions of the downsampled image. (a) The uniform regions. (b) The additional, overlapping regions. Notice how the corner at the intersection of 5^{th}, 6^{th}, 8^{th}, and 9^{th} regions are missed in those regions, but captured clearly in the 13^{th} region.

As fovea contents, we extract 64-dimensional real-valued vectors. These vectors are produced by concate-

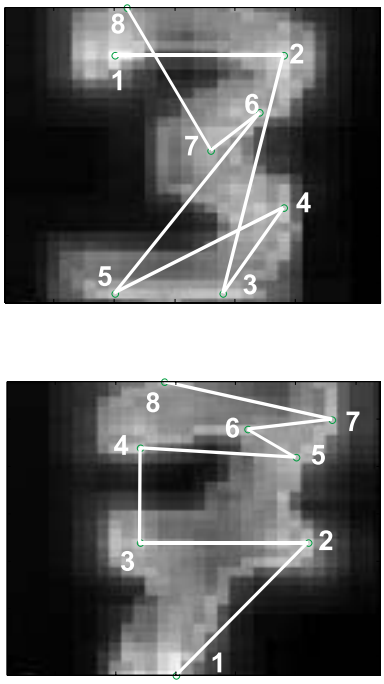

Figure 3: The saliency master maps of two examples from the Optdigits database. Locations with high intensity indicate high saliency values. The locations visited by the fovea are connected with a line, and enumerated in the order they are visited.

nating the corresponding 4 4 windows on the line maps. We prefer using the concatenated line maps to inspecting the original bitmap image, because the line maps indicate the presence of features more precisely. Furthermore, since they were constructed in the attentive level, they come at no additional cost. In any case, we need a vector quantization on the fovea contents before passing them to the associative level.

In order to efficiently quantize this information, we train artificial neural network experts at each region of the image. The experts are single-layer perceptrons (SLP) that are trained in a supervised manner (Bishop, 1995). Their input is the 64-dimensional fovea content vector. The output of the experts are 10-dimensional class posterior probability vectors, which are then clustered with k-means clustering (Duda & Hart, 1973) to obtain the *'what'* information stream. We select single-layer perceptrons over multi-layer perceptrons for a number of reasons. Multi-layer perceptrons overlearn the training data quickly, and perform worse on the cross-validation set. The number of parameters we need to store for the multi-layer perceptron is larger, and the training time is significantly higher. These properties make the single-layer perceptron the better choice of expert in the final model.

Associative Level

In the associative level, the two types of quantized information are combined with a discrete, observable Markov model (OMM) (Rabiner 1989). We treat the regions visited by the fovea as the states of a Markov model, and the quantized output of the local artificial neural network experts as the observations from each state. We simulate eight shifts for each sample in the training set, obtain the *'where'* and *'what'* streams, and adjust the probabilities of the single Markov chain of the corresponding class to maximize the likelihood of the training data. Training an observable Markov model is much faster than training a Hidden Markov Model.

In the observable model, the model parameters are directly observed from the data. Since we know the states, we can count the state transitions, and normalize the count to find the state transition probabilities a_{ij}, as well as the initial state distribution probabilities π_i. Similarly, we count the occurrences of the observation symbols (quantized outputs of the local neural networks) at each state, and normalize them to find the observation symbol probability distribution $b_j\ k$:

$$\pi_i \qquad \frac{\#\text{ of times in } S_i \text{ at time } t \quad 1}{\#\text{ of observation sequences}} \tag{1}$$

$$a_{ij} \qquad \frac{\#\text{ of transitions from } S_i \text{ to } S_j}{\#\text{ of transitions from } S_i} \tag{2}$$

$$b_j\ k \qquad \frac{\#\text{ of times in } S_j \text{ observing } v_k}{\#\text{ of times in } S_j} \tag{3}$$

Finding the probability of the observation sequence is much simpler in the observable Markov model, since the states are visible. We just multiply the corresponding state transition probabilities and the observation probabilities:

$$P\ O\ S\ \lambda \qquad \pi_{S_1} b_{S_1}\ v_1 \prod_{i\ 2}^{n} a_{S_i\ 1 S_i} b_{S_i}\ v_i \tag{4}$$

where S is the state sequence, O is the observation sequence, and $\lambda \qquad \pi_i\ a_{ij}\ b_j\ k$ stands for the parameters of the Markov model. $i\ j \quad 1\ N$ are indices for states, $k \quad 1\ M$ is the index for the observation symbols.

The Markov model is trained with a limited training set, and if the number of states and observation symbols is large, there will be connections that are not visited at all. Since the model is probabilistic, having a transition or observation probability of zero is not desired. Instead, the transitions that have not occurred within the training set should have a low probability in the model. This is what we do in the post-processing stage. We scan the probabilities of the trained Markov model, and replace all probabilities lower than a threshold (0 001) with the threshold value. Then we normalize the probabilities once more. This is a simple and fast procedure that achieves the desired effect.

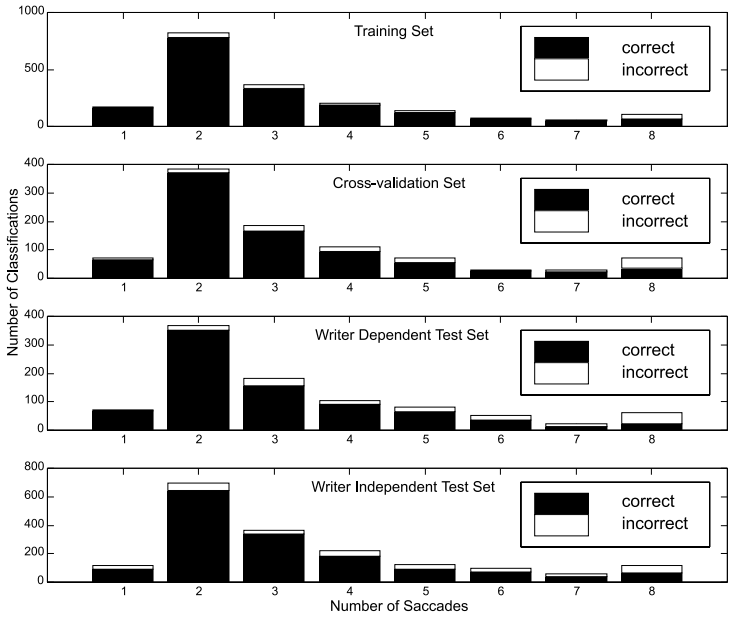

Figure 4: Dynamic fovea simulation results. These are the histograms of the number of correctly and incorrectly classified digits after each shift. See also Figs. 5 and 6.

We have also tried Hidden Markov Models where the states are not visible and where the concatenated *where-what* information is the observation, but this structure performed worse than the observable Markov model.

Dynamic Fovea

One important advantage of using a Markov model is the ease with which we can control the number of shifts necessary for recognition. In the training period, our model simulates eight shifts, which is set as the upper bound for this particular application. After each shift, the Markov model has enough information to give a posterior probability for each class. We may calculate the probability $\alpha_t\ c$ of the partial sequence in the Markov model, which reflects the probability of the sample belonging to a particular class, given the *'where'* and *'what'* information observed so far. Using Eq. 4, we have

$$\alpha_t\ c \quad P\ O_1 \quad O_t\ S_1 \quad S_t\ \lambda_c \tag{5}$$

where $O_1 \quad O_t$ is the observation sequence up to time t, $S_1 \quad S_t$ is the state sequence, and λ_c are the parameters of the Markov model for class c.

We can use this probability to stop our shifts whenever we reach a sufficient level of confidence in our decision. Let us define $\alpha_t\ c$, the posterior probability for class c at time t:

$$\hat{p}\ c\ O_1 \quad O_t\ S_1 \quad S_t \quad \alpha_t\ c \quad \frac{\alpha_t\ c}{\sum_{j\ 1}^{K} \alpha_t\ j} \tag{6}$$

Let τ be the threshold we use as our stopping criterion:

$$\alpha_t\ c \quad \tau \tag{7}$$

where the value of τ is in the range [0,1]. If we assume that absolute certainty is not reached anywhere in the model and $\alpha_t\ i$ is always below 1 0, selecting $\tau \quad 1\ 0$ is equivalent to treating all samples as equally difficult and doing eight shifts. Conversely, selecting $\tau \quad 0$ is equivalent to looking at the first salient spot and classifying the sample.

Selecting a large value for τ trades off speed for accuracy. With a well selected value, we devote more time for difficult samples, but recognize a trivial sample in a few shifts.

Results

In this section we present our simulation results. We give additional information about the techniques we employ in subsections.

Local Experts

Implementing local artificial neural network experts both increases the classification accuracy and decreases the complexity and classification time. The single-layer perceptron returns a 10-dimensional vector from a 64-dimensional linemap image. Since it is trained in a supervised manner, it provides more useful information for classification to the later Markov model, as our experiments indicated.

Dynamic Fovea Simulation

When we simulate the dynamic fovea with a fixed threshold of τ 0 95, we get 85 67 per cent classification accuracy with 5 46 per cent standard deviation on the writer-dependent test set. The average number of shifts is 3 33, which corresponds roughly to seeing one thirds of the image in detail. This justifies our claim that analyzing only a small part of the image is enough to recognize it. On the writer independent test set, the classification accuracy is 84 63 per cent, with a standard deviation of 7 58 per cent, and the average number of shifts is 3 37 (See Fig. 4 for the histograms depicting the distribution of classifications over the shifts). We are doing less than half the number of shifts we were doing, but the performance decrease is less than a standard deviation.

The advantages of simulating a dynamic fovea become apparent when we inspect Figs. 5 and 6. The accuracy of classification increases when we increase the threshold, because a higher threshold means making more shifts to get a more confident answer. A lower threshold means that a quick response is accepted. What happens is that the average number of shifts increase sharply if the threshold is set to a value very close to 1.0. In this case, the classifier cannot exceed the threshold probability with eight shifts, and selects the highest probability class, without doing any more shifts. This is the reason behind the relatively high number of correct and incorrect classifications after eight shifts in Fig. 4.

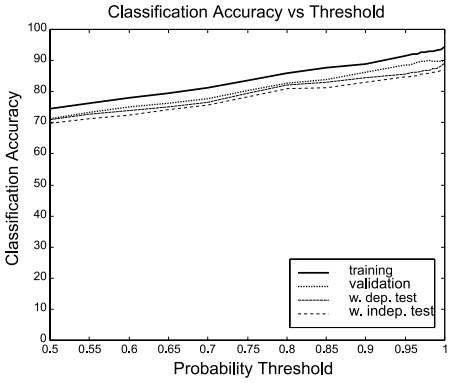

Figure 5: Accuracy vs threshold value in dynamic fovea simulation

Simulation Results

We summarize the results we obtain in Table 1. The first column of the table shows the method employed. The successive columns indicate the classification accuracy and its standard deviation on the training, cross-validation, writer-dependent test and writer-independent test sets.

In the first two rows, we do eight shifts, generate the posterior probabilities of classes by the local artificial neural network experts and take a vote without treating them as a sequence. Soft Voting takes into account the 10-dimensional outputs of the experts instead of a single class code. Comparing the results with the OMM results show that the order information which is lost during voting but used in OMM is useful. Another observation is that the post-processing method we use increases the performance by one standard deviation, which is a significant increase.

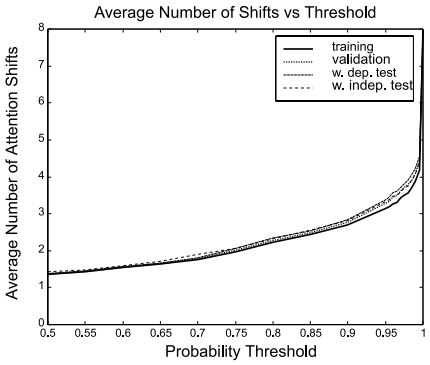

Figure 6: Average number of shifts vs threshold value in dynamic fovea simulation

The dynamic fovea simulation has a lower classification accuracy, but it only needs 3 2 shifts on the average, instead of the previous eight.

Finally, the last row indicates the accuracy of an all-parallel scheme. We use a multi-layer perceptron (MLP) with 32 32 binary input and 10 hidden units. Although the MLP has a good accuracy in this problem, it is not scalable due to the curse of dimensionality.

Conclusions and Future Work

The selective attention mechanism exploits the fact that real images often contain vast areas of data that are insignificant from the perspective of recognition. A low-resolution, downsampled image is scanned in parallel to find interesting locations through a saliency map, and complex features are detected at those locations by means of a high-resolution fovea. Recognition is done serially as the location and feature information is combined in time. By keeping the parallel part of the method simple, we can speed-up the recognition process considerably.

Our tests have demonstrated that an observable Markov model may replace an HMM for the two-pathway selective attention model. The observable scheme is easier to train and use, and performs better. The dynamic fovea simulation reveals further benefits of serializing the recognition process. We can control the time we spend on an image, and differentiate between simple and confusing images. This is a desirable property in a classifier, since it allows us to apply more reliable and costly methods to the confusing samples if we wish. It also reduces the average recognition time, but it

Table 1: Summary of Results

Method	Performance			
	Training	**Validation**	**Writer Dep. Test**	**Writer Indep. Test**
SLP+Simple Voting	86.74(9.90)	85.92(9.39)	64.51(25.62)	62.66(25.74)
SLP+Soft Voting	93.85(4.47)	91.25(7.07)	74.35(27.66)	73.89(26.67)
OMM+SLP	95.32(3.72)	83.98(15.37)	84.42(14.94)	80.92(16.24)
OMM+SLP + post-processing	94.37(3.33)	90.07(7.92)	89.73(8.68)	87.37(8.73)
Dynamic fovea	91.41(4.56)	88.47(7.98)	85.67(5.46)	84.63(7.58)
MLP	99.92(0.12)	97.45(0.28)	97.25(0.42)	94.54(0.21)

must be remembered that the construction of the saliency map is necessary for all samples. Although we reduce the time complexity of the associative level by half, the overall gain is less than that.

Our attempt to classify digits may be seen as a toy problem, since the ratio of the fovea area to the image is not high enough to demonstrate the benefits of our model. Although the accuracy is lower than the state-of-the-art parallel approaches in the literature (e.g. the MLP result in Table 1), the selective attention mechanism is much more appropriate for applications where parallel processing is too cumbersome to use, and the number of input dimensions is high.

We are planning to employ our model in a more difficult task, such as face recognition, where an all-parallel classifier, like the MLP, would be unnecessarily complex; in a face, small regions of the face like eyes, nose, mouth give us information. The saliency scheme has to be modified for this purpose, as facial features necessitate different and more complex feature detectors. The fovea size also needs to be adjusted for the specific task.

Solving arithmetic operations: a semantic approach

Emmanuel Sander (sander@univ-paris8.fr)
University of Paris 8, Department of Psychology, 2 Rue de la Liberté
Saint-Denis, 93526 France

Abstract

Systematic errors observed when solving arithmetic operations are often considered as being procedural. Rules induced by the learner and the errors committed are viewed as resulting by use of general problem solving methods. In this study, in the case of solving column subtractions, we show that some errors may be semantic: they are due to analogies involving different sources that guide the interpretation of both operations and procedures already learned. Two sources have been identified: (i) subtracting considered as removing something and (ii) subtracting considered as covering a distance between two elements. Results of the 2 experiments reported here show that (i) not only all of the predicted semantic errors were observed among beginner children, but also that (ii) semantic errors were still observed among more advanced learners, in a decreasing proportion for higher level of instruction. These results support the idea that (i) semantic aspects have a major influence in the learning process, and (ii) that this kind of errors still intervene in the learning process even if the procedural aspects become more influent (advanced students). These results suggest that a procedural approach might be articulated with a semantic approach.

Introduction

Many studies show that some errors made when solving arithmetic operations (e.g. Brown & Burton, 1978; Sleeman, 1982), and notably when solving column subtractions (e.g. Young & O'Shea, 1981, VanLehn, 1982, 1983, 1987, 1990), are systematic in nature. As it has been observed, some errors are quite stable, both for within or between subjects' measures. This led researchers to reject the idea that all errors are calculation errors or due to lack of attention, and therefore, to look for mechanisms that lead to these errors.

As it has been noticed by Ohlson and Rees (1991), most of the investigators in this field focused attention on procedural mechanisms. The most prominent view for column subtractions has been developed by VanLehn and his colleagues (e.g. Brown & VanLehn, 1980; VanLehn, 1982, 1990) and has promoted the repair theory that has been implemented in the SIERRA Model (VanLehn, 1987, 1990).

In this view, conjunction of two mechanisms may lead to error production. First, learning consists on inducing rules in a syntactic way from lessons composed of solved examples, using general problem solving methods. Second, errors result from application of problem solving heuristics to overcome the impasses encountered when solving a new operation.

This theory can be qualified as procedural because the only parameters which intervene in the model are (i) knowledge about specific arithmetic facts (for instance the fact that 2 is smaller than 5 or 7 – 4 = 3), (ii) heuristics for deriving rules from previously solved examples, (iii) heuristics for solving an impasse situation which has been encountered when previously learned rules have been applied to a new situation. One characteristic of a procedural approach is that the children's interpretation of both the whole operation and the procedure is not taken into account.

Framework

Although VanLehn (e.g. 1990) shows convincing evidence of procedural errors, the exhaustiveness of his description could be questioned. In this paper, we intend to provide evidence that a procedural approach doesn't provide an explanation for some of the systematic errors observed and that articulating this approach with a semantic point of view may increase the range of explained errors. This will show as well that in a procedural situation par excellence, such as solving column subtractions that could be solved in a purely syntactical manner (Resnick, 1982), semantic aspects still influence the solving process. This point has some implications on problem solving mechanisms.

Some work focused on the influence of semantic aspects in solving column subtractions (Carpenter, Franke, Jacobs & Fennema, 1996; Fuson, 1986; Fuson & Briars, 1990; Hiebert & Wearne, 1996; Resnick, 1982; Resnick & Omanson, 1987). Through the use of analogies and/or concrete materials, these studies evaluated the influence of a teaching method and aimed on helping children to understand some of the conceptual background of column subtractions solving methods. The efficiency of these methods is rather variable. In this work, we do not adopt any position in the debate concerning virtues of providing conceptual background versus teaching procedures as if they were arbitrary, but we shall show that semantic aspects are involved spontaneously even if they are not an explicit part of the teaching method. They are expressions of a basic analogical transfer mechanism that attributes a

meaning to a given situation. Such semantic influences have been identified for arithmetic operations by Fischbein (Fischbein, Deri, Nello & Marino, 1985 ; Fischbein, 1989) with the notion of tacit models. These are simple structural entities of a concrete and practical nature, which control the course of the reasoning process and are specific cases of analogy sources (Fischbein, 1987; Sander, 2000). Fischbein and his colleagues worked mainly with word problems and didn't extend their view to procedural situations such as column subtractions.

In the case of solving column subtraction, we hypothesize that errors are not necessarily due to a repair used in an impasse situation. Rather, they are sometimes a direct consequence of the interpretation of a learned procedure: the child applies the procedures according to her/his interpretation and the wrong result might be predicted from this irrelevant interpretation. In order to deal with the target situation (the column subtraction), s/he refers to a source knowledge, which is the knowledge associated with this new subtracting situation. In fact, we hypothesize that the semantic errors observed in column subtractions result from an analogical transfer in situations for which the source is non adequate. Thus, the errors are consequences of a negative transfer. We consider two sources of analogy for solving column subtractions: 'remove' and 'distance'. Both of them can be evoked spontaneously by the children or be due to the teaching method.

In the 'remove' view, subtracting is seen as taking a part out of a whole: the whole and the part are the two quantities and the result is what is left. In the 'distance' view, subtracting is seen as going from a given point to another: the departure and the arrival points are the two values and the result is the distance between them. These interpretations are valid for each value of the whole operation, but the negative transfer is due to its extension to each column and to each digit of the operation. If the operation is interpreted through these sources, the resulting errors can be predicted by these hypothesized sources. Using the terminology of VanLehn (1990), those errors are described in Table 1.

It can be noticed that most of the errors might result from distance or remove interpretations and thus, verbal reports might be useful for identifying the source. It can also be noticed that two errors (Diff 0-N=N and Diff 0-N=0) might sometimes be particular cases of other errors (respectively Smaller from Larger and Zero instead of Borrow) but they might also be specific to the cases involving zero, which could be identified either by verbal reports or by the presence of one error when the other is absent.

From our point of view, when starting to learn, children build interpretations of the operation and of the procedures through analogical transfer mechanism. This

Table 1: Definition and interpretation of semantic errors

Smaller from Larger (e.g. 457-168=311)
Definition: The smaller digit from each column is subtracted from the larger one wherever it is situated.
Remove interpretation: When a part is removed from a whole, the part is always smaller than the whole.
Distance interpretation: As a distance is symmetrical, the distance from the smaller to the larger is equal to the distance from the larger to the smaller.
Zero instead of Borrow (e.g. 457-168=300)
Definition: A zero is written instead of borrowing.
Remove interpretation: If what has to be removed is more than what is available, then it is removed and a zero is left. The impossibility of removing a quantity larger than the whole might also be marked by a zero.
Distance interpretation: In this case, distance is considered as oriented. If one considers that it is only possible to go upward, the distance is zero when the departure point is situated after the arrival point.
Blank instead of Borrow (e.g. 457-168=3 _).
Definition: Nothing is written instead of borrowing.
Remove interpretation: No answer is given in the corresponding column to signal the impossibility of removing something larger than what is actually there.
Distance interpretation: The impossibility to go backward is marked by a non-answer to the corresponding column.
Stutter subtract (e.g. 457-3=124)
Definition: The last digit of the same line takes the place of a blank.
Remove interpretation: Two quantities are needed when removing a part, thus the missing quantity is replaced by the closer one.
Distance interpretation: Departure point and arrival point are both needed to go from one place to another. Thus, the missing point is replaced by the closer one.
Diff 0-N=N (e.g. 400-168=368)
Definition: If one of the upward digits is zero, the downward digit is written as the result.
Remove interpretation: Nothing can be taken from zero so the original value is unchanged.
Distance interpretation: None.
Diff 0-N=0 (e.g. 400-168=300)
Definition: If one of the upward digits is a zero, zero is written as the result.
Remove interpretation: The impossibility of taking something from zero is marked by a zero result.
Distance interpretation: None.
Diff N-0=0 (e.g. 457-100=300)
Definition: If one of the downward digits is zero, the zero is written as the result.
Remove interpretation: The impossibility of taking zero from a quantity is marked by a zero result.
Distance interpretation: None

extends the range of application of the learned procedures.

For instance, with the "remove" and "smaller from larger" interpretations of a procedure, the child will extend to "3 – 6" what has been learned from "6 – 3". S/he will consider that they are both cases of "removing a part from a whole", and that the place of the digit (either upward or downward) is not relevant because the part is necessarily the smaller number and the whole is necessarily the larger number. With acquisition of new procedures, semantic influence will persist but will decrease since specific learned procedures will narrow the extension of semantic interpretation. At the same time, procedural errors, as it has been established (e.g. VanLehn, 1990) will be developed.

Thus, we make the following hypotheses:

(i) At the beginning of learning, children will mostly make semantic errors resulting from analogical transfer with the hypothesized sources.

(ii) Semantic errors will persist even among more experienced children

(iii) The relative proportion of semantic errors of the total number of errors decreases as child level increases.

The aim of the first experiment is to test the first hypothesis and the aim of the second experiment is to test hypotheses (ii) and (iii).

Experiment 1

Subjects

Subjects were 50 grade 2 children who begun studying how to subtract but haven't began studying how to borrow. In accordance with the ministerial directives, the teaching methods in the classrooms were focusing on the procedural aspects and not on the conceptual backgrounds.

Material and procedure

Children had to solve collectively in the classroom, and without any time limit, 20 subtractions used by VanLehn (1982), which allowed identification of a large variety of errors. The instruction was: "You have to solve 20 subtractions. Do the best you can. Take all the time you need." Since 17 of the 20 required borrowing, a high rate of wrong results was expected.

This situation is quite original in the didactical field, since students are usually tested on contents that they have supposedly already studied. However, it is standard in problem solving paradigms that specific knowledge about the problems is often considered as a bias that has to be avoided. In fact, to support the existence of a general cognitive mechanism involved in this situation, we used an usual problem solving paradigm in a school situation.

Furthermore, 14 of the 50 children were randomly chosen and were tested again the next week after the first test. They were asked to solve the same 20 operations for a new test and to explain the way by which they solved them. Their verbal reports were recorded.

Results

Protocols of 8 children were excluded from the data because of their use of the borrowing procedure, probably learned at home.

Quantitative results

Despite the fact that the subjects learned only how to solve 15% of the operations (3 out of 20), they answered 84.5% of the operations in average. Only one subject answered the 3 operations corresponding to what he had actually learned.

Table 2 displays the results. Dominant errors were distinguished from partial errors, depending on their rate of occurrence within a same protocol.

Table 2: Rate of semantic errors

Error	Dominant	Partial	Total
Smaller from Larger	47.6%	19.0%	66,6%
Zero instead of Borrow	38.1%	16.7%	54.8%
Blank instead of Borrow	4.8%	2.4%	7.2%
Stutter Subtract	9.5%	11.9%	21.4%
Diff 0-N=N	50.0%	7.1%	57.1%
Diff 0-N=0	38.1%	16.7%	54.8%
Diff N-0=0	9.5%	0.0%	9.5%

As it can be noticed, some errors are very usual: 4 types of errors are observed for more than half of the subjects. Furthermore, all the hypothesized errors were observed. Few non hypothesized errors were observed, but only for a minority of the subjects (9.5%): Small-Large = Small; Small-Large = Large; N-N=N.

These results have to be contrasted with predictions of procedural approaches. As a matter of fact, VanLehn (1990), observed all those errors but did not generate a large part of them with SIERRA, that generated only "Smaller from Larger" and "Blank instead of Borrow" from this list. In other words, errors as frequent as "Zero instead of Borrow", "Diff 0-N=N" and "Diff 0-N=0" were not produced by SIERRA. All in all, 76.2% of the children revealed errors that were not predicted by this model, when only 9.5% of them revealed errors not predicted by the semantic approach.

Simulations

3 levels of simulation were performed. At the first level, each protocol was associated with a list of non competitive errors that were observed for this protocol: for instance, Diff 0-N=0 and Diff 0-N=N could not be associated with the same protocol because they lead to different results. The actual results were compared with the ones obtained when applying the identified errors to

the operation. No calculation error was allowed for explaining differences.

At the second level, calculation errors were taken into account: a difference of plus or minus 1 was accepted if this was not corresponding to another systematic error.

At the third level, all the errors observed in the protocol were taken into account even if some of them were competitive.

Thus, several results could be compatible with the same simulation and calculation errors were taken into account as well. The results are presented in Table 3.

Table 3: Simulation with semantic errors

	Sim 1	Sim 2	Sim 3
Rate of prediction	77.9%	81.3%	89.8%

Verbal reports

Verbal reports were analyzed in the following way.

First, various expressions were identified as cues for specifying a source. For instance, "I have 3 and I remove 4" was indicating a 'remove' source since 'I have' was considered as referring to a quantity and 'remove' referring to the conception of taking part of a whole. "Going from 0 to 7…" indicates a distance source because of the reference of going from one place to another. This analysis of verbal reports showed that each child was using these kinds of expressions, which support the idea that the operation is actually interpreted in terms of taking part of a whole or going from one place to another.

Second, explanations for each error were compared to the predicted interpretations. The explanations produced were consistent with the expected ones.

Leaving apart the debate concerning verbal protocols, we would like to point out that verbal reports here coincide with the expected interpretations.

Hereafter, few examples are presented.

Subject J (83-44=40; Zero instead of Borrow; remove): "There are 3. We have to remove more than what is there. It remains 0"

Subject A (1564-887=1000; Zero instead of Borrow; remove): "… I have 5 candies in my hand, I cannot take 8 out of them to eat, so I take the 5 and nothing is left…"

Subject H (6591-2697=4106; Smaller from Larger; remove): "I have 1, no I have 7, I remove 1, 6 is left; I have 9, I remove 9, 0 is left; I have 6, I remove 5, 1 is left …"

Subject D (8305-3=5002; Stutter Subtract and Diff 0-N=0; remove): "We put 5 on the fingers, we remove 3 and we notice that 2 are left. 0 can't be removed from any number so it makes 0. And 3, I remove 3, 0 is left. For 8, I remove 3 and 5 are left from the 8."

Subject F (6591-2697=4106; Smaller from Larger; distance): " We count in our head what is missing to go from a given number to the one we need. From 1 to 7, 6 is missing, thus 7 minus 1 is 6; from 9 to 9, 0 is missing; from 0 to 9, 9 is missing; from 5 to 6, 1 is missing …"

Subject B (562-3=231; Stutter Subtract & Smaller from Larger; distance). "3 minus 2 is 1 and then since there is nothing I have to use the 3. From 3 to 6, 3 is needed. From 3 to 5, 2 is needed".

Discussion

As a summary, results of this first experiment support the hypothesis that interpretative aspects are involved in solving column subtractions.

First, despite the fact that children didn't know how to solve most of the problems, they tried to answer nearly all of them. From our point of view, this result supports the idea that what the children learned was interpreted in a conceptual framework that provided solutions for new situations.

Second, all the errors predicted by the semantic perspective were actually observed, and unpredicted errors appeared only seldom, supporting the idea that they resulted from the predicted interpretations. Third, depending on the kind of simulation, the semantic perspective allowed prediction of 77.4% to 89.1% of the errors, supporting the idea that semantic errors are prominent in the beginning of learning. Fourth, the analysis of the verbal reports showed that all the children were referring to the hypothesized sources with the predicted interpretations.

Experiment 2

Subjects

409 children who had already studied subtractions with borrowing participated in this experiment. 158 were children of grade 2 and 251 were grade 3. The teaching method was the same as in experiment 1. Given that errors rate might decrease with learning, a greater number of participants was necessary in this experiment to identify the errors.

Material and procedure

The material and procedure were the same as in experiment 1. 16 participants, randomly chosen among the ones who revealed semantic errors, were selected here for verbal reports.

Results

Quantitative results

As in experiment 1, dominant errors were distinguished from partial errors. 39.4% of the children had at least one semantic error. For 13.0% of them, at least one semantic error was dominant and for the remaining 26.4%, the semantic errors were partial. The results per error are presented in Table 4. Results show that the

semantic errors don't disappear with learning. They are still present, and with a great variety, for more than one third of the children, and they stay dominant for a minority of the participants.

Differences between grade 2 and grade 3 children are significant. 52.5% of the grade 2 versus 31.0% of grade 3 children had at least one semantic error ($Chi2(1)=18.70$; $p<.01$). The difference is also significant for the dominant errors: 25.9% of grade 2 versus 4.8% of grade 3 children had at least one dominant semantic error ($Chi2(1)=38.52$, $p<.01$). These differences do not reflect only the better performance of the grade 3 children but also a decrease in the proportion of semantic errors among the whole range of errors as indicated by the simulations.

Table 4: Rate of error for each semantic error

Error	Dominant	Partial	Total
Smaller from Larger	3.1%	11.3%	14.4%
Zero instead of Borrow	0.5%	5.6%	6.1%
Blank instead of Borrow	0.0%	0.0%	0.0%
Stutter Subtract	0.0%	7.1%	7.1%
Diff 0-N=N	8.7%	14.5%	23.2%
Diff 0-N=0	3.6%	16.7%	12.2%
Diff N-0=0	2.0%	6.6%	8.6%

Simulations

The method is similar to the one used in experiment 1. Table 5 displays the results of the simulations, i.e. the percentage of the errors that the semantic approach can explain. Even if there is a strong discrepancy with the beginners' simulation, the semantic perspective allows to predict within 1/4 to 1/5 of the errors for grade 2 children, depending on the kind of simulation, and about 1/7 of the third grade's errors. The differences between each level (grade 2 no borrow, grade 2 borrow, grade 3) are significant for each simulation (Fisher-Pitman Homogeneity Tests with z values from 2.74, $p=.006$ to 12.07, $p<.0001$).

Table 5: Simulation depending on participant level

	Sim 1	Sim 2	Sim 3
Grade 2 no borrow	77.9%	81.3%	89.8%
Grade 2 borrow	21.7%	22.8%	25.3%
Grade 3	14.1%	14.7%	16.3%

These results support our hypothesis that semantic errors persist even after procedural learning and that their importance decreases among the whole range of errors.

Verbal reports

Analysis of the verbal reports leads to the same conclusion as in experiment 1: all of the children referred to the predicted sources, with the predicted interpretations.

Discussion

The results of experiment 2 are consistent with hypotheses (ii) and (iii), supporting the idea that procedures are interpreted within a conceptual framework that definitely has a decreasing influence, yet does not completely disappear even after learning.

This may suggest that not only two kinds of errors exist (procedural and semantic ones) but also that the influence of one decreases when that of the other increases.

The plausibility of this suggestion is reinforced by some of VanLehn's (1990) results. Indeed, VanLehn illustrates (chapter 7) the performance of SIERRA with 33 systematic errors. SIERRA generates 25 of them. Among these 25, only 2 are considered as semantic by our approach. In contrast, among the 8 that SIERRA failed to generate, 5 are predicted by our approach. Thus, it appears that SIERRA's successes are failures of the semantic approach and vice-versa. This supports the idea of different mechanisms.

General Discussion

In this study, we showed through several converging measures that semantic aspects were involved in a procedural task par excellence: solving column subtractions.

Results are consistent with the idea that interpretative aspects should be taken into account in problem solving situations, as it has already been demonstrated in a body of research with some mathematical word problems (e.g. Bassok & Olseth, 1995; Bassok, Wu, & Olseth, 1995), with puzzle problems (Clément & Richard, 1997; Zamani & Richard, 2000), and in learning devices (Sander & Clément, 1997; Sander & Richard, 1997).

Do Perceptual Complexity and Object Familiarity Matter for Novel Word Extension?

Abstract

This paper examines the relationship between shape complexity and familiarity in extending novel adjectives. Previous research has suggested that familiarity with an object's basic level label determines the likelihood that a novel adjective will be extended to new instances. The present results do not support that conclusion. Instead the results suggest that given an adjectival syntactic frame children are likely to extend novel words to other objects of the same material when the objects are simple in shape. This result suggests that the perceptual properties of objects and the lexical form class cues are integral to understanding how children come to learn new words.

Introduction

How do children come to extend words to new instances? This question is at the heart of research understanding language development partially because much of language learning presumably takes place using ostensive definition: children learn a label for one object, event, or property and are able to extend that label to new instances. The task used to study this is the novel word extension task. In this task a child is shown an exemplar and the exemplar is labeled. The child is then given other objects that match the exemplar on different dimensions and the child is asked to select the one that also has the same label. Although much of the research in this area tends to focus on how children extend novel count nouns, other grammatical classes have been studied as well.

For example, previous work has suggested that when encountering novel adjectives, children are likely to extend the novel adjective to other objects of the same material only if the objects are familiar to them. (Hall, Waxman, & Hurwitz, 1993). Thus, young children can extend the novel adjective "plush" to other objects of the same material if the plush objects are familiar to the child e.g. a shoe, but not if the objects are unfamiliar to the child, e.g. a widget, even when the children are provided with an adjectival syntactic frame. This finding has been interpreted as evidence that children are biased to expect a novel word to refer to a kind of object. By this account children should extend novel words to other objects of the same shape if the object is unfamiliar to them and children should extend novel words to objects sharing some other property when the object is familiar to them.

However, Landau, Smith, and Jones (1992) and Smith, Jones, and Landau (1992) have shown that young children can generalize novel adjectives to other objects that match in material. These results are seemingly at odds with Hall, Waxman, & Hurwitz (1993) because the objects presented to children in these studies were unfamiliar objects and thus by Hall et al's proposal children should initially interpret the novel words as referring to objects of the same shape or object kind.

In addition, other research has shown that children take the specific perceptual properties of objects into account when extending novel words. For example, several researchers (Soja, 1992; Dickinson, 1988; but see Markman & Wachel, 1988 for contradictory findings) have demonstrated that children extend novel nouns to solid objects with the same shape, but children extend novel nouns to non-solid substances with the same material as an exemplar. Further, Imai and Gentner (1997) have shown that children as young as two years of age generalize simple objects, complex objects, and substances differently.

Based on these previous results, we propose an additional constraint that may guide whether children are likely to extend a novel word to objects that match an exemplar in shape vs. objects that match in other properties. We call this the perceptual complexity hypothesis. By this hypothesis, complex objects, objects like tractors with multiple parts may be labeled by more possible words than simple objects, like ball. This may foster attention to shape if these other labels point to properties (wheels, smokestack, engine) are themselves correlated with shape. Thus, we predict that attention to shape should be a stronger pull when the objects are complex than when they are simple. This idea is supported by previous findings by Imai and Gentner (1997) that show when Japanese 2 year olds

are presented with simple objects or materials they are likely to extend by material. However, when Japanese 2 year olds are presented with complex objects they are likely to extend by shape.

We test this idea by presenting children with objects that are either perceptually simple or complex and objects that are either familiar or unfamiliar. If perceptual complexity matters for word extension we would expect children to more readily select objects that match in material when the objects are simple. However, if the perceptual complexity of the objects is unimportant for word learning we would expect to see no differences between the complex and simple objects. In Experiment 1 we present the novel words in an adjectival frame. In Experiment 2 we present the novel words in a count noun frame.

Experiment 1

In Experiment 1 we ask whether children are more likely to extend novel adjectives to objects of the same material or shape when the objects are simple or complex and familiar or unfamiliar. We do so by providing children with a novel word in an adjectival syntactic frame. Previous work has shown that when novel words are presented in a adjectival frame children may match by material kind (Hall, Waxman, & Hurwitz, 1993; Landau, Smith, & Jones, 1992; Smith, Jones, & Landau, 1992).

Method

Participants Fifty-six 4-year-olds participated. Half were male and half were female. The four year olds ranged in age from 48 to 59 months. Fourteen children (7 boys and 7 girls) were randomly assigned to each of four conditions. Children were tested individually in their preschools during normal school hours or in the laboratory.

Design Subjects were assigned to one of four conditions. In each condition the stimuli presented varied in the level of shape complexity (simple vs. complex) and familiarity (familiar or unfamiliar). Simple shapes were defined as objects that were composed of one or two parts whereas complex shapes were defined as objects that were composed of many parts. We assessed the shape complexity of the objects by asking 10 undergraduates to rate each of the 48 objects used in the experiment on shape complexity using a 5-point scale. Objects that were judged as not very complex were given a score of 1 and objects that were judged as very complex were given a score of 5. Table 1 shows the mean complexity ratings for each of the four conditions. As can be seen objects in the simple conditions were judged as less complex than objects in the complex conditions.

Table 1: Shape Complexity Ratings for the Four Conditions

Condition	Rating
Simple familiar	1.41 (.59)
Simple unfamiliar	1.53 (.61)
Complex familiar	3.72 (.97)
Complex unfamiliar	3.94 (.91)

We defined objects as familiar if they were listed on the MacArthur Communicative Development Inventory: Words and Sentences, (Fenson et al, 1994) a checklist of words known to 50% of all children by 30 months of age. However, two objects, heart and bucket/pail, were not included on the MacArthur, but pre-testing indicated these objects were known by many four-year-old children. To ensure that unfamiliar objects were truly unfamiliar to children, the unfamiliar objects were made in the laboratory and did not resemble any nameable objects.

Four triads of objects were used in each condition. In each triad there was a target object, a shape matching object and a material matching object. The shape matching object matched the target in shape and object kind but differed in material kind and related properties such as color and texture. The material matching object matched the target in material kind and related properties but differed in shape and object kind. Figure 1 shows an example of a triad from each of the four conditions. In each condition the exemplar object matched one object by material and one by shape. The four material matches were blue plush, natural wood, silver metal, and paper.

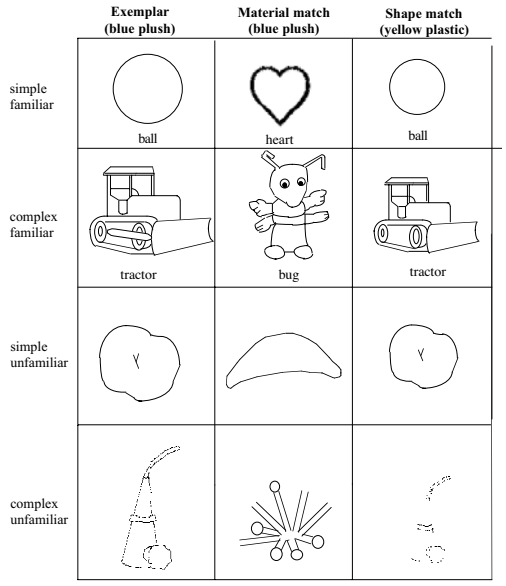

Figure 1 Examples of stimuli for the four conditions of Experiments 1 and 2.

Procedure In each condition of the adjective extension trials children were presented with an exemplar object while the experimenter labeled it with a novel adjective. For example, "See this? This is very wuggish. Can you say wuggish?" A shape match and a material match were then placed in front of the child, and the child was asked, "Can you find another one that is very wuggish?" This process was repeated for all four sets in the condition. The words blickish, fepish, wuggish, and zavish were used as the novel adjectives. The novel adjectives and the adjective syntax were taken from Hall, Waxman, and Hurwitz (1993).

Children were next presented with familiarity trials to ensure that the familiar objects were indeed familiar and the unfamiliar objects were unfamiliar to the children. Children were first "trained" to answer the familiarity trials by first presenting them with one familiar object (a shoe). Children were asked "What is this? What's this called?" Children were liberally praised for correctly labeling the shoe. Children were next presented with two unfamiliar objects and again asked "What is this? What's this called?" Children were liberally praised if they responded "I don't know." If children labeled the unfamiliar object the experimenter responded by telling the child that it was appropriate to say "I don't know" if they did not know the name of the object and children were encouraged to reply "I don't know" and were again liberally praised. Children were then randomly presented with the 12 stimulus objects from the adjective extension trials and asked of each "What is this? What's this called?" During these 12 trials children were not provided with feedback.

Results and Discussion

We first asked whether the objects we deemed as familiar were indeed familiar to children and the objects we deemed unfamiliar were indeed unfamiliar. Children responded with an appropriate label for the objects in the simple familiar condition 97% of the time on average and for objects in the complex familiar condition 91% on average. In contrast children responded that they did not know the name of the objects in the simple unfamiliar condition 89% of the time on average and for the objects in the complex unfamiliar condition 71% of the time on average. The remainder of responses in the two unfamiliar conditions involved children providing a description of the object, e.g. a green thing, an inappropriate object name, e.g. that looks like a tooth, correctly naming a piece of the object, e.g. it has a ribbon on it, or providing the novel adjective, e.g. wuggish. Thus, the results of the familiarity trials confirm that the objects in the two familiar conditions were largely familiar to children and the objects in the two unfamiliar conditions were largely unfamiliar to children.

We next examined children's performance in the adjective extension trials. Figure 2 shows the mean number of material matching selections children made in each of the four conditions. As can be seen, the number of material choices was higher in the two simple conditions than in the two complex conditions. An ANOVA conducted on the number of material choices confirmed this and revealed a main effect of complexity $F(1,52) = 25.19$, $p < .01$, but no effects of familiarity (power = .36) and no interaction (power = .21). Thus the results suggest that the shape complexity of the object, and not children's familiarity with the object, affects whether children generalize a novel adjective to a material match or to a shape match.

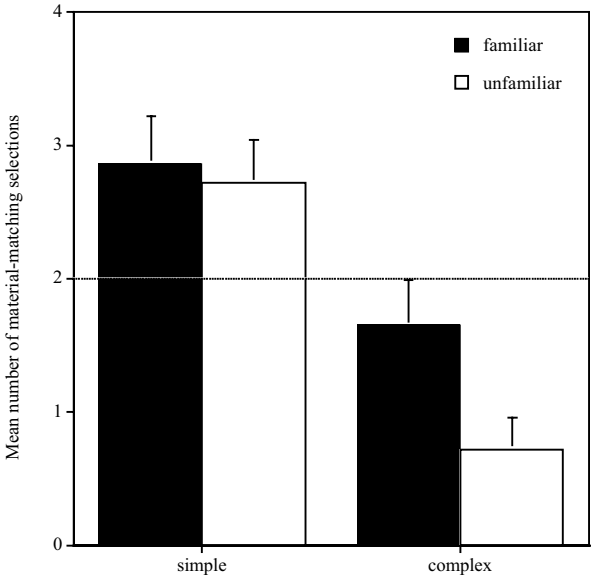

Figure 2. The number of material matching selections for the four conditions of Experiment 1.

We next compared children's selections to chance. If children responded randomly they would be expected to make material match selections in 2 of the 4 trials. The results showed that children made more material match selections than expected by chance in the simple familiar condition, $t(13) = 2.38$, $p < .05$, and in the simple unfamiliar condition , $t(13) = 2.22$, $p < .05$. Children also made less material matches than expected by chance in the complex unfamiliar condition, $t(13) = -5.26$, $p < .01$. Thus children exceed the number of material matches predicted by chance performance in the two simple conditions, but selected equal to or less material matches than predicted by chance in the two complex conditions.

Finally we asked whether knowing the object name made individual children more or less likely to match that object by material. One object included in the study made a nice test case for this question. We selected "sprinkler" as a complex familiar object in part because it was listed on the MacArthur Communicative

Developmental Inventory indicating that over 50% of all 30 month olds had produced the term. Thus we expected that 4-year-old children should be able to readily identify the object. However, only seven of the fourteen 48-60 month olds were able to appropriately identify the object as a "sprinkler" or a "sprayer". We thus asked whether correctly labeling the object coincided with more or less material choice matches. Table 2 presents the distribution of material and object matches for the 7 children who produced "sprinkler" and the 7 children who responded "I don't know" when asked what the sprinkler was. As can be seen the distributions are exactly equal suggesting that the ability to produce the basic level object name does not affect whether children are more or less likely to make a material kind selection.

Table 2: Number of material and object selections for children who did and did not produce the label "sprinkler"

	produced "sprinkler"	did not produce "sprinkler"
Object match	4	4
Material match	3	3

However, one possible explanation for our results could be that children are selecting material matches in the two simple conditions, not because they are correctly identifying the novel word as an adjective and correctly extending the word to objects that match in material in the simple object conditions, but instead that children are selecting material matches for other reasons. To test this possibility, in Experiment 2 we present children with the same sets of objects but use a count noun syntactic frame. Because count noun syntax has been shown to encourage extension to objects that match in shape, if the results of Experiment 1 are not due to idiosyncratic properties of our stimuli we would expect children in Experiment 2, who are presented with the same stimuli to make many more shape selections than material selections, regardless of the complexity of the stimuli.

Experiment 2

In Experiment 2 we again ask whether children are more likely to extend novel words to objects of the same material or shape when the objects are simple or complex and familiar or unfamiliar. We do so by providing children with a novel word in a count noun syntactic frame.

Method

Participants Fifty-six 4-year-olds participated. Half were male and half were female. The four year olds ranged in age from 4-0 to 4-11. Fourteen children (7 boys and 7 girls) were randomly assigned to each of four conditions. Children were tested individually in their preschools during normal school hours.

Stimuli and Design The stimuli and design were identical to Experiment 1

Procedure The procedure was identical to Experiment 1 with one exception. The novel word was provided to children in a count noun syntax (instead of adjective syntax). For example, "See this? This is a wug. Can you say wug?"

Results

To confirm the findings of the first experiment, we again asked whether the objects we deemed as familiar were indeed familiar to children and the objects we deemed unfamiliar were indeed unfamiliar. Children responded with an appropriate label for the objects in the simple familiar condition 97% of the time on average and for objects in the complex familiar condition 91% on average. In contrast children responded that they did not know the name of the objects in the simple unfamiliar condition 97% of the time on average and for the objects in the complex unfamiliar condition 91% of the time on average. The remainder of responses in the two unfamiliar conditions involved children providing a description of the object, e.g. a green thing, an inappropriate object name, e.g. that looks like a tooth, correctly naming a piece of the object, e.g. it has a ribbon on it, or providing the novel noun, e.g. a wug. Thus, the results of the familiarity trials confirm that the objects in the two familiar conditions were largely familiar to children and the objects in the two unfamiliar conditions were largely unfamiliar to children.

We next examined children's performance in the extension trials. Figure 3 shows the mean number of material matching selections children made in each of the four conditions. As can be seen, children generalized the novel name to the material matching object infrequently in all four conditions. An ANOVA conducted on the number of material choices revealed no main effects and no interactions. Thus, when children are provided with count noun form class cues, neither the shape complexity of the objects or children's familiarity with the basic level label of the objects affect whether children generalize a novel count noun to a material match or to a shape match. That is, children generalize by shape regardless of the particular object and its perceptual properties.

We next compared children's selections to chance. If children responded randomly they would be expected to make material match selections in 2 of the 4 trials. The results showed that children made less material match

selections than expected by chance in all conditions: the simple familiar condition, $t(13) = -6.27$, $p < .01$, the simple unfamiliar condition , $t(13) = -7.87$, $p < .01$, the complex familiar condition, $t(13) = -15.69$, $p < .01$, and the complex unfamiliar condition, $t(13) = -8.63$, $p < .01$. Thus these results confirm that children made less material matches, that is more shape matches, than expected by chance regardless of the particular object condition.

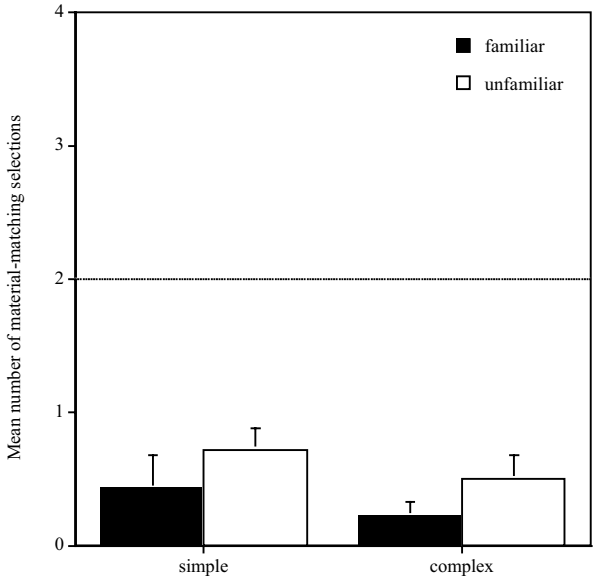

Figure 3. The number of material matching selections for the four conditions of Experiment 2.

General Discussion

Thus, the results suggest that given a count noun syntactical frame children selected objects that matched the exemplar by shape. However, given a adjectival syntactical frame children more often selected objects that matched the exemplar by material in the two simple-object conditions and shape in the two complex object conditions.

These results conflict with previous findings that children extend novel adjectives to objects of the same material only when the object kinds are familiar to the child. One possibility for this discrepancy is that the unfamiliar stimuli selected by Hall Waxman, and Hurwitz (1993) may have been inadvertently more complex than the familiar stimuli. Because Hall Waxman, and Hurwitz sought to control for taxonomic kind between the two conditions, the types of items that were unfamiliar to children may have also been slightly more complex than items that were familiar to children. For example, in the familiar condition one set of stimuli contained a cup and a spoon. In the unfamiliar condition the analogous set contained a garlic press and an apple corer. Thus the stimuli used in Hall Waxman, and Hurwitz may have inadvertently confounded familiarity with complexity.

These findings may help by providing a unifying explanation for discrepant results in the literature. One reason why some research (Hall, Waxman, & Hurwitz, 1993; Markman & Wachel, 1988) may have found that familiarity is necessary for enabling children to extend novel words by properties other than shape may have much to do with the perceptual properties of the stimuli presented to children.

Decomposing Interactive Behavior

Michael J. Schoelles (mschoell@gmu.edu)
&
Wayne D. Gray (gray@gmu.edu)
George Mason University
Fairfax, VA 22030 USA

Abstract

Interactive behavior emerges from the interaction of embodied cognition with task and the artifacts designed to accomplish the task. The current study focuses on how subtle changes in interface design lead to changes in the cognition, perception, and action operations that compose interactive behavior. The Argus Prime task is explained and the nature of the modeling effort is discussed. Insights obtained by exploring differences between model and human performance in one aspect of the Argus Prime task are presented.

Introduction

The Argus Prime simulated task environment (Gray, in press) places subjects in the role of radar operators whose job it is to assess the threat value of targets on a radar display. Our goal is to determine the strategies that people use in performing the task and to study how these strategies change as a function of subtle changes in interface design. Cognitive models are built that implement these strategies at the embodiment level (Ballard, Hayhoe, Pook, & Rao, 1997). Changes in strategy that accompany changes in the interface are interpreted as due to least-effort trade offs among the cognitive, perceptual, and action elements of embodied cognition. This work has implications for interface designers of dynamic systems characterized by rapid shifts of attention and time-pressured decision making such as in air traffic controllers, emergency medical systems, and nuclear power plant systems.

Our models are written using ACT-R/PM (Byrne & Anderson, 1998) — an architecture of cognition that enables us to capture the parallelism between cognition, perception, and action. By getting the interactions right at the embodiment level (approximately one-third of a sec), we hope to reproduce process and outcomes all the way up to the scenario level (each scenario requires 12-15 min to complete).

In comparing our models to human performance, we have been alternatively pleased and disappointed. It is not uncommon for our models to match the overall performance of our human subjects (at the 12-15 min level) only to mismatch greatly at a finer level of analysis.

When part of the model misfits its part of the data, we attempt to base changes of the model on a combination of two classic approaches. First, we observe subjects and analyze action protocols of their behavior. The action protocols include response times, eye movements, and mouse movements. Second, we introduce a small change to one part of the interface. We then run the model on the two versions of Argus and compare it s predictions with empirical data collected from human subjects.

Subtle changes in interface design may result in large changes in the strategies used to perform the task. For example, in Argus Prime it is important to maximize time on unclassified targets by, in part, minimizing time spent on targets that have already been classified. Hence, a change in interface design that varies the display-based indication of a target s classification status (classified or not classified) may have a profound effect on the number and combination of cognition, perception, and action operations used to perform Argus Prime.

In this paper, we marshal both human and model data to interpret the effect of interface changes on cognitive as well as on perceptual-motor performance. We use a broad brush to describe our task, current study, and model. After discussing how well the model s performance matched overall human performance, we limit the rest of the paper to two subparts of the Argus Prime task; namely, target selection and target check. These subparts provide an example of how subtle changes in interface design can produce unexpected interactions at the embodiment level.

Argus Prime: Simulated Task Environment

Argus Prime is a complex but tractable simulated task environment. In Argus Prime the subject s task is to assess the threat value of each target in each sector of a radar screen depicted in Figure 1. The screen represents an airborne radar console with ownship at the bottom. Arcs divide the screen into four sectors; each sector is fifty miles wide. The task is dynamic since the targets have a speed and course. A session is scenario driven; that is, the initial time of appearance, range, bearing, course, speed, and altitude of each target are read from an experimenter-generated file. The

scenario can contain events that change a target s speed, course, or altitude. New targets can appear at any time during the scenario.

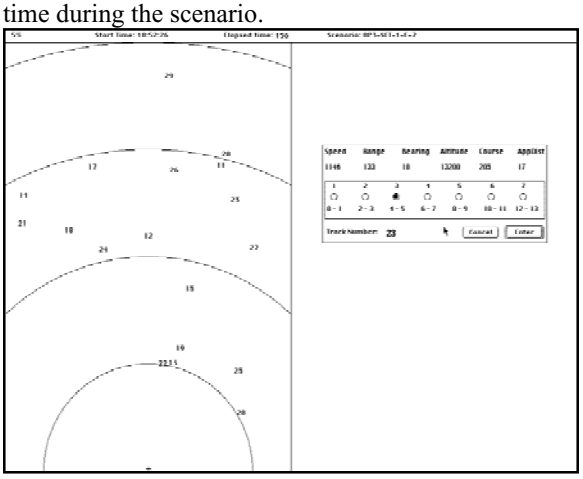

Figure 1: Argus Prime Radar Screen (left) and Information/Decision Window (right)

The subject selects (i.e., hooks) a target by moving the cursor to its icon (i.e. track number) and clicking. When a target has been hooked, an information window appears that contains the track number of the target hooked and the current value of target attributes such as speed, bearing, altitude, and course. The subject s task is to combine these values, using an algorithm that we have taught them, and to map the result onto a 7-point threat value scale (shown on the right side in Figure 1.)

Targets must be classified once for each sector that they enter. If a target leaves a sector before the subject can classify it, it is considered incorrectly classified and a score of zero is assigned.

For the versions of Argus Prime discussed here, immediate feedback was provided for each classification decision. In addition, summative feedback was provided on the percentage of targets correctly classified. (See Schoelles & Gray, in press, for more details.)

Empirical Study

This paper provides a partial report on the third study that we conducted. The results of prior studies indicated that a ubiquitous feature of the task was keeping track of which targets had been classified. In those studies there was nothing on the radar screen to indicate whether a target had been classified; that is, when a classification was made, its on-screen icon did not change (noChange). However, in both studies, if an already classified target was reselected, the target s current classification (CC) was shown in the information window (i.e., its radio button, see Figure 1, remained highlighted). We call this combination of no change to the target s on-screen icon and persistence of the classification in the information window the noChange-CC interface.

The current study manipulates the ease of retrieving status information (i.e., Is this target classified?) from the display. In addition to noChange-CC, two new interfaces are used. The noChange-noCC interface is similar to the noChange-CC in that the target s on-screen icon does not change when a classification is made. It differs from noChange-CC in that the information window contains no record as to whether a target is currently classified (i.e., once the ENTER key is pressed, the radio button is unhighlighted, see Figure 1). In contrast, for the Change interface the on-screen icon for targets that have been classified changes color. When a target is no longer classified (i.e., when it crosses a sector boundary) the icon reverts to the unclassified color.

In the first two studies subjects frequently reselected already classified targets. Their pattern of behavior suggested that for the noChange-CC interface subjects did not try to remember whether a target had already been classified. Rather, the pattern suggested that subjects simply clicked on targets until they found one that was not classified.

It was unclear in the previous studies whether this memory-less strategy (Ballard, Hayhoe, & Pelz, 1995) is adopted by choice or whether, under the conditions of the study, human cognition is incapable of retrieving target status information. This issue is tested empirically and analytically by the data and models built for the current study.

Performance on the noChange-CC interface is used as a baseline with which to compare the other conditions. We expect the noChange-noCC interface to force the memory versus memory-less issue. If subjects have no memory for having classified a target, they will be required to waste time re-computing the algorithm to reclassify already classified targets. In contrast, the Change condition provides a memory-less way to avoid classified targets and to focus on unclassified ones. Hence, subtle changes in the interface will enable different sets of strategies between the three conditions. These different strategies are expected to be differentially successful and to result in stable differences in performance.

The experiment was conducted over two sessions. In the first 2-hr session the subjects were instructed on how to do the task, did a sample scenario with the experimenter, and then did five 12-min scenarios in the noChange-CC condition. In the second 2-hr session the subjects did a 12-min practice scenario in the noChange-CC condition and then did two scenarios in each of the three conditions (noChange-CC, Change, noChange-noCC).

The Model

Our model runs under ACT-R/PM with the Eye Movements and Movements of Attention Extension (EMMA) (Salvucci, 2000). The ACT-R/PM architecture combines ACT-R s theory of cognition (Anderson & Lebiere, 1998) with modal theories of visual attention and motor movement (Kieras & Meyer, 1997). ACT-R/PM explicitly specifies timing information for all three processes as well as parallelism between them. The software architecture facilitates extensions beyond the modal theory of visual attention and motor movements.

The ACT-R/PM code executing the model runs as a separate process from Argus Prime. This process starts when the scenario starts. All communication between the model and Argus Prime is through the motor and vision module commands of ACT-R/PM.

Model Description

The recurrent task of hooking a target can be analyzed into a series of unit tasks (Card, Moran, & Newell, 1983): target selection; target check; target classification; and feedback. Each unit task has memory retrieval, visual attention, and mouse movement requirements. In ACT-R retrieval latency is a function of the activation of the memory element being retrieved. In addition, if the activation of a memory element is not above threshold, the retrieval will fail.

Movement of attention is a combination of two ACT-R/PM commands. The *Find Location* command is a pre-attentive search for a feature that returns a location to use as a parameter in the *Move Attention* command. The Move Attention command encodes a declarative memory element representing the visual object at the specified location. With the EMMA extension, a series of eye movements follows the initiation of the move attention command. The time to encode the visual object is a function of the eye movements.

Mouse movements are executed via ACT-R/PM s *Move Mouse* command. The input to this command is an object representation. The time to complete the movement is a function of Fitts Law. Mouse clicks are executed with the *Click Mouse* command. The overall operation of the model is an interleaving of productions that perform the cognitive operations of memory retrieval and goal modifications with the perceptual-motor operations of pre-attentive search, movement of attention, eye, and mouse movement.

In this paper, we focus on the target selection and target check unit tasks. In all three conditions (noChange-CC, noChange-noCC, and Change) the model begins target selection by retrieving a memory trace of the area in which it is currently searching; for example, the lower right-hand portion of the radar screen. It then pre-attentively searches for targets within this area. If a target is found, attention is moved to the feature to encode the target. (The track number is part of the encoded representation.) At that point the Move Mouse command fires and the cursor moves to and clicks on the target.

The above procedure varies slightly as a function of interface condition. In the noChange-CC and the noChange-noCC conditions, after a target is found and encoded, but before the Move Mouse command is executed, the model attempts to perform a target check by retrieving an episodic trace of a previous classification of the track number. If it retrieves this trace then it knows that the target is already classified; hence, the model will search for another target. If it cannot retrieve the trace, then the actions of moving the cursor to the target and clicking on it are performed.

In the noChange-CC condition, after clicking on a target the model will do a second target check by conducting a feature search in the information window to detect the highlighted radio button. If one is found the search for a new target will begin. Otherwise the Target Classification unit task begins. The noChange-noCC condition does not have this double-check. If it cannot retrieve a memory that the target is already classified, it will reclassify the target.

In the Change condition, targets change color after they are classified. As a consequence, the distinction between the target selection and target check unit tasks disappears. Hence, after a search area is retrieved, the pre-attentive search looks for the color feature that separates the unclassified targets (yellow) from the classified ones (blue). This strategy is purely memory-less in that no use is made of the episodic information regarding a target s prior classification. (After all targets in the retrieved area have changed color to blue, the model will do a feature search over the entire screen for yellow targets.)

Model and Subject Data Comparison

There are three limits to the model and analysis. The first is that the model was not fit to individuals. The same configuration and architectural parameters were used for all runs of the model.

Second, within an interface condition, the model uses the same strategies throughout the scenario. For example, the model uses the same target selection and target check strategies for the initial phase of the scenario when no targets had been classified as for the later stages when most targets had been classified.

Third, the base model was developed on the noChange-CC condition. In general, the way in which the model performed each unit task (i.e., target selection, target check, target classification, and feedback) was based on strategies that we observed our subjects using in the first two studies. As the unit task strategies required from 3 to 30 sec to execute, our

caveat is that in ACT-R/PM these strategies were implemented at the embodiment level using productions that required 50-100 msec to execute. Hence, the implementation of the various unit task strategies required us to make assumptions regarding memory retrieval, attention shifting, and motor movements for which we did not yet have empirical support.

In summary, at the unit task level of analysis the models implemented strategies that were cognitively plausible. For example, for the Change interface condition, pilot subjects told us that they performed target selection by looking for yellow targets. The implementation of such strategies at the embodiment level was based on our knowledge of the pre-attentive search literature, the ACT-R/PM cognitive architecture, and inspired guesses. The testing of those inspired guesses is what the current effort is all about.

Statistics Used

To compare human and model data, we report ANOVA and planned comparisons. A measure of variability for our model subjects is derived as follows. For each of 12 human subjects, a model subject was created. This model subject received the same six scenarios as the corresponding human subjects received during the second session. That is, if subject 1 did scenario 1 and 2 in the noChange-CC condition, scenario 3 and 4 in the Change condition and scenario 5, and 6 in the noChange-noCC condition, then a model subject was run on the same set of scenarios and under the same interface conditions. Hence any variability between model subjects (within condition) can be attributed to (a) unintended differences in how the 12 scenarios were designed, and (b) the randomness built into the architecture. Unlike human subjects, all model subjects in the same condition always follow the same strategies.

We confess that our second set of statistics is a willful abuse of ANOVA. The practical outcome of this is to inflate our Type I error rate; that is, the reduced variability due to model subjects should lead us to identify more differences between model subjects and human subjects than actually exist. We accept this inflated Type I error rate. The cost to our research of an inflated Type I error rate will be to cause us to spend time and attention looking for differences in strategies at the embodiment level that may not exist.

For each figure, we present the 95% confidence interval for human subjects and model subjects. The root mean square deviation (RMSD) of each human subject from his or her scenario-matched model subject is also reported.

Total Task Performance Comparison

Interface condition has a significant effect on the performance of human subjects, $F(2, 22) = 31.71$, $p < .0001$, $MSE = 33.9$. As Figure 2 shows, the Change condition does best (85.5%), followed by noChange-CC (76.4%), with noChange-noCC (66.6%) the worst. Planned comparisons show that the difference between each pair of conditions is significant at the level of significance adopted for this report ($p < .05$).

Overall, our model subjects do about as well as our human subjects (see Figure 2). However, although the main effect of model versus human is not significant, $F(1, 22) = 1.64$, $p = .21$, the interaction by interface condition is [$F(2, 44) = 7.3$, $p < .002$]. The Figure suggests that humans do slightly better than the model for noChange-CC and Change conditions but about equal to the model for noChange-noCC. As Figure 2 shows, the model makes the explicit prediction that the two noChange groups will have equal performance (noChange-CC = 67.8%; noChange-noCC = 67.5%). The significant interaction suggests that our human subjects are reacting to the interface conditions in a way that the model does not.

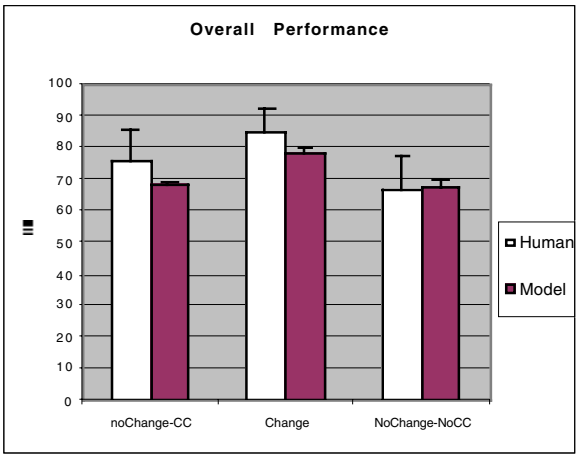

Figure 2: Overall Performance comparison of human and model. The RMSDs are 17 for noChange-CC, 13 for Change and 16 for noChange-noCC.

The variability shown by the model reflects differences between scenarios, not differences in strategies within conditions, and not differences inherent to individual subjects. Hence our model-driven approach provides us with an independent way of accessing the equivalence of the scenarios. As shown by the small confidence interval for the model subjects, our efforts to create equivalent scenarios was largely successful.

Target Selection Comparison

The three interface conditions showed significant differences in the number of *unclassified* targets

selected. The Change condition selected the most unclassified targets (68.3), followed by noChange-CC (58.3), and then by noChange-noCC (50.0). The model differences mirrored the human differences.

The more interesting comparison examines the probability of reselecting (or rehooking) an already classified target. For humans, planned comparisons show that noChange-CC rehooks the most targets (79.1) with there being no statistical difference in the number of targets rehooked by the Change (3.7) and noChange-noCC (16.3) conditions. [The overall ANOVA yields a significant effect, $F(2, 22) = 44.3$, $p < .0001$, $MSE = 441.3$.]

Comparing model performance with human performance yields a number of small surprises. Although the overall human versus model comparison is not significant ($F < 1$), we find a significant interaction of model versus human by interface condition, $F(2, 44) = 5.3$, $p < .008$, $MSE = 228.8$). Compared to humans, the model rehooks fewer targets in the noChange-CC condition, the same number of targets in the Change condition, and more targets in the noChange-noCC condition.

In both noChange conditions, prior to selecting a target the model attempts to retrieve a memory of whether that target had been classified. Only if the retrieval fails will the model rehook an already classified target. The fact that humans rehook more targets than the model in the noChange-CC condition, implies that humans rely less on memory retrieval, in this condition, than does the model. In this condition, a memory check is, in some sense, unnecessary as clicking on the target will open the information window that will clearly show whether a radio button is highlighted or not.

It may be that the cost of a perceptual-motor check is so much less than the cost of encoding and retrieving a memory that the noChange-CC condition relies on a single activity strategy, rather than one that involves dual activities (i.e., memory and perceptual-motor).

To investigate this further, the model was modified to only perform a perceptual-motor check; that is, to exclude the attempted memory retrieval. As shown in Figure 3, the model without memory selects many more targets than do human subjects. The fact that the two models bracket human performance (see also Gray & Boehm-Davis, 2000) suggest that the memory-less strategy is the preferred but not the exclusive strategy. We are currently interrogating the human data for clues as to the circumstances under subjects in the noChange-CC condition will use a memory retrieval strategy.

In contrast to noChange-CC, the perceptual-motor strategy is not available to the noChange-noCC condition. In this condition, the cost of the failure of the memory retrieval strategy is high. Reclassifying an already classified target is effortful; consuming time that would be better spent classifying an unclassified target. Hence, this greater downstream cost may lead human subjects to encode a memory trace to a higher level of activation than the model. Alternatively, it may lead them to more attempted retrievals than the model or, perhaps, to adopt a lower retrieval threshold than the model.

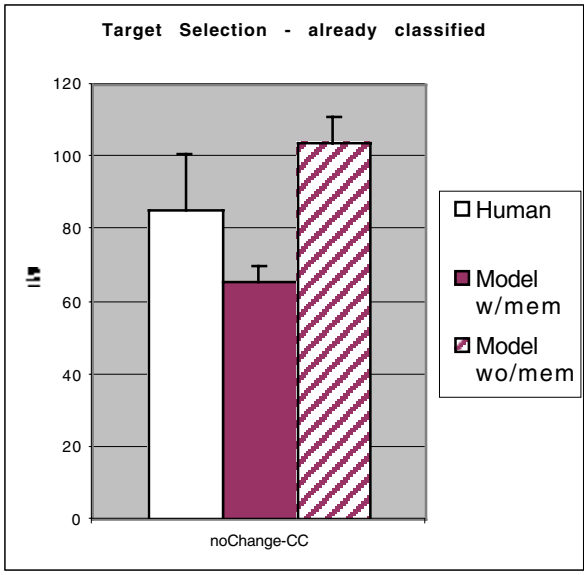

Figure 3: Target Selection for Human and Model with and without a memory retrieval. Model w/mem attempts to retrieve an episodic trace of the encoded target; only if the retrieval fails will a perceptual-motor check be performed. Model wo/mem will only perform the perceptual-motor check. The RMSDs are 42 for the human and model w/mem and 47 for the human and model wo/mem.

Our empirical data shows that subjects in the noChange-noCC condition reliably require 100 msec more than in the other conditions to classify a target. As it is not obvious why classification per se should take longer. However, the extra 100-msec is just enough time to sneak in one extra retrieval of the trace of the target just classified (Altmann & Gray, 1999), thereby increasing the success of the memory strategy for the Target Check unit task. Models incorporating this 100 msec of extra strengthening are being built and will be tested to determine if this strengthening suffices to produce the increment in performance shown by humans over the current model.

Discussion

Performance of the model subjects can be viewed as the embodiment of our theory of human performance. Comparisons that yield a significant main effect of model versus human signal places where our theory of human performance breaks down. Comparisons that yield a significant interaction of model versus human signal places in which our understanding of how

interface design influences interactive behavior are deficient. With this as our perspective, what does the performance of our model subjects tell us about our understanding of human interactive behavior?

A message that comes through loud and strong is that if our goal is to understand cognitive processes and not simply to predict performance outcomes, then obtaining good fits to an overall performance measure, such as Total Task Performance, can be misleading. The fit between model and human on overall performance can mask large and important differences in unit task performance.

On the first two unit tasks, Target Selection and Target Check, neither the main effect nor interaction of model versus human was significant for number of unclassified targets selected (first hook). This excellent fit of model to data broke down when we examined the number of times a target was rehooked. In this case the interaction indicated much more rehooking for noChange-CC than expected and less rehooking for noChange-noCC than expected. This interaction could be explained if the noChange-CC condition relied more on a perceptual-motor strategy and less on memory than did the model. Similarly, the noChange-noCC condition may be encoding the episodic trace of already hooked targets more highly than we had anticipated.

Conclusions

The goal of our research effort is to understand how subtle changes in interface design may lead to large changes in overall performance. As interactive behavior emerges from the interaction of embodied cognition with task and the artifacts designed to accomplish the task, an explanation of performance changes requires a consideration of the fine details of this interaction. In this article we have focused on one type of change and its effect on one part of task performance.

Although the fit of our model to overall performance was good, examining the fit of the model at the unit task level revealed important mismatches. For the Target Selection and Target Check unit tasks, the initial selection of unclassified targets was well fit by the model but the rehooks were not. Analyses of the model and the ways in which it matched and mismatched the data suggested three distinct target checking strategies that varied in their reliance on perceptual-motor versus memory operations.

The Influence of Causal Interpretation on Memory for System States

Wolfgang Schoppek (wolfgang.schoppek@uni-bayreuth.de)
Department of Psychology, University of Bayreuth
D-95440 Bayreuth, Germany

Abstract

This paper reports an experiment that investigated the influence of causal interpretation on acquisition and use of two knowledge types about a static system: I-O knowledge (instances of system states) and structural knowledge (knowledge about causal relations within the system). One group of subjects saw system states without being informed about the causal nature of the material. Another group saw the same states as switches and lamps. It is assumed that the group without causal interpretation can only acquire I-O knowledge. If I-O knowledge is the predominant type when dealing with small systems, then there should be no group differences in a recognition task. Actually, the group with causal interpretation discriminates much better between targets and distractors, but with longer RTs. This is interpreted in terms of structural knowledge acquired by the group with causal interpretation, which was used to reconstruct system states in cases of doubt. Results of a task where subjects had to judge single causal relations support that interpretation, but also indicate that the knowledge about effects is probably not represented in an explicit, symbolic form. An ACT-R model that uses associations between events as a subsymbolic form of structural knowledge reproduces the data well. Thus, data and model support the significance of I-O knowledge but also shed some light on the role and the development of structural knowledge.

One central question in the psychological research on complex dynamic systems refers to the knowledge that is used for controlling a system. One important aspect of that question refers to the content of the acquired knowledge. Subjects may acquire structural knowledge, defined as general knowledge about the variables of a system and their causal relations. They may as well acquire input-output knowledge (I-O knowledge), which represents instances of input values and the corresponding output values.

There is evidence for the influence of both types of knowledge on performance in system control, but currently many authors emphasize the role of I-O knowledge, particularly when dealing with small systems like the "Sugar Factory" (a dynamic system with one input and one output variable, connected by a linear equation; Berry & Broadbent, 1988). Computational models developed on the basis of Logan's Instance Theory (Dienes & Fahey, 1995) or ACT-R (Lebiere, Wallach & Taatgen, 1998) demonstrate the sufficiency of I-O knowledge for the control of the "Sugar Factory". The strategy of relying on I-O knowledge seems to be preferred by most subjects, even in the control of more complex systems. However, in systems of at least six variables, high performance is usually associated with structural knowledge (Funke, 1993; Vollmeyer, Burns & Holyoak, 1995).

A second aspect of the question as to what knowledge is used in system control refers to its status as explicit or implicit knowledge. In an experiment with the "Sugar Factory", Dienes and Fahey (1998) found stochastic independence between the solution of studied control problems and the recognition of the same situations as studied. The authors concluded that memory for the situations was implicit. This result extends the common finding of dissociations between recognition and completion tasks (e.g. Tulving & Hayman, 1993) to the domain of system control.

In the present paper these questions were investigated by using stimuli that can be either interpreted as states of a system or simply as spatial patterns. The rationale of the experiment is that learning of instances does not depend on the causal interpretation of stimuli. Consequently, if knowledge about instances (I-O knowledge) is the main knowledge type learned, there should be no effect of causal interpretation on recognition of system states. On the other hand, if structural knowledge is learned additionally, then causal interpretation should have positive effects, particularly in a causal judgment task.

The assumptions about the two knowledge types are explicated with a computational model based on the ACT-R theory (Anderson & Lebiere, 1998). The model reproduces the results of the experiment quite well, and can be considered being an explanation for the stochastic independence between completion and recognition tasks.

Experiment

The significance of I-O knowledge and structural knowledge was studied with a system consisting of four lamps operated by four switches. Figure 1 shows a screenshot with the effects of the switches mapped (the arrows were not visible for the subjects). Each switch

affects one or two lamps. Two of the effects are negative, which means that the corresponding lamp is switched off when the switch is turned on.

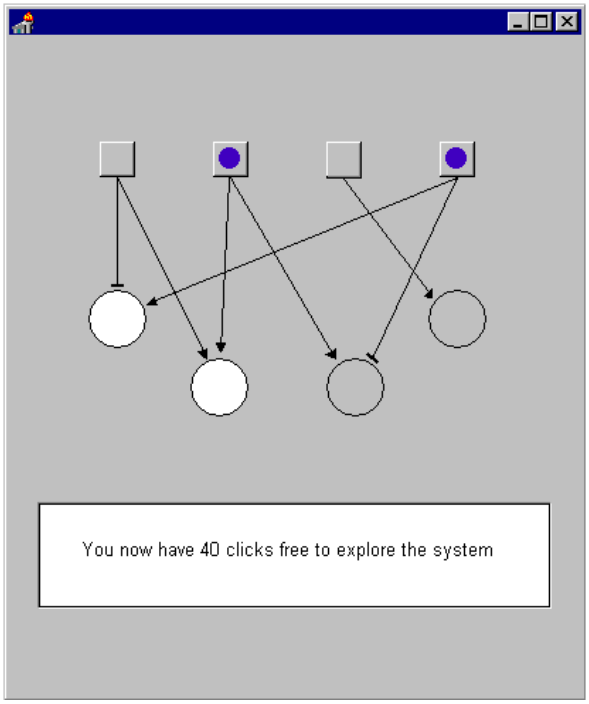

Figure 1: The system used in the experiment. The arrows were not visible for the subjects; ↓: on relation, ⊥: off relation.

Two tasks were used, each more sensitive to a different type of knowledge: A recognition task - easiest to be done with I-O knowledge, and a causal judgment task - easiest to be done with structural knowledge. Additionally, a pattern completion task was administered, which is not expected to be particularly sensitive to one knowledge type.

In the speeded recognition task subjects saw ten possible and ten impossible system states two times each, and had to decide if they had seen the state in the learning phase or not. The items of the speeded judgment task were pictures of the switches and lamps with one switch and one lamp highlighted. Subjects had to decide if there was a causal relation between the highlighted elements. The 16 possible combinations were shown twice. In the completion task subjects were shown eleven arrays of switches or lamps and asked to complete the missing parts, i.e. complete the lamps when switches were shown and vice versa.

Two factors were varied between subjects: (1) the possibility to interprete the pictures of system states shown in the learning phase as causal, and (2) the subject's activity, i.e. if the system states were either observed, or produced by operating the switches. I will focus on the effects of the first factor (that were the strongest ones, anyway), and report the data of the two groups who observed the system states in the learning phase, either with causal interpretation (ci), or without causal interpretation (nci). Each of the groups consisted of 12 subjects.

Other factors were varied within subjects: (1) the number of presentations of each state in the learning phase (1-2 presentations vs. 3-5 presentations), and (2) the number of switches that were "on" in each item of the recognition task (1 switch on vs. 3-4 switches on).

The experiment started with a learning phase where subjects saw 40 system states in intervals of four seconds. Each possible state of the system was shown at least once. The group without causal interpretation (nci) was told that they would see spatial patterns, which they should memorize. The group with causal interpretation (ci) was informed that the patterns were states of a system of switches and lamps.

Three minutes after completion of the learning phase the recognition task was administered followed by another 25 system states. Next, subjects worked on the completion task. Then the subjects of the group without causal interpretation were debriefed about the causal nature of the stimulus material. After that the judgment task was provided, followed by two other tasks that are not reported here.

Given the assumption that knowledge about the system is primarily stored as specific instances, the factor "causal interpretation" should have no effects on performance in the recognition task. If, however, subjects acquire structural knowledge - which is expected only in the group with causal interpretation - that group should outperform the nci group, particularly in the judgment task.

As a measure of performance in the recognition and judgment tasks, discrimination indices P_r were calculated according to the Two-High-Threshold-Model (Snodgrass & Corvin, 1988). A discrimination index of 1 indicates perfect discrimination; a value of 0 indicates random performance.

Table 1: Discrimination indices for two tasks

	ci	nci
Recognition	M = 0.48 s = 0.23	M = 0.30 s = 0.22
causaljudgment	M = 0.55 s = 0.18	M = 0.17 s = 0.23

Table 1 shows means and standard deviations of these indices. In both tasks the group with causal interpretation is significantly better ($F_{1,22} = 10.76$, $p < .01$), and there is an interaction between task and group ($F_{1,22} = 7.26$, $p < .05$). The ci group is better at judging causal relations than at recognition; for the ci group the reverse is true. Latencies for hits are longer in the group

with causal interpretation (ci: 2250 ms, nci: 1493 ms). The fact that the variance is also significantly higher in the ci group points to the use of different strategies: If a system state could not be retrieved in the recognition task, subjects of the ci group might have tried to reconstruct the state by using knowledge about the effects of the switches. That would mean that subjects used both, I-O knowledge and structural knowledge.

This interpretation is supported by the effects of the within-subjects factors on recognition performance (Figure 2, left panel). If the reconstruction hypothesis is true, then there should be an effect of the number of switches on in the ci group, because the reconstruction process is harder the more switches have to be considered. Actually, a significant interaction between group and number of switches on was found in the proportion of hits ($F_{1,22} = 6.13$, $p < .05$). States with three or four switches in on position are particularly badly recognized by the subjects of the ci group. On the other hand, in the group without causal interpretation the influence of number of presentations is higher (interaction marginally significant: $F_{1,22} = 3.63$, $p = .07$). All this supports the assumption that the group with causal interpretation used I-O knowledge and structural knowledge in both tasks.

Further inferences about the application of one vs. two knowledge types can be drawn from contingency analyses between the tasks. Since the mapping between the items of the recognition task and the items of the judgment task is ambiguous, I calculated contingencies between recognition and completion.

If there is only one (explicit) knowledge type, items that were completed correctly should also be recognized as studied. For two knowledge types, the contingency prediction is less clear. If each task is solved with different knowledge, stochastic independence between the tasks should be the consequence.

The items of the completion task were entered into contingency tables depending on their solution and their recognition (e.g. Item 1 was solved correctly and not recognized as studied). The entries were summed over all subjects of each condition and over all items. Empirical contingencies, measured by Δp, were compared with maximum contingencies that can result with the given marginal distributions[1]. In the ci group the empirical contingency between recognition and correct completion is 0.17. This is considerably lower than the maximum of 0.65. In the nci group the contingency is 0.41, which is much closer to the maximum of 0.53 in that group. Thus, in the group with causal interpretation the solution of completion items does not depend on correct recognition of these items as studied, whereas in the group without causal interpretation a moderate degree of dependency was found between the two tasks. Again, the results are compatible with the assumption that the nci group used only one type of knowledge, whereas the ci group used two types.

[1] The maximum possible memory dependence as suggested by Ostergaard (1992) could not be calculated because only studied items were used in the completion task.

Discussion

Overall, the results support the assumption that causal interpretation enabled subjects to gain an additional type of knowledge. This raises the question about the nature of that knowledge. In the introduction I hypothesized that it should be structural knowledge. But there is one result that is problematic for this conclusion: Since structural knowledge is ideal for solving the judgment task it is surprising that the mean latency for hits is as long as 2234 ms (see also Schoppek, 1998 for similar results). If subjects tried to retrieve structural knowledge right away, the latency should be much shorter. A possible explanation is that most subjects try to use I-O knowledge first and use knowledge about effects only after retrieval of relevant I-O knowledge fails. The reason for that might be that knowledge about causal relations is not represented explicitly in symbolic form, but rather in form of associations between events. In the ACT-R theory (Anderson & Lebiere, 1998), associations between declarative memory elements and their baselevel activations are described as the subsymbolic level of declarative memory. This level is implicit in the sense that it affects symbolic processing (e.g. retrieval) without being directly accessible. In the next section I describe a computational model that uses the distinction between symbolic and subsymbolic level to explain the effects of causal interpretation.

ACT-R Model

In order to test how the above interpretation can reproduce the data, I developed an ACT-R model that simulates the learning phase, the recognition task, and the judgment task. There are two versions of the model. One of them entails additional production rules for modeling causal interpretation. These rules reconstruct a system state when no relevant memory representation of the state can be retrieved. The state is reconstructed on the basis of associations between events.

In the learning phase a new declarative element (called chunk in ACT-R) is created for each system state and pushed on the goal stack. After processing the goal it represents a system state with its slots holding the arrays of switches and lamps. These state chunks are the basic units of I-O knowledge. Also in each cycle, a change-image is created as a subgoal, representing the changes between the previous and the current system state. Most of the change-images are not strong enough to be retrieved later on, but during goal elaboration associative weights are learned between

switch- and lamp-events (e.g. between the events "Switch A turned on" and "Lamp 1 turns dark"). Afterwards these associations are used to reconstruct system states in the condition with causal interpretation. No structural knowledge is explicitly induced, because otherwise the model would predict much shorter response times in the judgment task.

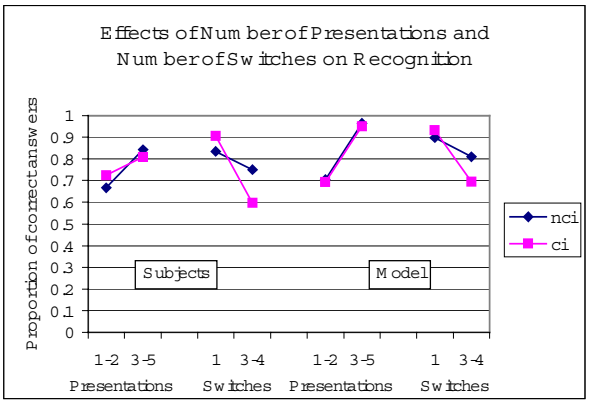

Figure 2: Experimental (left) and model (right) results

In the recognition task both model versions try to retrieve an instance similar to the probe. The constraints for retrieval are either "retrieve a chunk that has the probe's combination of switches in its switches slot" (retrieval by input), or "retrieve a chunk that has the probe's combination of lamps in its lamps slot" (retrieval by output). The model has a bias towards using the tactic of retrieval by input. Partial matching is turned on, which means that not only perfectly matching instances can be retrieved, but also instances that are similar to the retrieval constraints. If retrieval fails, the version without causal interpretation guesses, the other version starts the reconstruction process. Reconstruction is based on the lamp-events that are most strongly activated by the switch-events shown in the probe ("switch on"). The probability of false reconstructions rises with the number of switches that are on - an effect that explains the bad recognition performance under condition ci & 3-4 switches.

I simulated two samples with 24 cases each[2]. Some results are shown in the right panel of Figure 2. In both simulated between subject conditions recognition performance depends more on the number of presentations as compared to the real subjects. But the interaction between number of switches and causal interpretation is well reproduced by the model. In general, the model overestimates recognition performance. This effect is mainly due to the excellent recognition of the frequently shown system states. Latencies for hits are very close to the data: 2314 ms in the simulated ci group and 1541 ms in the simulated nci group (note that the latency factor was fitted for the nci group only).

After fitting parameters for the recognition task, the model was extended with a few production rules to solve the causal judgment task. In that task the model tries to retrieve a diagnostic instance appropriate to confirm the causal relation. For example, when the item requires judging the causal relation between Switch A and Lamp 3, the model tries to retrieve a chunk that represents the system state with Switch A as the only switch on. Assume the model retrieves the appropriate state (Switch A on, Lamp 2 on), it will produce the answer "no". If no diagnostic state can be retrieved, the model reconstructs the state in the same way as in the recognition task.

In the simulation with this part of the model, I assumed that the judgment task was done right after the learning phase. Recall that the groups of subjects that have been discussed so far did the judgment task later in the experiment. Therefore, the simulation results were compared to a group of subjects (N=12) who did the judgment task in the first place. That group was informed about the causal interpretation of the stimuli.

The model matches the subjects' data quite close without fitting any parameters (Figure 3). Mean latencies for hits were 2305 and 2234 ms in the model's and subjects' data, respectively.

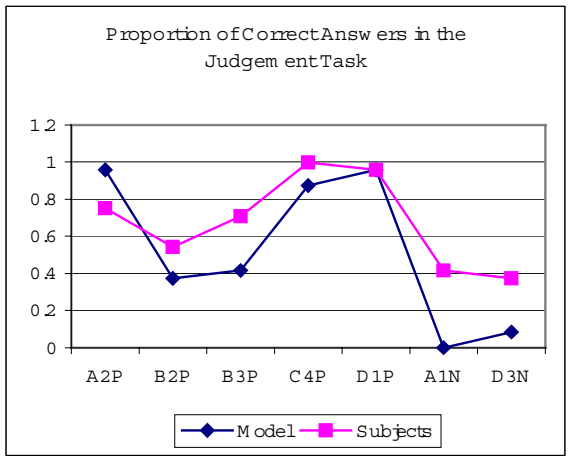

Figure 3: Proportions of correct answers in the judgment task. A2P through D1P are the five "on" relations of the system, A1N and D3N the two "off" relations. (A2P: Switch A – Lamp 2 - positive)

General Discussion

Model and data support the view that I-O knowledge is the primary type of knowledge used when dealing with a small system. But longer latencies, together with

[2] Parameter values were as follows: partial matching=on, mismatch penalty=2.5, baselevel learning=0.5, retrieval threshold=0.75, parameter learning=off, associative learning=3.0, activation noise s=0.5, expected gain noise s=0.5, latency factor=2.5. The source code of the model is available at www.uni-bayreuth.de/departments/psychologie/cogsci01.html

better recognition in the group with causal interpretation point to the use of an additional type of knowledge. It has been modeled as subsymbolic associations between events, used to reconstruct a mental image of the system state in question.

The results of the group with causal interpretation parallel the findings of Dienes & Fahey (1998), but the interpretations are slightly different. Dienes and Fahey assume that subjects learn a lookup-table of system states and conclude from their data that this table is stored in implicit memory. The lookup-table is similar to I-O knowledge. The difference is that in the present conception I-O knowledge is always explicit, and a second type of knowledge is assumed – subsymbolic associations between events. In this interpretation it is the subsymbolic knowledge that would be considered implicit.

Applying the distinction between symbolic I-O knowledge and subsymbolic associations between events to the "Sugar Factory" could explain the results of Dienes & Fahey (1998). If subjects used I-O knowledge about past situations in the recognition task and associations between events in the control problems, stochastic independence between the two tasks could be the consequence. The explanatory potential of the subsymbolic level of ACT-R for implicit memory phenomena has also been demonstrated by Taatgen (1999) with a model of word recognition and completion. In his model it is the dynamics of baselevel learning rather than associative learning that accounts for dissociations.

The present research yielded effects that are similar to those known from other paradigms. It is a common finding that providing additional information about stimuli enhances memory or other kind of performance, e.g. in classification learning (Nosofsky, Clark, & Shin, 1989), Schema acquisition (Ahn, Brewer, & Mooney, 1992), or text comprehension (Bransford & Johnson, 1973; Kintsch & van Dijk, 1978). Also the finding that most subjects spontaneously rather use I-O knowledge or knowledge about specific instances than using structural knowledge or rule knowledge has parallels in these paradigms. Nosofsky et al. (1989) found that even simple rules defining a concept were only used when subjects were explicitly told to do so. Ahn et al.'s (1992) subjects used the experimentally provided background knowledge only when they were engaged in tasks requiring the active use of that knowledge.

An important question is at what point in the whole process the causal interpretation effect arises. The present model assumes that the associations between events are learned incidentally in both conditions, and the effect occurs during recall, when only the ci subjects use this knowledge. This assumption shall be tested in future experiments.

The next step in this research is modeling the completion task to test if the model really predicts the effect of causal interpretation on the contingency between recognition and completion tasks. Further research is also necessary to explore if the effects of causal interpretation can be generalized to similar tasks. If the effects can be confirmed, the model provides an interesting basis for a more general theory about implicit memory phenomena.

Metarepresentation in Philosophy and Psychology

Sam Scott (sscott@ccs.carleton.ca)
Department of Cognitive Science
Carleton University, Ottawa, ON K1S 5B6

Abstract

This paper brings together two definitions of metarepresentation: Dennett's notion of metarepresentation as second-order representation, and an alternative definition of metarepresentation found in the work of Leslie, Frith, and Baron-Cohen on autistic children. I show that the two definitions are not in any way compatible with one another, and that the assumption that they *are* compatible can lead to confusion about the nature of higher cognition. I illustrate this potential for confusion through the analysis of some claims made in a paper by Whiten and Byrne on primate cognition.

Representation

I will use the term "representation" to mean *mental representation* as defined in Von Eckardt's (1999) MITECS entry. Her definition of mental representation is (I hope) sufficiently broad and uncontroversial to be acceptable to most of the various competing currents in cognitive science. According to Von Eckardt, a (mental) representation has four important aspects: "(1) it is realized by a representation bearer; (2) it has content or represents one or more objects; (3) its representation relations are somehow 'grounded'; (4) it can be interpreted by (will serve as a representation for) some interpreter." (p. 527) Points (1) and (4) in the above establish that a (mental) representation requires a subject that both bears and can interpret the representation.

Point (2) establishes what the representation can be about. The point about representing one or more objects is fairly clear, but the point about "having content" needs some unpacking. Fortunately, Von Eckardt does that unpacking for us. A (mental) representation is something that can stand for "concrete objects, sets, properties, events, and states of affairs in this world, in possible worlds, and in fictional worlds as well as abstract objects such as universals and numbers; that can represent both an object (in and of itself) and an aspect of that object (or both extension and intension); and that can represent both correctly and incorrectly." (p. 527) Von Eckardt's list is probably not exhaustive, but it does cover the ability of cognitive systems to "think about" objects in the world, counterfactual situations, and propositions and predicates, all under the umbrella term *representation*.

The only point that remains undeveloped in Von Eckardt is point (3), which states that relations must be "grounded". I take that to mean simply that there must be an external referent of some kind for any representation, although this "external" referent may only exist in a possible or fictional world.

Metarepresentation

The prefix "meta" can mean a number of different things in different contexts (e.g. "metaphysics", "metaphilosophy", "metamorphosis" to name but a few) but the usual sense attributed by philosophers is that a metarepresentation is a higher-order representation of some kind. That is, a metarepresentation is a representation of a representation. Following Dennett (1998), it stands to reason that if a representation exists as an object in the world, then it too can be represented. Dennett's examples of metarepresentation tend to be of a hybrid nature. For instance a drawing on a piece of paper is a type of non-mental representation, which is represented in the mind of the person viewing it. The mental representation is of the drawing, but since the drawing is itself a representation, the viewer has a (mental) metarepresentation of whatever it is that the drawing represents.

Despite the drawing being an "external" rather than a mental representation it does share many of the properties of the latter. Following Von Eckardt as quoted above, the drawing: (1) has a representation bearer (the paper); (2) has content (whatever the drawing represents); (3) has a referent; and (4) can be interpreted by some interpreter. Most of Dennett's examples are to do with hybrid metarepresentation – mental representations of external representations. An interesting question is whether hybrid metarepresentation is the same sort of thing as purely mental metarepresentation. Some would say no, arguing that in the hybrid case, there is a difference of content – the external and the mental represent in different ways, therefore a representation of an external representation has a different type of content from a representation of a mental representation. Dennett would not want to take this approach, opting for an intentional stance in which he could avoid discussing matters such as internal content – things represent if we can sensibly treat them as representing, regardless of whether the representation has any further degree of reality. For the

current discussion, I would like to leave aside issues of content and the differences between hybrid and purely mental metarepresentation. In any case, this paper discusses purely mental metarepresentation almost exclusively. I hope I can safely take from Dennett the intuitively satisfying notion that the definition of "metarepresentation" corresponds roughly to the definition of "higher-order representation".

In addition to being intuitive, the "higher-order" definition of metarepresentation is also the one that has seen most use in philosophical circles. Unfortunately, in a large part of the psychological literature, it is not clear that this is the definition that is in use. In what follows, I will show that the so-called "metarepresentational conjecture" that is postulated to explain certain aspects of autistic behavior is making use of a very specific and technical definition of the word "metarepresentation". Of course this fact on its own should be neither surprising nor cause for alarm – any group of scientists should always feel free to redefine terms in technical ways that suit their needs. But unfortunately, the different definitions have lead to confusion even within the psychological literature. Before moving on to this literature, however, it is worth spending some time sorting out potential confusions lurking within the definitions articulated above.

What Metarepresentation is NOT

First of all, a representation can *contain* other representations without being a metarepresentation. For instance, consider the representations that might be necessary to entertain the thought corresponding to the following proposition:

(1) Mélissa's dog is dead

At the very least, we need a representation of Mélissa's dog. We will also need a representation of some one-place predicate DEAD. Finally, it is possible that we would also need a representation of the saturated predicate DEAD(Mélissa's dog). Depending on your personal biases (i.e. connectionist or classical), you may therefore want to assert that understanding sentence (1) requires a representation of Mélissa's dog which is *contained within* a representation of the predicate DEAD(Mélissa's dog). If so, this is not the same thing as the representation of DEAD(Mélissa's dog) being (even partially) a metarepresentation *of* Mélissa's dog. That is, there is nothing necessarily metarepresentational going on in this situation.

So far so good, but the next assertion may be more controversial. Second-order beliefs and desires do not necessarily require metarepresentations either. To see why, consider the following first-order belief:

(2) Mélissa BELIEVES that her dog is dead

This first-order belief requires Mélissa to have a mental representation of the proposition "my dog is dead" and believe that the proposition is true (perhaps it is marked as "true" in her mental database, or perhaps she has it in her "belief box", or whatever). The important observation here is that Mélissa need not be aware of her belief. If she were, she would require a representation of it, but to simply hold the belief, no such special mental machinery is required. She need not think to herself "I believe my dog is dead" in order to believe her dog is dead. She just needs to believe that her dog is dead. Thus "believe" is a definitional label we apply to any state of affairs in which someone holds a proposition to be true. This is why we can speak of animals having beliefs, even if we are not comfortable with the notion that they may be aware of them.

Now consider the following second order belief:

(3) Anne BELIEVES that Mélissa BELIEVES that her dog is dead

What kinds of representations do we need to ascribe to Anne in this case? First, she needs the representation of Mélissa's dog, the predicate DEAD, and so on. What she doesn't need is a representation of *Mélissa's representation of* her dog, the predicate DEAD, and so on. That is, she doesn't need a second-order representation of any of these things. She can get by with her own first-order representations. But it would appear that Anne also needs to have a representation of Mélissa's BELIEF. That is to say, she needs a representation of Mélissa's mental state of believing in a way that Mélissa does not. She must be aware of Mélissa's BELIEF, while Mélissa need not be. If we consider Mélissa's mental state of believing to be an object in the world, then this mental state must be represented somehow in Anne's belief. The question of whether we need a metarepresentation here hinges on whether Mélissa's belief state counts as a representation. But as I pointed out above, for Mélissa to simply *have* the first order belief, no first order representation of belief is required. Since neither Mélissa nor Anne has any particular need of belief representation in order to be a believer, Anne's representation of Mélissa's belief need not be second-order.

So what *does* Anne require in order to hold belief (3) above? It would seem that certain processing requirements are necessary to be able to form such complex thoughts. (Recall that what she actually believes corresponds to sentence (2) above, and not to sentence (3).) First of all, Anne must be able to perform some kind of *propositional embedding*. She needs to be able to represent Mélissa's belief as a proposition with two arguments: a representation of Mélissa, and a representation of the proposition that she believes.

Furthermore, Anne needs to be capable of dealing with *referential opacity*. She must be able to remain agnostic about the truth-value of the embedded proposition ("Mélissa's dog is dead") and recognize that it has no effect on the truth-value of the belief proposition.

"Metarepresentation" in Autism Research

A particular definition of "metarepresentation" has played a very important role in research on Autism, where researchers have proposed the existence of a metarepresentational module to explain some of the deficits that autistic people exhibit. Alan Leslie, along with Simon Baron-Cohen and Uta Frith, are the principal proponents of metarepresentational modules in the psychological literature (Leslie, 1991; Baron-Cohen, 1991). Leslie in particular has put forward the *metarepresentational conjecture*: "Autistic children are impaired and/or delayed in their capacity to form and/or process metarepresentations. This impairs (/delays) their capacity to acquire a theory of mind." (Leslie, 1991, p. 73) Before dissecting what Leslie means by "metarepresentation", let's take a quick look at the evidence on which this statement is founded.

The three most classic experiments on autistic children are the picture sequencing task, the Sally/Anne task and the Smarties task, all of which reveal a selective deficit in autistic children in understanding false beliefs. For space reasons, I discuss only the Sally/Anne task (see Leslie, 1991 for the others). In this experiment dolls are used to act out a scenario in which Sally hides a marble in a basket and leaves the room. While she is gone, Anne enters and transfers the marble to a box. Sally returns, and the children are asked, "Where will Sally look for her marble?" Autistic children consistently make the incorrect prediction that Sally will look in the box. They fail to realize that in the absence of new information, Sally will retain her (now false) belief that the marble is still in the basket – to use the common term, autistic children lack an adequate Theory of Mind.

In the first act of the puppet show, the child presumably believes the following:

(4) The marble is in the basket, and
(5) Sally BELIEVES that the marble is in the basket.

Then in act 2, the child learns that:

(6) The marble is in the box

and presumably updates her beliefs incorrectly to infer that:

(7) Sally BELIEVES that the marble is in the box

Recall the conclusions of the previous discussion: 1) second-order beliefs do not necessarily require metarepresentations (it is only necessary to have the ability to *represent* first order beliefs in order to *have* second-order beliefs), and 2) propositional embedding and referential opacity are required for second-order beliefs. Following from these conclusions, it seems clear that the Sally/Anne test does not imply an autistic deficit to do with second-order representations. Rather, it implies that either: 1) the autistic child does not have a concept of belief, or 2) the autistic child has a concept of belief but cannot handle the processing requirements of referential opacity and/or propositional embedding. In fact, the evidence quoted in (Leslie, 1991) is insufficient to distinguish between these two possibilities. Children are never directly asked about the beliefs of others ("Where does Sally *think* her marble is?") Rather, they are asked something like, "Where will Sally *look* for her marble?"

The second area of evidence quoted by Leslie is the apparent lack of pretend play in autistic children, and it is on this basis that he develops the metarepresentational conjecture and defines what he means by "metarepresentation". "I have used the term 'metarepresentation' in a specific sense: to mean (e.g., in the case of understanding pretence-in-others) an internal representation of an epistemic relation (PRETEND) between a person, a real situation and an imaginary situation (represented opaquely)…" (Leslie, 1991, p. 73) This definition doesn't sound at all like the definition of metarepresentation as higher-order representation pursued above. It seems like a highly technical redefinition of the word. This is a fact that Leslie seems to be quite aware of, as he says in a footnote that "'metarepresentation' can mean something like 'a kind of proprietary (internal) representation in ToM mechanisms' and something like 'a particular concept of representation which someone grasps'." (p. 77) It is not clear what Leslie's second possibility in the above refers to, but what he probably has in mind is Perner's (1991) account, which differs from both Leslie and Dennett. Unfortunately, he does not elaborate any further. From now on, I will call the definition of "metarepresentation" as higher-order representation "metarepresentation$_1$", while Leslie's version will be "metarepresentation$_2$" (and I'll forget about Perner's definition for the purposes of this discussion).

With that in mind, let's take a look at Leslie's formalism of the PRETEND example. In his view, the predicate PRETEND (which is supposed to behave similarly to BELIEVE and DESIRE) works something like this:

(8) Mother PRETEND the empty cup "it contains tea" (p. 73)

In addition to the new definition for metarepresentation$_2$, Leslie is also using a very different formalism for his psychological predicates – three arguments instead of two. Two questions immediately arise: 1) is Leslie's formalism plausible and/or compatible with the BELIEF/DESIRE formalism pursued above? and 2) putting aside Leslie's metarepresentation$_2$, is there anything metarepresentational$_1$ in his alternative formalism?

The Plausibility of Leslie's Formalism

Much of what I have to say in this section and the next parallels critiques from Pernerwith which I am in broad agreement (for example, Perner, 1991) . Rather than give a full analysis of Leslie's ideas, I will concentrate on the points I need to make for the discussion to follow.

The first observation is that there appears to be an important difference between pretending and believing, so we need to be cautious about generalizing from one to the other. Although it is possible to have beliefs without any representation of belief, it is not at all clear that this also holds for pretence. The possibility of pretending that something is true without being aware that one is doing so seems unlikely. So whereas to believe that the cup is empty does not require the self-conscious reflection that

(9) I BELIEVE that the cup is empty,

there is no way to pretend that the cup contains tea without self-conscious reflection by the subject on her own mental state. That is, the subject would have to BELIEVE:

(10) I PRETEND that (the cup contains tea).

Therefore, unlike beliefs and desires, being able to pretend seems to imply the ability to understand pretence in oneself, and thus in others, since the forms are the same. For instance believing that:

(11) Mother PRETENDS that (the cup contains tea)

requires exactly the same representational capacities as believing that one is pretending oneself.

Getting back to the substance of the issue, Leslie's formalism is actually quite different from the above. In his system, pretence is represented more like this:

(12) Mother PRETENDS (the empty cup) ("it contains tea")

That is, he has three elements: the subject (Mother), the real situation (the empty cup), and the pretend situation (it contains tea). But why is it that in order to understand pretence, you must be aware of exactly how the real situation differs from the imagined one? In reality, you can simply say "Mother pretends that the cup contains tea" and remain unsure of whether the cup is empty, contains orange juice, or whatever. That is, you do not need to know the "real" situation to understand the pretence. All you need to know is the fact, contained in the semantics of PRETEND with it's implied referential opacity, that the real situation must differ in some way from the imaginary one. If this is clear in the case of PRETEND, it is even more so in the case of BELIEVE. It would be much too restrictive to suppose that BELIEVE requires knowledge of the actual situation as in:

(13) Mélissa BELIEVES (her dog is dead) ("her dog is dead"), or
(14) Mélissa BELIEVES (her dog is **not** dead) ("her dog is dead")

Again, the information one needs is bound up in the semantics and referential opacity of BELIEVE. When you believe that *p*, *p* may or may not be true. Further problems arise when we try to embed Leslie's formalizations of psychological predicates to form second order beliefs. For instance, to believe (12) above would require:

(15) I BELIEVE [Mother may or may not PRETEND (the empty cup) ("it contains tea")]$_a$ ["Mother PRETENDS (the empty cup) ("it contains tea")"]$_o$

where the subscript "a" above marks the actual situation and "o" marks the referentially opaque proposition. This situation just seems unnecessarily complicated. You simply don't need to know the real situation in order to evaluate the truth of psychological predicates. The principle of referential opacity gives you everything you need to know – that the embedded proposition may or may not be true regardless of the truth-value of the psychological predicate.

Metarepresentation$_1$ in Leslie's Formalism

Is there anything metarepresentational$_1$ in Leslie's formulation of the semantics of psychological predicates? Leslie has made the unusual move of including the actual situation alongside the imagined situation in his formulation of at least one of the psychological predicates. Does this move change anything in the analysis of metarepresentations$_1$ in psychological predicates? The only real complication here is the introduction of dual representations for the same object – for example, the cup as an empty cup and the cup as a cup with tea in it. This dual representation

is well accounted for in Von Eckardt's (1999) definition of mental representation. The first refers to a concrete object and/or a property of a concrete object, while the second refers to an object/property in a possible or fictional world, or in the case of BELIEVE may simply represent an object/property incorrectly. So the dual representation does not imply metarepresentation$_1$.

One other aspect of Leslie's formulation deserves consideration. In the "Mother PRETENDS" example above, the first situation (the empty cup) is referred to again in the imaginary situation (it contains tea). The anaphoric reference in the imaginary situation ("it") could perhaps be taken to imply that the *representation* of the empty cup, rather than the empty cup itself, is the subject of the imaginary representation, thus making the latter a metarepresentation$_1$, but this is probably not the interpretation Leslie had in mind.[1] In fact it is hard to imagine how such an interpretation could be made coherent, since unpacking the imaginary situation would lead to "(the representation of the empty cup) contains tea" – and that can't be right.

Metaconfusion

Leslie is self-consciously using a technical definition for metarepresentation$_2$ that does not intersect in any way with Dennett's metarepresentation$_1$. Nevertheless, for other authors, the distinction may not be so clear. The potential for confusion is quite neatly demonstrated in a paper by Whiten and Byrne (1991). In an otherwise excellent article about the implications of Leslie's ideas for studies of pretend play in primates, they explicitly state that Leslie's metarepresentation$_2$ is second-order representation (i.e. metarepresentation$_1$). But the confusion doesn't stop there. They go on to offer a summary of Leslie's theory of metarepresentation$_2$ that is worth quoting at length.

"Leslie argues convincingly that the isomorphism between the properties of mental state terms and those of pretend play is not coincidental, but signifies a fundamental psychological achievement which can generate both pretence and an ability to represent the mental states of others. What these two share is that they are *representations of representations* – labeled variously as second-order representations (Dennett) or metarepresentations (Pylyshyn, Leslie).

"In the case of mental state terms, what 'second-order' means is fairly obvious: the child's mind represents a mental state in another's mind, *believing* (for example) that her father *thinks* there is a mouse behind the chair.

"In the case of pretence, the implication is less obvious. The key point is that in pretence, as strictly defined by Leslie, two simultaneous representations of the world must coexist in a precise relationship. When a child talks into a banana as if it were a telephone …the child has a primary representation of the object as a banana and, simultaneously, a representation of it as a telephone … The pretend representation is coded or marked off in some way as metarepresentational…" (Whiten and Byrne, 1991, p. 269, their italics.)

The first two paragraphs above demonstrate the confusion nicely. The authors are explicitly running together Dennett's metarepresentation$_1$ with Leslie's metarepresentation$_2$. Furthermore, they are committing the error of assuming that second order beliefs require second order representations. To see this, consider their example in the final paragraph, which makes use of the psychological predicate THINK. They make it seem like the child must have a representation of her father's thoughts, which of course consist of representations. Therefore the child must be engaging in second-order representation, or metarepresentation$_1$. But "thinks" in this context means the same thing as "believes", and so the appropriate formulation is actually:

(16) The child BELIEVES that her father BELIEVES that there is a mouse behind the chair.

This is straight-up second-order belief, which I have shown to *not* necessarily involve second-order representation, or metarepresentation$_1$.

The final paragraph picks up on the "real situation" vs. "imaginary situation" component of Leslie's formulation and reads into it another sense of "metarepresentation", which I'll call "metarepresentation$_3$" – definition: a representation of a counterfactual state of affairs. But counterfactual representations are fully compatible with the fairly non-controversial theory of first-order mental representations put forth by Von Eckardt (1999).

The confusion in Whiten and Byrne really comes to the fore in their concluding sections, where they talk about a "cluster of metarepresentational capacities." The first capacity they discuss is indirect sensorimotor coordination – the ability that humans and some other primates have to direct the actions of parts of their bodies by looking in a mirror or at a video image of the body parts they are trying to control. This, according to Whiten and Byrne, requires "a capacity to represent the remote representation of parts of self available in the mirror or video image: second-order representation" (p. 279). This ability is straightforwardly metarepresentational$_1$ in the Dennettian sense. In fact, it is a case of hybrid metarepresentation$_1$, requiring a mental representation of an external representation.

The other two "metarepresentational" abilities are tool use and insight. Tool use (in this case, a chimpanzee using a branch to probe for termites)

[1] Recall Leslie's definition above: "…an internal representation of an epistemic relation…"

apparently requires "a capacity to generate, simultaneously with the primary perception of the branch as branch, a metarepresentation of it as probe" (p. 280). Insight is a leap from pretence to re-description as in, "'I *pretend* this rock is a hammer' … 'Aha, I could *use* this rock as a hammer'...." (p. 280, Whiten and Byrne's italics). This is much closer to Leslie's technical definition of metarepresentation$_2$ in which the representation of the world as it really is coexists with a pretend representation of the world. But as I argued above, Whiten and Byrne appear to have drawn on the occurrence of a counterfactual in Leslie's formalism to build a third sense (metarepresentation$_3$), which is at work in the above.

In conflating metarepresentation$_1$ with their own interpretation of metarepresentation$_2$ (metarepresentation$_3$), Whiten and Byrne have made two mistakes, one of which comes directly from Leslie, and one that is not explicitly present in (Leslie 1991). In the former case, they have imported Leslie's notion that psychological predicates require an explicit representation of how the world actually is in addition to the representation of how the world is believed, pretended, or desired to be, and used it to unwittingly arrive at a new definition of metarepresentation$_3$. But they have also made another mistake in equating Leslie's metarepresentation$_2$ with Dennett's metarepresentation$_1$, even to the point of citing Dennett and Leslie in the same sentence.

To be fair to Whiten and Byrne, their dissection of Leslie is itself an attempt to criticize and make some new distinctions. For instance, they point out that not all pretend play involves a real object. Humans and other apes appear quite capable of having imaginary friends, and interacting with imaginary objects. In this case, it is difficult to see what the "real situation" component of Leslie's formulation would amount to, and is evidence for at least sometimes abandoning it in favor of two-place intentional predicates. But confusion over the two original senses of metarepresentation, and the unwitting introduction of yet a third sense really manages to confuse the issue. For instance, in summing up, they speculate that perhaps, "what convinces those who interact intensively with them that chimpanzees are 'intelligent' is a facility in second-order representation." (p. 280) This is a nice parsimonious account, but it is built by equating three different definitions of metarepresentation based on a number of confusions about the nature of psychological predicates. As I have attempted to show, second-order beliefs and desires as well as the pretend play studied in Whiten and Byrne's work require propositional embedding and referential opacity, but do not necessarily require second-order representations (metarepresentation$_1$).

Conclusions and Prospects

In Dennett's *Making Tools for Thinking* (Dennett, 1998), he invites us to speculate along with him on the difference between what he terms "florid" and "pastel" representations. Florid representations are those that become explicit as objects in the world, by being encoded in language or some other physical medium (drawings on paper, for instance.) He notes that the capacity to form florid representations seems to imply the ability to manipulate the representations themselves, which leads him to raise the slogan "no florid representation without metarepresentation." He further speculates that "belief about belief" may not be the same thing at all as "thinking about thinking" – that is, having the ability to self-consciously reflect, compare notes with other thinkers, and so on. The considerations in this paper may help to shed a little light on all of these questions.

If I am right that second-order belief does not require metarepresentation$_1$, and Dennett is right that thinking about thinking requires florid representations and therefore metarepresentations$_1$, then maybe we do have the basis for a nice account of one possible difference between humans and other apes – a capacity to form and manipulate higher-order representations (that is, metarepresentations$_1$).

Connectionist modelling of surface dyslexia based on foveal splitting: Impaired pronunciation after only two half *pint*s

Abstract

In cases of surface dyslexia and phonological dyslexia there is a dissociation between the reading of irregular words and nonwords. This dissociation has been captured in connectionist models of dyslexia in terms of impairments to the models' phonological representations. We report a series of connectionist simulations based on an alternative neuro-anatomically motivated theory that dyslexia is at least partly caused by hemispheric desynchronisation. Problems of interhemispheric transfer affect the mapping between orthography and phonology because the human fovea is precisely vertically split: a fixated word is initially split and the two parts contralaterally projected to the two hemispheres of the brain. Much of lexical processing can be reconstrued as the integration of this information (Shillcock, Ellison & Monaghan, 2000). We demonstrate that the dissociation between the reading of irregular words and nonwords can be understood in terms of a failure to integrate the initially split input.

Introduction

The word *pint* is pronounced differently from its orthographic neighbours *dint*, *hint*, *lint*, *mint*, *tint*. In this sense its pronunciation is irregular. Because of the presence of such words in its lexicon, English is said to have a deep orthography. Irregular pronunciations have been observed to cause processing problems both for normal readers and for certain impaired readers: in the former a low frequency irregular word such as *pint* may take measurably longer to pronounce than a matched regular word, and in the latter such a word might be erroneously regularised (*pint* pronounced to rhyme with *mint*). For these reasons irregular words have been used in a large number of studies of how readers translate the orthographic representation of a word into its phonological specification. In this paper we approach the pronunciation of irregular words from the perspective of a new model of visual word recognition based on the neuro-anatomical observation of foveal splitting (Shillcock, Ellison & Monaghan, 2000). We will argue that this model provides a principled motivation for some of the problems associated with irregular pronunciations in both normal and impaired readers.

The measurable processing problems that normal adult readers have with low frequency irregular words (*pint*) do not extend to high frequency irregular words such as *have* (whose pronunciation cannot be predicted from *cave*, *rave*, *pave*, *knave*) (Paap & Noel, 1991; Seidenberg, Waters, Barnes & Tanenhaus, 1984; Taraban & McClelland, 1987). Perhaps the most productive approach to modelling this interaction between regularity and frequency has been that developed by Seidenberg and McClelland in their (1989) connectionist model of reading and by Plaut and others subsequently (e.g. Plaut & McClelland, 1993; Plaut, McClelland, Seidenberg & Patterson, 1996; Harm & Seidenberg, 1999). Seidenberg and McClelland's original model was a simple feedforward model; later models have contained recurrent connections and more structured input and output layers. In general, in these models the apparently rule-based behaviour that generates regular pronunciations is recast in statistical terms, so that a low frequency irregular pronunciation (*pint*) is militated against by the more frequently occurring regular pronunciation of the relevant vowel in similar contexts. Thus, when the irregular pronunciation is itself high frequency (*have*), that particular mapping between orthography and phonology is sufficiently emphasised to co-exist with the regular mapping. The superpositional storage that characterises these models means that a minority mapping such as that required by *pint* is disproportionately demanding in terms of computational resources compared with the efficient generalisation represented by a regular pronunciation. This fact is also demonstrated in Plaut and McClelland's (1993) model in which attractors behave componentially when the input and output representations of words are split into onset, nucleus and coda. In their model, pronunciation of the vowel in *pint* involves the connections from all three input slots (onset, nucleus and coda), whereas the regular, default pronunciation of the *i* involves only the nucleus.

Irregular words pose particular problems for surface dyslexics, who are liable to produce regularisation errors (Patterson, Coltheart & Marshall, 1985; Manis et al., 1996). In connectionist models, the learning and retention of irregular pronunciations are generally vulnerable. For instance, Seidenberg and McClelland showed that restricting the number of hidden units impairs learning low frequency irregular words, and Harm and Seidenberg (1999) produced a similar effect by lowering the learning rate overall. Plaut et al. (1996) and others explore the idea that a division of labour occurs between the direct orthography-phonology mapping and the same

mapping mediated by semantics: the irregular pronunciations are seen as relying more on the route that proceeds via semantics, leaving the direct route to concentrate on the regular pronunciations. This behaviour of the models seems to capture the observation that developmental dyslexics frequently have impaired phonological processing (see Snowling, 2000, for a comprehensive review of the phonological processing problems of dyslexics).

Some of the most critical data in this area concerns the dissociation between the ability to pronounce irregular words and the ability to pronounce nonwords. This dissociation is found between the surface and phonological subtypes of dyslexia (Beauvois & Derouesné, 1979). Surface dyslexics cope moderately well with novel words and nonwords, but are liable to make regularisation errors on known irregular words, whereas phonological dyslexics cope moderately well with irregular words but are disproportionately impaired when reading novel words and nonwords. This dissociation motivated Marshall and Newcombe's (1973) original dual-route model and its later development and computational implementation by Coltheart and others (e.g. Coltheart, Curtis, Atkins & Haller, 1993), in which a lexical route and a non-lexical route (containing grapheme-to-phoneme correspondence rules) can be differentially impaired to produce the desired impairments.

In this paper we claim that developmental surface dyslexia, characterised by problems with irregular words, arises naturally from impaired hemispheric interaction in a model based on the observation that the human fovea is precisely vertically split. There are long-standing observations that dyslexia is frequently associated with problems of callosal transfer (e.g. Davidson & Saron, 1992). By modelling word recognition within a split network, we ground these observations of impaired reading in an implemented model of normal reading. We claim that impaired hemispheric interaction is a fundamental, qualitative explanation of problems in pronouncing irregular words, and is a more parsimonious account than resource-based explanations.

The split-fovea model of reading

Shillcock, Ellison and Monaghan (2000) present a model of lexical access based on the precise vertical splitting of the human fovea. Information presented in the left visual field (LVF) projects, initially, to the right hemisphere (RH), whereas information in the RVF projects to the LH. This long-recognised initial contralateral projection of the visual field to the two hemispheres of the brain is also true of the human fovea – a fact that has not been extensively explored in research in visual word recognition. When a word is directly fixated, the two parts of the word on either side of the fixation point are projected to different hemispheres. In order for a word to be recognised and pronounced correctly, the information in the two hemispheres has to be integrated. Shillcock et al. (2000) investigate some of the implications of foveal splitting for a full-sized lexicon and show that the initial splitting of the word is an informationally attractive starting point for word recognition, rather than being merely an inconvenience.

Consider the word *pint*, centrally fixated. The two sides of a split model will receive the two letters *pi* and *nt*, respectively. In order to pronounce the vowel correctly, the model must process information from both sides of the model: *pi* on its own may be pronounced as in *pine*, or as in *pill*. If this integration is not complete then a regularisation error is likely to occur, so that *pi* will be pronounced in its most frequent form: /pI/ (see Table 1). As Harm and Seidenberg (1999) observe, the task of reading irregular words is akin to solving the XOR problem. In the case of a split model without recurrence, this task is impossible, as the structure is akin to a perceptron.

Table 1: Pronunciation of *pi*.

Pronunciation of vowel	Example	Count	Frequency (per million)
/I/	pith	14	424
/ii/	piece	2	175
/&I/	pint	10	164
/I@/	pier	2	16

When a single word is read it may be fixated to the left of the first letter, to the right of the last letter, or at all points in between. Elsewhere (e.g. Shillcock & Monaghan, *2001*) we have implemented an idealised version of the initial splitting of these different visual inputs in reading single words in a series of neural network models, so that there are five different fixation positions across the input for a four letter word (only "fixations" between letters are considered). In the simulations we report here, we employ a simplified version of this model, in which each word is only fixated at one fixation point within the word. This simplification allowed us to stay closer to Harm and Seidenberg's (1999) simulations, which provide an important point of comparison. We show that impairments to the integration of information in the two parts of the word results in the behaviour associated with surface dyslexia.

One version of the split model of reading is shown in Figure 1. The model comprises two orthographic input layers, corresponding to the left and right visual fields. Each input layer has 4 letter slots. If a letter is present in a slot then one of 26 units representing the letters of the alphabet will be active. The output layer is a representation of phonology, with two slots each for onset, nucleus and coda. Phonemes are represented in terms of 11 phonological features. We have used the features described by Harm and Seidenberg (1999), although we have augmented their phonology to accommodate the transcriptions found in the CELEX database (Baayen, Pipenbrock & Gulikers, 1996). These changes to the phonological transcription principally involved the representation of diphthongs and the role of schwa; the changes consid-

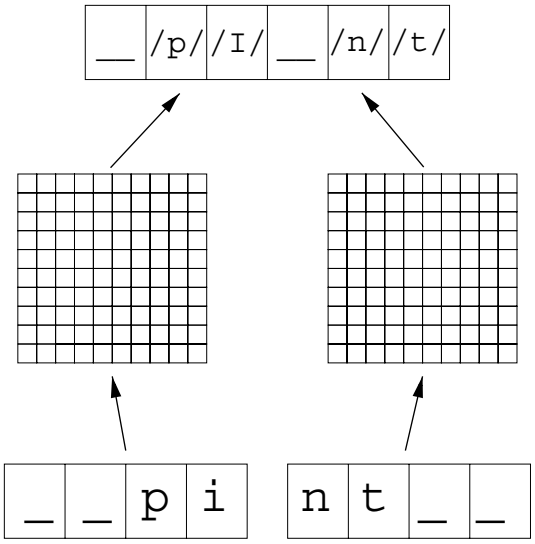

Figure 1: The split model of reading.

erably increased the problems of learning the mapping from orthography to phonology. Each input layer in the model is fully connected to one of two hidden layers each with 100 units. These hidden layers are fully connected to the output. The model has to learn to map orthography onto phonology given the constraints of a split input.

The model was trained on 3835 single-syllable word lemmas from the CELEX English database with up to two consonants in the onset and coda. Four words were omitted because they contained orthographic consonant clusters that would not fit within the input[1]. Words were presented in the input so that the first vowel was justified immediately to the left of centre. In total, 57.5% of words were fixated at or to the left of their physical centre, which is the usual site of fixation during reading (Rayner, 1998). Words were presented randomly to the model according to the log-frequency of the word, and backpropagation was used to train the connections between the layers.

Several versions of the model were trained: (a) a feedforward version with no phonological attractors ("Split-No Attractors"), (b) a recurrent version with phonological attractor units ("Split-Attractor"), and (c) a recurrent and interconnected version with phonological attractors, with the hidden layers fully connected to one another ("Split-Interconnected"). The attractor models had a set of 35 "clean-up" units connected to the output layer, which were pretrained in learning a phonology to phonology mapping. Orthography to phonology trials were then interdispersed with phonology to phonology trials during training of the attractor models. Two nonsplit models were also trained as controls, equivalent to those employed by Harm and Seidenberg (1999). These models were required to make the same mapping between orthography and phonology, except that all the input units were connected to a single hidden layer of 100 units. Feedforward ("Nonsplit-No Attractor") and recurrent attractor ("Nonsplit-Attractor") versions were trained.

The 361 nonwords used by Harm and Seidenberg (1999) were employed[2]. The model was tested with 44 irregular words taken from Taraban and McClelland's (1987) materials[3].

We predicted that the Nonsplit-Attractor model would perform well on both irregular words and nonwords, following Harm and Seidenberg's demonstration of the capabilities of that model. The Nonsplit-No Attractor version should perform relatively poorly on irregular words and nonwords; this model corresponded to Harm and Seidenberg's (1999) unimpaired model, and their phonologically impaired model, respectively). We predict that the split models will exhibit surface dyslexia to varying degrees according to the level of interaction between the two hemispheres. Furthermore, this deficit will be robust in the face of further training on the model – additional training will not reverse the pattern of difficulties in reading irregular words and nonwords, as happens in Harm and Seidenberg's (1999) delayed model of reading.

Results

Figures 2, 3 and 4 show the performance of the different models, in terms of percentage of words correctly pronounced, at different stages of training. Figure 2 shows how well the models learned the whole training set, and we see that the NonSplit-No-Attractors model performs comparably to the same architecture presented by Harm and Seidenberg, climbing steadily to levels in excess of 90% correct. Even though the current training set contained more elaborate phonological representations than those used by Harm and Seidenberg for the same type of model, we see that the curve has not asymptoted even after the presentation of 5M words in training; further training promises to improve performance even more. We see a similar level of success for the NonSplit-Attractors model, though this model is slower to learn than the NonSplit-No-Attractors model due to the interleaving of phonology to phonology trials during training. These models replicate Harm and Seidenberg's (1999) success with the same architectures.

In contrast, Figure 2 shows that the Split-No-Attractors model asymptotes early, after about 3M words of training, and never exceeds 70% of words correct. The simple split model is fundamentally incapable of more than this modest performance. The remaining learning curves in Figure 2 demonstrate the value of connectivity between the two halves of the split model: the Split-Attractors model behaves on a par with the different

[1]The omitted words were *eighth*, *borscht*, *touched*, and *schnapps*.

[2]Three nonwords were omitted because they appeared as real words in our training corpus: *plop*, *mo*, and *peep*.

[3]4 of the original 48 items were omitted because they were wordforms that did not occur in our word lemma training set: *does*, *said*, *says*, and *were*.

Non-Split models, and the most rapid learning of all occurs in the Split-Corpus-Callosum model, although the latter model is not directly comparable with the others as it contains more weighted connections and hence more computational resources. The principal result from the training of the different models is that sharing information between the two halves of the input is critical to successful learning.

Figure 3 shows relatively successful generalisation by all of the models to the set of nonwords. The Split-No-Attractors model performs least well as we might predict from Figure 1, but all of the models asymptote within the 55%-70% region, in generalising to pronounce nonwords that were not encountered in training.

The central result of all of these simulations can be seen by comparing Figures 3 and 4. In Figure 4 we see differences between the models in their performance on pronouncing irregular words. The Split-No-Attractors model performs extremely poorly on these words, pronouncing only about 50% of the irregular words correctly. The Split-Attractors and NonSplit-Attractors models perform comparably well, and the NonSplit-No-Attractors and Split-Corpus-Callosum models perform extremely well on these irregular words. In relation to the performance of the other architectures, the simple split architecture shows a dramatic dissociation between

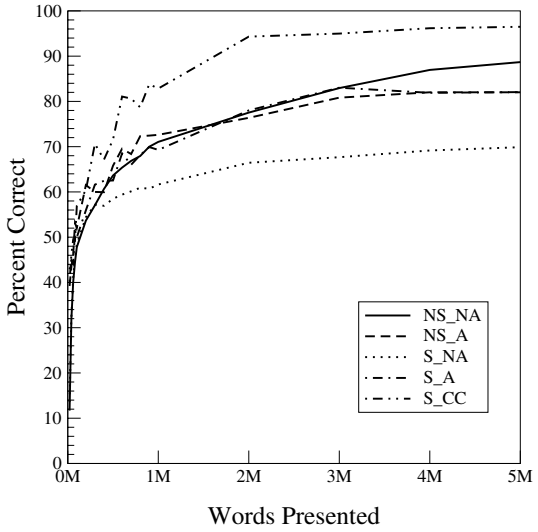

Figure 2: Performance of the split and nonsplit models on the training set.

The errors produced by the simple split model resembles those found in surface dyslexia. Table 2 compares the performance of the Split-No Attractors and NonSplit-No-Attractors models on an example set of irregular words after 5 million words had been presented to the models. The NonSplit model converges to correct pronunciations for all these words, whereas the Split model

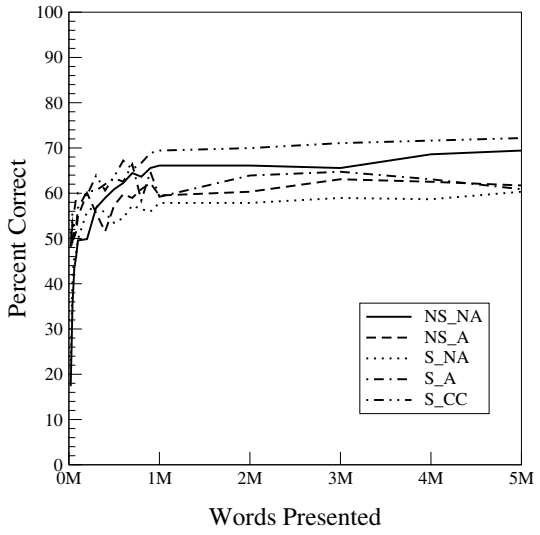

Figure 3: Performance of the split and nonsplit models on nonwords.

produces regularisation errors even after such lengthy training. The differences between the Split and NonSplit models are not only quantitative but qualitative, with the Split model producing plausible over-regularisations for irregular words.

Table 2: Productions of the Split and NonSplit No-Attractor models for irregular word examples.

	Pronunciation		
Word	Correct	NonSplit model	Split model
bind	b&Ind	b&Ind	b&nd
broad	brOOd	brOOd	brOOd
come	kVm	kVm	kVm
hood	hUd	hUd	huud
mild	m&Ild	m&Ild	mEIld
pear	pE@r	pE@r	pIEr
pint	p&Int	p&Int	pInt
quay	kii	kii	kEI
tomb	tuum	tuum	tOm

Discussion

We have successfully reproduced the dissociation between the reading of irregular words and nonwords observed in surface dyslexia. We started by observing that the human fovea is precisely vertically split, and that a fixated word is initially divided between the two hemispheres. We reconstrued the task of lexical processing as one of integrating the information contained in the two hemispheres. We explored the performance of neural network models of reading which had been similarly vertically split, and demonstrated that simple split archi-

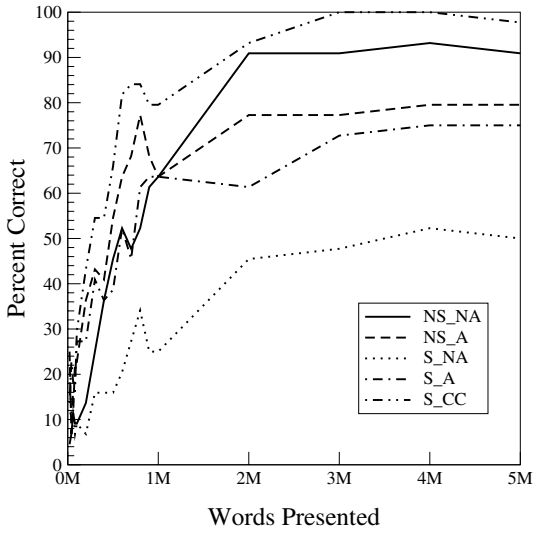

Figure 4: Performance of the split and nonsplit models on irregular words.

tectures are crucially limited in their success in mapping from orthography to phonology.

The problem of pronouncing a divided irregular word like *pint* resembles the XOR problem. The two halves cannot map directly and independently onto the output to solve the problem. There is no purely componential solution, as there is with the pronunciation of a regular word like *mint*. Instead, there have to be intermediate representations that combine the two halves and then map onto the eventual solution. The problem is not restricted to the pronunciation of vowels, although they are the main part of the problem. The consonant cluster at the beginning of *chef* is liable to be regularised to resemble that in *chad* and *cheat* if the whole of the word is not present.

A paradox of the connectionist modelling of cognitive neuropsychological data is the emergence of complex dissociations from relatively undifferentiated architectures. Such demonstrations are parsimonious accounts of the data because they seem to emerge from the structure of the problem, "out there" in the world rather than from the details of some putative functional processing architecture. Researchers have produced successful connectionist accounts of the pattern of dissociations found in the different dyslexias. These dissociations have been achieved in a variety of ways, and we can distinguish three broad strategies. The first is the *Representational Strategy*. Thus, in Plaut and Shallice's (1993) model of deep dyslexia the authors show that the proportion of the different types of error produced by the lesioned network can be changed by lesioning in different parts of the model; lesioning around the model's semantic clean-up units causes more semantic errors, for instance. Similarly, Harm and Seidenberg (1999) show that impairing the phonological attractors in their model increased the errors on irregular words. The psychological reality of this strategy is relatively easy to assess. For instance, Harm and Seidenberg's impairing of the phonological attractors is motivated by the data showing that surface dyslexia is often accompanied by phonological impairment (see, e.g., Snowling, 2000). The second strategy we identify is the *Parametric Strategy*. Examples are the manipulation of the computational resources available to the model, or changes in the details of training. Seidenberg and McClelland (1989) reduced the numbers of hidden units available to the orthography-to-phonology mapping, showing that it militated against learning the irregular words. Similarly Harm and Seidenberg (1999) produced the same outcome by reducing the learning rate. Such manipulations are quantitative, compared to the qualitative effects of the Representational Strategy, and their psychological reality is more difficult to assess. There are clear demonstrations that the orthography-to-phonology mapping for irregular words is the hardest aspect of the pronunciation problem, but equally there are demonstrations that the problem can be solved by a network model with only a few hundred nodes, given the correct representations. Are irregular words still hard for a processor with the resources of the human brain, and with several years to spend on the problem? Additional training of Harm and Seidenberg's model with a low learning rate producing surface dyslexia behaviour leads to the convergence of performance on regular and irregular words, for example. Parametrically based models of dissociations in dyslexia carry with them costly assumptions concerning the capacities of the human brain.

Our own approach has been to introduce a discrete, qualitative neuro-anatomical distinction into the modelling: the effects of foveal splitting. We characterise surface dyslexia as being caused, at least in part, by hemispheric desynchronisation. No amount of extra training and no amount of extra computational resources devoted to either half of a split processor can improve performance on irregular words in a direct mapping between orthography and phonology. The problem is a qualitative one.

Thus, we have provided an account of the dissociation between irregular words and nonwords in surface dyslexics. We do not see this hemispheric desynchronisation account as a necessarily exclusive one. There may also be a contribution from the impairment of phonological representations, as is generally assumed. The relative contribution of each account, and any possible interaction between them, is an empirical question. However, it may be possible to ground phonological impairment itself in hemispheric desynchronisation, despite the fact that expressive phonology is conventionally viewed as the sole preserve of the LH.

A further aspect of the dissociation between regular words and nonwords concerns the performance of phonological dyslexics, who can be highly proficient readers of known words, but can also be dramatically poor at reading nonwords and unknown words, even to the extent of not being able to generate the sound of an isolated letter. We interpret phonological dyslexia as also

resulting from hemispheric desynchronisation. We propose that the desynchronisation is more severe in phonological dyslexia, compared with surface dyslexia, and that a different relationship emerges between the orthographic, phonological and semantic forms of words to compensate for the inability to integrate the orthographic information in the two hemispheres and to map it directly onto a phonological representation. We propose that orthographic information is mapped directly onto semantic information independently in the two hemispheres; each hemisphere partially activates the semantic representations of all the words corresponding to its own orthographic input. Identification of the word is achieved by the interhemispheric transfer of semantic information. The routes by which semantic information might be transferred interhemispherically are more extensive, compared with those concerned with vision, and the problem of finding the intersection of two sets of partially activated semantic representations is, we claim, an easier problem than integrating the corresponding visual information. In this account, a novel word can only be pronounced ad hoc by analogy with known words. This account is therefore a qualitative explanation of the often dramatic problems with novel words observed in phonological dyslexia.

Assessing Generalization in Connectionist and Rule-based Models Under the Learning Constraint

Thomas R. Shultz (shultz@psych.mcgill.ca)
Department of Psychology; McGill University
Montreal, QC H3C 1B1 Canada

Abstract

Although it is commonly assumed that rule-based models generalize more effectively than do connectionist models, the comparison is often confounded by pitting hand-written rules against learned connections. Three case studies from cognitive development show that, under the constraint that both types of models learn their representations from equivalent examples, generalization is consistently superior in connectionist models.

Generalization Problems

A significant part of the ongoing debate between rule-based and connectionist modeling in psychology has focused on the ability to generalize. A common claim from supporters of the classical, symbolic approach is that rule-based models are superior because they generalize more effectively than do connectionist models (Ling & Marinov, 1993; Pinker, 1997; Marcus, 1998). Generalization is considered important by most modelers because it distinguishes understanding of a problem from mere memorization of solutions.

The generalization ability of rules is often enhanced by the use of variables that can be bound to any number of objects or events. Consider the following rule, written in Common Lisp for a production system program. It generates correct responses on some Piagetian conservation of number problems:

```
((response more ?x ?y)
 (and
  (initially-same-number ?x ?y)
  (or (add1 ?x)
      (subtract1 ?y))))
```

The rule says to conclude that row *x* has more items than row *y* if the two rows initially had the same number of items and if one item was subsequently either added to row *x* or subtracted from row *y*. It has plenty of generality because the variables *x* and *y* can be bound to any rows with any number of items. It could be made even more general by adding a third variable *n*, representing the number of items added or subtracted.

More generally, a rule can be defined as a conditional statement in which conjunctively and disjunctively connected conditions, if verified as true, produce a set of conjunctively connected conclusions. Each condition and conclusion is a proposition that can be stated in predicate-argument form, where arguments can be constants, variables, or other propositions.

Leaving aside the issue of whether people actually generalize as well as such rules do, the claim has commonly been made that connectionist models rarely learn to generalize that well. Indeed, this argument seems to have been accepted by many connectionists (e.g., Anderson, 1995), and is at least partly responsible for the many attempts to improve generalization in neural network learning (e.g., Reed & Marks, 1995).

However, closer inspection reveals a serious confound in this argument. The symbolic rules are often written by hand, or perhaps merely alluded to, while the neural network learns its own connection weights by processing examples. The purpose of this paper is to remove this confound between representation and learning by requiring both types of model to learn their representations from equivalent examples. It is already well known that an alternate method of removing this confound, by hand-designing neural networks to explicitly implement rules and variables, also produces excellent generalization (Shastri, 1995).

The learning constraint proposed here is reminiscent of the developmental tractability constraint proposed by Klahr (1984). In discussing cognitive development, Klahr argued that any two plausible, consecutive developmental states must be integrated in a transition theory that can transform one state into the other. Similarly, and a bit more generally, I propose a constraint that acquired knowledge representations, whether rules or weight vectors, must be learned by a model in order to be considered plausible. Knowledge representations that are instead hypothesized to be produced through biological evolution may be dealt with by hand designing rule-based and connectionist models as noted earlier, or even more ambitiously, by simulated evolution. Covering both inherited and acquired representations is the more general principle that other, non-representational features must be held constant when assessing generalization ability. Otherwise claims about superior generalization ability may be confounded with acquisition issues and possibly other differences.

Choice of Algorithms and Domains

A systematic test of generalization under a learning constraint should eventually involve many algorithms and problem domains. To begin this process, this paper compares one leading connectionist algorithm to one leading rule-learning algorithm in three different domains of cognitive development.

One of the most frequently used connectionist algorithms in cognitive development, and the principal one used in my laboratory, is cascade-correlation (CC). CC creates feed-forward networks by recruiting new hidden units that correlate well with network error and installing them in cascaded layers (Fahlman & Lebiere, 1990). It has been used to simulate a wide variety of cognitive developmental phenomena, including conservation (Shultz, 1998), seriation (Mareschal & Shultz, 1999), the balance scale (Shultz, Mareschal, & Schmidt, 1994), shift learning (Sirois & Shultz, 1998), pronoun acquisition (Oshima-Takane, Takane, & Shultz, 1999), infant familiarization to rule-governed sentences (Shultz & Bale, 2001), and integration of the concepts of velocity, time, and distance for moving objects (Buckingham & Shultz, 2000).

Choosing an equivalent rule-learning algorithm encounters the problem that there are not all that many successful rule-based models of cognitive development, in the sense of implementing developmental transitions. A good case can be made that the largest number of successful rule-based developmental models have been achieved by the C4.5 algorithm (Quinlan, 1993) and its immediate predecessor ID3 (Quinlan, 1986). These include models of English past tense morphology (Ling, 1994; Ling & Marinov, 1993), the balance scale (Schmidt & Ling, 1996), grammar learning (Ling & Marinov, 1994), and reading (Ling & Wang, 1996). There is also a simulation of non-conscious acquisition of rules for visual scanning of a matrix (Ling & Marinov, 1994), and numerous applications in engineering and decision support (Quinlan, 1993). Among alternative symbolic rule-learning algorithms applied to the same phenomenon, the balance scale, C4.5 produced an arguably superior model.

C4.5 learns to classify examples described with features and values by forming a smallish decision tree that can be converted into production rules. It is a greedy (i.e., non-backtracking) algorithm that repeatedly finds the most informative feature with which to classify so far unclassified examples.

There are a number of intriguing similarities between C4.5 and CC. Both algorithms use supervised learning of examples, focus on largest current source of error, gradually construct a solution based on what is already known, and aim for a small solution that generalizes well. In this paper, I report on generalization performance of the CC and C4.5 algorithms on the three problems of conservation acquisition, number comparison, and infant familiarization to sentences in an artificial language.

Conservation Acquisition

A recent CC model of conservation acquisition focused on Piaget's conservation of number problems (Shultz, 1998). In one version of these problems, a child first agrees that two rows have the same number of items, and is then asked which row has more after one of the rows is transformed, for example, by compression. Children below about six years of age typically judge the longer row to have more items, whereas older children correctly judge the rows to remain equal. The vast psychological literature on conservation (over 1000 studies) has produced a number of well-replicated regularities. Among them are acquisition (with a sudden jump in performance), the problem size effect (with better performance and earlier success on small number problems than on large number problems), length bias in pre-conservation children (choosing the longer row as having more), and the screening effect (with young children giving a correct answer to a screened transformation until the screen is removed).

CC networks were trained on 420 examples of number conservation problems of row lengths and densities ranging between 2 and 6, with number of items being the product of length and density. Using inputs coding the length and density of each row, both before and after the transformation, the identity of the transformed row, and the identity of the transformation (addition, subtraction, compression, and elongation), networks learned to judge whether the rows had equal numbers or not, after the transformation. Both equal and unequal initial rows were included. Length and density were coded as real numbers, and the other inputs were coded in a localist binary fashion. There were 100 test problems of the same type, not used in training, to assess generalization performance.

C4.5 was trained with the same examples, learning to classify them into three numerical judgments: one row has more, the other row has more, or both rows have the same. C4.5 was equipped with ability to deal with continuous, as well as qualitative inputs,[1] and to use the option for information gain ratio, which is generally superior to simple information gain (Quinlan, 1993).

Proportions correct on training and test problems, respectively, were 1.0 and .95 for 20 CC networks, and .40 and .35 for 20 C4.5 trees. For both algorithms, generalization performance (on the test problems) was just a bit worse than performance on the training problems; but training and generalization performance was much higher for CC than for C4.5. If the learned

[1] C4.5 finds the gain ratios for each possible cutoff on a continuous feature and then chooses the partition of examples with the highest gain ratio in the usual way.

knowledge representation is inadequate, it does not afford good generalization. This makes a pure test of generalization ability difficult. To control for learning success, proportion correct on the test problems can be divided by proportion correct on the training problems, creating a generalization ratio. This ratio is .95 for CC and .87 for C4.5.

Because a failed model is not by itself very meaningful, I adopted the strategy of changing the input coding to C4.5 until learning was successful and then evaluating what is required to learn in terms of both theoretical plausibility and psychological coverage.

Following the lead of other C4.5 modelers (Schmidt & Ling, 1996), I coded the length and density input in relational, rather than absolute terms. For example, was the first row longer or shorter or the same length as the second row? Although this relational coding produced 100% success on training and test problems, it created knowledge representations that are unlike any that have been reported with children. For example, an English gloss of one of the smaller rules is: *If the first row is longer than the second row before the transformation, and shorter than the second row after the transformation, then the first row has more items.*

Because of this exclusive focus on relative length and density of the rows, there was never any reference to information on the transformation or the identity of transformed row. Nor could the C4.5 models cover any of the various psychological regularities. This is in distinction to both the CC model and children, characterized by a shift from concern with how the rows look to the nature and identity of the transformation. The CC model also covers all of the psychological regularities mentioned: sudden jump in acquisition, problem size effect, length bias, and the screening effect. Thus, although relational input coding can produce perfect learning and generalization in C4.5, it creates implausible knowledge representations and fails to cover the psychological data. In contrast, the CC model can learn and generalize effectively from raw input coding, acquire knowledge representations that are similar to those seen in children, and cover the psychological regularities.

Number Comparison

One of the most basic of numerical skills is that of comparing the size of two numbers. Prominent psychological regularities in number comparison are the min and distance effects. The min effect refers to earlier success and quicker performance the smaller the smaller of the two numbers. The distance effect refers to earlier success and quicker performance the larger the absolute difference between the two numbers.

My simulations focus on pairs created from the integers 0-9. In a study of interpolation, a randomly selected 50 pairs comprised the training set and the remaining 50 pairs comprised the test set. The integers were coded as real numbers, and there were three discrete output classes, including ties. Mean proportion correct on training and test problems, respectively, over 20 runs was 1.0 and 1.0 for CC and .75 and .66 for C4.5. The mean generalization ratio of test correct to train correct was 1.0 for CC and .89 for C4.5. Not only did CC learn the problem and generalize more effectively than did C4.5, but only CC captured the min and distance effects.

Knowledge representation analysis revealed a sensible solution for CC networks that involved positioning a hyper-plane near the diagonal axis designated by $x = y$, where x and y are the two numbers being compared. The fact that this hyper-plane is anchored at the origin and drifts away from the ideal diagonal at the higher values generates the min effect. The soft boundary created by the sigmoid activation function in CC networks produces the distance effect. In contrast, the rules learned by C4.5 made no psychological sense, e.g., *If $x > 5$ and $y > 7$, then $x > y$.*

Another coding trick employed by C4.5 modelers uses the difference between two numbers that are being compared (Schmidt & Ling, 1996). Mean proportions correct on training and test problems, respectively, were .902 and .875 for C4.5 difference coding in the interpolation experiment. This is an improvement, but again there is no coverage of the min and difference effects, and the rules are psychologically inappropriate, e.g., *If difference > 1, and $y > 2$, then $y > x$.*

In a study of extrapolation, the models were trained on pairs of the integers 0-4 and tested on pairs of the integers 5-9. There is no variation in C4.5 performance here because training patterns are not randomly selected for each run. Training and test results are shown in Table 1. Again, the CC algorithm learns and generalizes better than the C4.5 algorithm, whether input coding uses standard raw integers or differences.

Table 1: Proportion correct and generalization ratio for extrapolation.

Algorithm/coding	Train	Test	Ratio
CC	1.00	.99	.99
C4.5/standard	.56	.40	.71
C4.5/difference	.76	.40	.53

In conclusion, C4.5 does not learn or generalize well with either standard or difference coding of input on number comparison problems. It also fails to cover the min and difference effects, and the rules it learns are psychologically implausible. The only apparent way to get C4.5 to learn appropriate number comparison rules and generalize effectively is to build those rule conditions into the input coding, in which case there is nothing to learn. In contrast, CC learns and generalizes

well, while covering min and difference effects and generating reasonable knowledge representations, and it does so with raw numerical inputs.

Infant Familiarization to Sentences

The third case study concerns infant familiarization to sentences in an artificial language. A recent paper in this area has been of particular interest because it claimed to have data that could only be accounted for by rules and variables (Marcus, Vijayan, Rao, & Vishton, 1999). That study found that 7-month-olds attend longer to sentences with unfamiliar structures than to sentences with familiar structures. Particular features of the experimental design and some unsuccessful neural network models allowed the authors to conclude that unstructured neural networks cannot simulate these results. Several unstructured connectionist models have since disproved that claim (Shultz & Bale, 2001), but the current focus is on generalization ability of connectionist and rule-based models that learn representations of these sentences.

The present simulations focus in particular on Experiment 1 of Marcus et al. (1999). In this experiment, infants were familiarized to sentences with an ABA pattern, for example, *ga ti ga* or *li na li*. There were 16 of these ABA sentences, created by combining four A words (*ga*, *li*, *ni*, and *ta*) and four B words (*ti*, *na*, *gi*, and *la*). Subsequently, the infants were tested with two novel sentences that were consistent with the ABA pattern (*wo fe wo*, and *de ko de*) and two others that were inconsistent with ABA in that they followed an ABB pattern (*wo fe fe*, and *de ko ko*). There was also a condition in which infants were familiarized instead to sentences with an ABB pattern. Here the novel ABB sentences were consistent and the novel ABA sentences were inconsistent with the familiarized pattern. Infants attended more to inconsistent than to consistent novel sentences, suggesting that they were sensitive to syntactic properties of the sentences.

For consistency, I focus on a particular CC model of these data (Shultz & Bale, 2001). In this model, sentences were coded by real numbers representing the sonority (vowel likeness) of particular consonants or vowels. An encoder version of CC was used, enabling the network to learn to reproduce its inputs on its output units. Deciding on whether a particular sentence is correctly rendered in such networks is somewhat arbitrary. A more natural index of performance on training and test sentences is mean error, which is plotted in Figure 1. Test patterns inside the range of the training patterns were the same as those used with infants. Two additional sets tested extrapolation by using sonority values outside of the training range, by a distance that was either close or far. The greater error to inconsistent sentences corresponds to the attention difference found with infants. The fact that this consistency effect extends to patterns outside of the training range reveals substantial extrapolation ability in these networks. As well, the CC networks exhibited the typical exponential decrease in attention to familiarization stimuli that are found with infants.

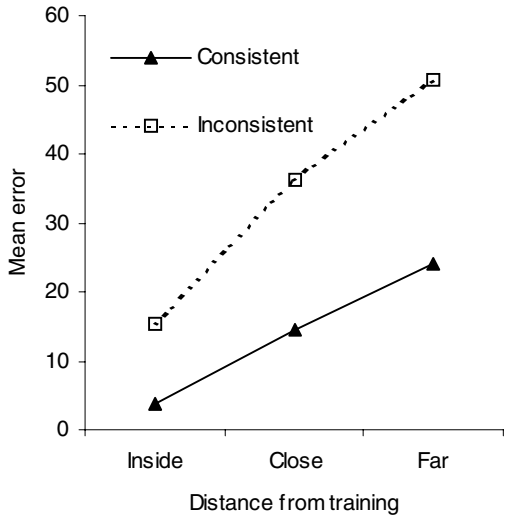

Figure 1: Mean error for CC networks simulating infant interest in consistent and inconsistent test sentences.

I did C4.5 simulations in several different ways to try to achieve successful learning and generalization. The initial attempt involved a literal symbolic encoding of each word in the sentences. For example, the word *ga* was coded as the symbol *ga*. Because there was only one output class when only one type of sentence was used as in the infant experiment (ABA or ABB), the resulting decision tree had only one leaf labeled with the syntactic class. In other words, if exposed only to ABA sentences, then expect more of the same. This is not really a rule and it captures none of the gradual characteristics of familiarization in infants. There is no variation in any of these C4.5 runs of the familiarization problem because each run uses all of the examples, rather than a random selection of examples.

The next C4.5 simulation added the 16 ABB sentences to the examples to be classified, in order to ensure that rules would be learned. This effectively changes the experiment to one of discrimination rather than familiarization. In this case, C4.5 focused only on the third word, concluding that the ABA syntax would be signaled by *ga*, *li*, *ni*, or *ta* as the third word, whereas the ABB syntax would be identified by *ti*, *na*, *gi*, or *la* as the third word. This is a sensible focus because the third word does distinguish the two syntactic types, producing a training success rate of 1.0, but it does not reflect Marcus et al.'s (1999) assumptions about infants

comparing the first and third words in each sentence. Moreover, because the test words are novel, this solution does not enable distinction between consistent and inconsistent test sentences. The generalization success rate is 0, as is the generalization ratio.

To obtain successful generalization with this kind of literal symbolic coding in C4.5, it is necessary to code the input relationally, explicitly representing equality of the first and second words, the first and third words, and the second and third words. When the first and third words are the same, then one has an ABA sentence; when the second and third words are the same then one has an ABB sentence. This allows perfect generalization to novel words, but the problem is that C4.5 can learn this relation perfectly with only one example of each pattern because the entire solution is explicitly presented in the inputs. Infants presumably require more examples than that to distinguish these syntactic patterns, reflecting the fact that their inputs are not coded so explicitly and fortuitously.

C4.5 was also trained with discrimination examples coded on sonority values as in the CC model. This model yielded 62.5% of training sentences correct, 0% correct on ABA and ABB test sentences, and a generalization ratio of 0. Moreover, the rules learned by this model were rather odd, e.g., *If C1 < -5, C3 < -5, and C2 > -6, then syntax is ABA*, where *C1* refers to the consonant of the first word, *C3* is the consonant of the third word, etc.

In contrast, the knowledge representations learned by the CC model were psychologically interesting. The hidden units were found to use sonority sums of the consonant and vowel to represent variation in sonority. This was achieved first in the duplicated-word category and next in the single-word category. This hidden unit representation was then decoded with similar weights to outputs representing the duplicate-word category.

Summarizing the results of the familiarization simulations, C4.5 did not show gradual familiarization effects. When the problem was changed to a discrimination problem, C4.5 did not learn the proper rules and did not generalize effectively. With explicit relational coding, C4.5 learns and generalizes perfectly, but it requires only two examples. When trained with sonority codes, C4.5 does not master the training examples, learns inappropriate rules, and does not generalize. In contrast, CC learns and generalizes well, both inside and outside of the range of the training examples, and acquires sensible knowledge representations.

Discussion

When learning of knowledge representations is required, CC reveals a number of advantages over C4.5: familiarizing to a single category, learning both simple (number comparison) and difficult (conservation) problems, finding structural relations that exist implicitly within training examples, learning rule-like functions that are psychologically plausible, covering psychological effects, and generalizing to novel examples, even to the extent of extrapolating outside of the training range. A pure comparison of generalization is difficult because of differences in learning success. However, comparison of generalization ratios that scale test performance by training performance, to control for learning success, consistently showed an advantage for CC over C4.5. This advantage occurred both with identical input coding for the two algorithms and with a variety of coding modifications that made it easier for C4.5 to learn.

Some of the generalization success of CC networks can be traced to the use of analog coding of inputs. In analog codes, the amount of unit activation varies with the intensity of the property being represented. Analog codes are well known to facilitate learning and generalization in artificial neural networks (Jackson, 1997), and exploratory comparative simulations suggest that they were important determinants of the present results. Their use in some of the present simulations can be justified by psychological evidence that people also employ analog representations, for example, of number.

Analog coding is not the entire story, however, because of two considerations. One is that not all of the CC inputs were analog. Some of the inputs to conservation problems that are essential to mature knowledge representations are coded in a discrete binary fashion. A second qualifier is that analog input codes were insufficient to allow successful learning and generalization in C4.5 models, even though C4.5 is equipped to deal with continuous inputs.

For a learning system to generalize effectively, it must of course learn the right sort of knowledge representation. This is why the present results show a close correspondence between success on the training examples and generalization performance. It was typical for performance to be slightly worse on test problems than on training problems, although generalization was considerably worse in some C4.5 runs, as indicated by low generalization ratios.

Because connectionist models generalized better than rule-based models under the learning constraint in three different domains, the argument that rule-based models show superior generalization is highly suspect. However, it is reasonable to ask whether connectionist models invariably generalize better than rule-learning models. Would this finding hold up in different domains and with different learning algorithms? Obviously, more research is needed, but we are now beyond facile comparisons of hand-written or imagined rules to laboriously learned connections.

Choice of algorithm is a key issue because both symbolic and neural algorithms may vary considerably in their ability to learn and generalize. Certainly, CC benefits from its ability to learn difficult problems that are beyond the ability of other neural learning procedures and its tendency to build the smallest network necessary to master the problem on which it is being trained. Likewise, C4.5 benefits from its use of information gain to select the best feature on which to partition unclassified examples. Both algorithms have led the way in their respective class in producing successful simulations of cognitive development. Nonetheless, it is important for other algorithms of each type to be tried. It is possible that other rule-learning algorithms would have better success in finding more abstract and thus more general knowledge representations than C4.5 does. Although C4.5 is adept at learning from examples, it seems unable to represent those examples in anything more abstract than the features used in their input descriptions. This limitation could make learning and generalization difficult.

Finally, it is important to stress that generalization ability should not be taken as the ultimate criterion on which to evaluate different cognitive models. Surely, it is more critical to determine whether a given model generalizes like human subjects do. This is an issue that has not yet been adequately addressed.

Abstract

Beliefs tend to persevere even after evidence for their initial formulation has been invalidated by new evidence. If people are assumed to rationally base their beliefs on evidence, then this belief perseverance is somewhat counterintuitive. We constructed a constraint-satisfaction neural network model to simulate key belief perseverance phenomena and to test the hypothesis that explanation plays a central role in preserving evidentially challenged beliefs. The model provides a good fit to important psychological data and supports the hypothesis that explanations preserve beliefs.

Introduction

It is perhaps surprising that people are so often reluctant to abandon personal beliefs that are directly contradicted by new evidence. This tendency to cling to beliefs in the face of subsequent counterevidence has been well demonstrated for opinions (Abelson, 1959), decisions (Janis, 1968), impressions of people (Jones & Goethals, 1971), social stereotypes (Katz, 1960), scientific hypotheses (T. S. Kuhn, 1962), and commonsense ideas (Gilovich, 1991).

Belief perseverance is puzzling because it is commonly assumed that beliefs are based on evidence. If it is rational for people to form a belief based on evidence, then why is it not equally rational for them to modify the belief when confronted with evidence that invalidates the original evidence?

Debriefing Experiments

Some of the clearest cases of apparently irrational belief perseverance come from debriefing experiments. In these experiments, subjects learn that the initial evidential basis for a belief is invalid. For example, Ross, Lepper, and Hubbard (1975) first provided subjects with false feedback concerning their ability to perform a novel task. Their subject's task was to distinguish authentic from fake suicide notes by reading a number of examples. False feedback from the experimenter led subjects to believe that they had performed at a level that was much better than average or much worse than average. Then, in a second phase, subjects were debriefed about the random and predetermined nature of the feedback that they had received in the first phase. There were three debriefing conditions. In the outcome debriefing condition, subjects were told that the evidence on which their initial beliefs were based had been completely fabricated by the experimenter. Subjects in the process debriefing condition were additionally told about the procedures of outcome debriefing along with explanations about possible mechanisms and results of belief perseverance. Subjects in this condition were also told that belief perseverance was the focus of the experiment. Finally, subjects in a no-debriefing control condition were not debriefed at all after the feedback phase. Subsequently, subjects in all three conditions rated their own ability at the suicide-note verification task. This was to assess the perseverance of their beliefs about their abilities on this task that were formed in the feedback phase.

The mean reported beliefs for the three debriefing conditions are shown in Figure 1. There is an interaction between debriefing condition and the nature of feedback (success or failure at the note-verification task). The largest difference between success and failure feedback occurs in the no-debriefing condition. In this control condition, subjects who were initially led to believe that they had succeeded continue to believe that they would do better than subjects initially led to believe that they had failed. After outcome debriefing, there is still a significant difference between the success and failure conditions, but at about one-half of the strength of the control condition. The difference between success and failure feedback effectively disappears after process debriefing. This sort of belief perseverance after debriefing has been convincingly demonstrated for a variety of different beliefs and debriefing techniques (Jennings, Lepper, & Ross, 1981; Lepper, Ross & Lau, 1986).

One explanation for such belief perseverance is that people frequently explain events, including their own beliefs, and such explanations later sustain these beliefs in the face of subsequent evidential challenges (Ross et al., 1975). For example, a person who concludes from initial feedback that she is very poor at authenticating suicide notes might attribute this inability to something about her experience or personality. Perhaps she has had too little contact with severely depressed people, or maybe she is too optimistic to empathize deeply with a suicidal person. Then in the second

phase, when told that the feedback was entirely bogus, these previously constructed explanations may still suggest that she lacks the ability to authenticate suicide notes. Analogously, a subject who is initially told that he did extremely well at this task may explain his success by noting his familiarity with some depressed friends or his sensitivity to other people's emotions. Once in place, such explanations could inoculate the subject against subsequent evidence that the initial feedback was entirely bogus.

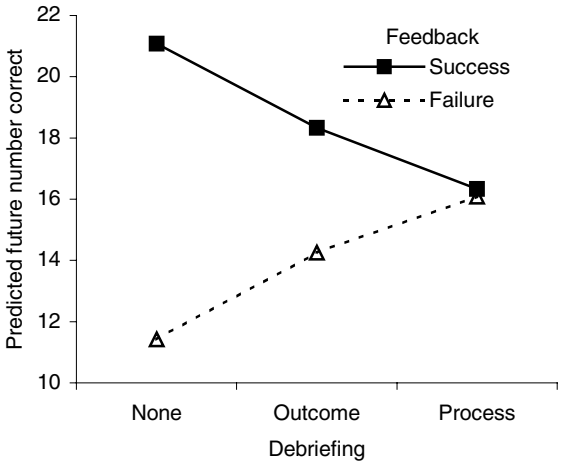

Figure 1: Mean predicted ability in the Ross et al. (1975) experiment after debriefing.

The assumption is that even though contradictory evidence may weaken a belief, it is unlikely to alter every cognition that may have derived from that belief, such as explanations for the belief's existence. The well-known frame problem emphasizes the computational intractability of tracking down every implication of an altered belief (Charniak & McDermott, 1985). People generally do not have the time, energy, knowledge, or inclination to decide which other beliefs to change whenever a belief is changed.

In contrast to the view that people have difficulty distinguishing explanations from evidence (D. Kuhn, 1991), recent research suggests that people can distinguish explanations from evidence and that they tend to use explanations as a substitute for missing evidence (Brem & Rips, 2000).

In this paper, we report on our attempt to simulate the belief perseverance phenomena reported by Ross et al. (1975). Our basic theoretical premise in designing these simulations is that belief perseverance is a special case of a more general tendency for people to seek cognitive consistency. Striving for consistency has long been considered to cause a wide variety of phenomena in social psychology (Abelson, Aronson, McGuire, Newcomb, Rosenberg, & Tannenbaum, 1968). In the case of belief perseverance, we assume that people form percepts that are consistent with external evidence, then acquire beliefs that are consistent with these percepts, and finally construct explanations that are consistent with these beliefs. We view resistance to new evidence that contradicts existing percepts, beliefs, or explanations as part of an attempt to achieve overall consistency among current cognitions, given that not all implications of contradictory evidence are actively pursued.

There was a simulation using non-monotonic logic of how belief can be preserved despite ordinary debriefing, but it did not cover the quantitative differences between conditions in the Ross et al. experiment (Hoenkamp, 1987).

Neural Constraint Satisfaction

Our simulations use a technique called constraint satisfaction, which attempts to satisfy as many constraints as well as possible within artificial neural networks. The present model is closely related to models used in the simulation of schema completion (Rumelhart, Smolensky, McClelland, & Hinton, 1986), person perception (Kunda & Thagard, 1996), attitude change (Spellman, Ullman, & Holyoak, 1993), and dissonance reduction (Shultz & Lepper, 1996).

Constraint satisfaction neural networks are comprised of units connected by weighted links. Units can represent cognitions by taking on activation values from 0 to 1, representing the strength or truth of the cognition. Connection weights can represent relations between cognitions and are assigned positive or negative values representing the sign and strength of the relations. Connection weights are bidirectional to permit cognitions to mutually influence each other. External inputs to units represent influences from the environment. Biases are represented by internal inputs to a given unit that do not vary across different network inputs.

Networks attempt to satisfy the soft constraints imposed by fixed inputs, biases, and weights by changing activation values of the units. Unit activations are updated according to these rules:

$$a_i(t+1) = a_i(t) + net_i\left(ceiling - a_i(t)\right), \text{ when } net_i \geq 0 \quad (1)$$

$$a_i(t+1) = a_i(t) + net_i\left(a_i(t) - floor\right), \text{ when } net_i < 0 \quad (2)$$

where $a_i(t + 1)$ is the updated activation value of unit i, a_i is the current activation of unit i, ceiling is the maximum activation value for a unit, floor is the minimum activation value for a unit, and net_i is the net input to unit i, as computed by:

$$net_i = in\left(\sum_j w_{ij} a_j + bias_i\right) + ex(input_i) \quad (3)$$

where in and ex are parameters that modulate the impact of the internal and external inputs, respectively, with default values of 0.1, w_{ij} is the connection weight between units i and j, a_j is the activation of sending unit j, $bias_i$ is the bias value of unit i, and $input_i$ is the external input to unit i.

These update rules ensure that network consistency either increases or stays the same, where consistency is computed as:

$$consistency = \sum_{ij} w_{ij} a_i a_j + \sum_i input_i a_i + \sum_i bias_i a_i \quad (4)$$

When a network reaches a high level of consistency, this means that it has settled into a stable pattern of activation and that the various constraints are well satisfied. In such stable solutions, any two units connected by positive weights tend to both be active, units connected by negative weights tend not to be simultaneously active, units with high inputs tend to be more active than units with low inputs, and units with high biases tend to be more active than units with low biases.

Increases in consistency and constraint satisfaction occur gradually over time. At each time cycle, *n* units are randomly selected for updating, where *n* is typically the number of units in the network. Thus, not every unit is necessarily updated on every cycle and some units may be updated more than once on a given cycle.

Unusual Simulation Features

The foregoing characteristics of neural constraint satisfaction are quite common. In addition, the present modeling has a few somewhat unusual features. Perhaps the most important of these is a two-phase structure that accommodates the two main phases of belief perseverance experiments. It is more typical for neural constraint satisfaction models to operate in a single phase in which networks are designed and updated until they settle into a stable state. Our two phases correspond to the feedback and debriefing phases of these experiments. After a network settles in the initial feedback phase, new units can be introduced, and inputs, connection weights, and biases may be changed in a second, debriefing phase. To implement continuity between the two phases, a simple type of memory was introduced such that activation values from the feedback phase would be partially retained as unit biases in the debriefing phase. Final activations in the feedback phase were multiplied by 0.05 to transform them into biases for the debriefing phase. This is not a detailed implementation of a memory model, but is rather a convenient shorthand implementation of the idea that there is a faded memory for whatever conclusions were reached in the previous, feedback phase.

Two other unusual features derived from our earlier simulations of cognitive dissonance reduction (Shultz & Lepper, 1996): a cap parameter and randomization of network parameters. The cap parameter is a negative self-connection weight for every unit that limits unit activations to less than extreme values. The purpose of this activation cap is to increase psychological realism for experiments about beliefs that reach no more than moderate strength.

Robustness of simulation results was assessed by simultaneously randomizing all network parameters (i.e., biases, inputs, and connection weights) by up to 0%, 10%, 50%, or 100% of their initial values according the formula:

$$y = x \pm \{rand \ (abs \lfloor x * rand\% \rfloor) \} \quad (5)$$

The initial parameter value x is multiplied by the proportion of randomization being used (0, .1, .5, or 1) and converted to an absolute value. Then a random number is selected between 0 and the absolute value under a uniform distribution. This random number is then randomly either added to or subtracted from the initial value. This parameter randomization allows efficient assessment of the robustness of the simulation under systematic variations of parameter values. If the simulations succeed in matching the psychological data, even under high levels of parameter randomization, then they do not depend on precise parameter settings. This randomization process also enhances psychological realism because not every subject can be expected to have precisely the same parameter values.

Network Design

Units

Units represent external input and the three types of cognitions that are critical to belief perseverance experiments, i.e., percepts, beliefs, and explanations. Percept units represent a subject's perception of external input, in this case feedback provided by the experimenter. Belief units represent a subject's beliefs, and explanation units represent a subject's explanations of particular beliefs. In each case, the larger the activation value of a given unit, the stronger the associated cognition. Activation values range from 0 to 1, with 0 representing no cognition, and 1 representing the strongest cognition. All unit activations start at 0 as a network begins to run.

Unit names include a sign of +, -, or 0 to represent the direction of a given cognition. For example, in these simulations, *+percept* refers to a perception of doing well on a task, *-percept* to a perception of doing poorly on the task, and *0percept* to not knowing about performance on the task. Percept units sometimes have an external input, to reflect the feedback on which the percept is based. A *0percept* unit is required for simulating debriefing experiments, where information is encountered that explicitly conveys a lack of knowledge about performance. Analogously, *+belief* represents a belief that one is performing well at a task, *–belief* represents a belief that one is performing poorly at a task, *+explanation* represents an explanation for a *+belief,* and *-explanation* represents an explanation for a *–belief*.

Connections

Units are joined by connection weights that have a size and a sign. The sign of a weight represents a positive or negative relation between connected units. A positive weight signals that a cognition follows from, leads to, is in accordance with, or derives support from another cognition. A negative weight indicates that a cognition is inconsistent with or interferes with another cognition. Decisions about signs are based on descriptions of psychological procedures. Initial nonzero connection weights are + or - 0.5 in our simulations. Connection weights of 0 indicate the absence of relations between cognitions. All connection weights are bi-directional to allow mutual influences between cognitions.

The general connection scheme in our simulations of belief perseverance has external inputs feeding percepts, which are in turn connected to beliefs, which are in turn connected to explanations. For failure conditions, a -percept unit receives external input and is connected to a -belief unit, which is in turn connected to a -explanation unit. For success conditions, a +percept unit receives external input and is connected to a +belief unit, which is in turn connected to a +explanation unit. Connection weights between incompatible cognitions, such as between +belief and -belief or between -percept and 0percept, are negative.

The principal dependent measure in many belief perseverance studies is a subject's self-rated ability on a task. This is represented as net belief, computed as activation on the +belief unit minus activation on the -belief unit, after the network settles in the debriefing phase. This technique of using two negatively connected units to represent the different poles of a single cognition was used by Shultz and Lepper (1996) in their simulation of cognitive dissonance phenomena.

Networks for Feedback Phase

Figure 2 shows specifications for the negative feedback condition. Negative feedback, in the form of external input, with a value of 1.0, is positively connected to the –percept unit. This same network design is used for the no-debriefing condition of the debriefing phase.

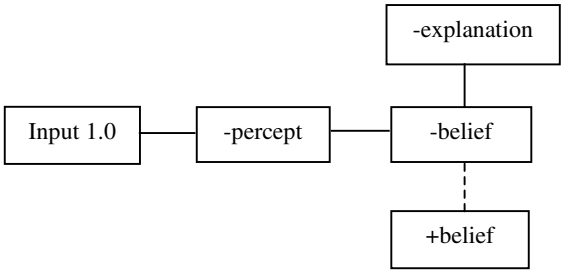

Figure 2: Network for negative feedback. Positive connection weights are indicated by solid lines; negative connection weights by dashed lines.

A feedback phase represents the presentation of information on how a subject is doing on a task. It is assumed that this information forms the basis for a belief about ability and to explanations of that ability. Because of the connection scheme and the fact that all unit activations start at 0, percept units reach activation asymptotes first, followed by belief units, and finally by explanation units.

Networks for Debriefing Phase

Figure 3 shows network specifications for the debriefing phase. This network was used for both outcome debriefing and process debriefing. The particular network shown in Figure 3 shows a debriefing phase that follows negative feedback. As noted earlier, an unusual feature here is the inclusion of biases for percept, belief, and explanation units from the earlier, feedback phase. These biased units are represented by bolded rectangles around unit names, and implement a faded memory of the feedback phase. There is also a new unit, the 0percept unit, with an input of 1.0, to represent that nothing valid is known about task performance. This unit has no bias because it was not present in the previous phase. It is negatively connected to the – or + percept unit to represent the idea that the feedback data from the previous phase are false, and thus convey no information about task ability.

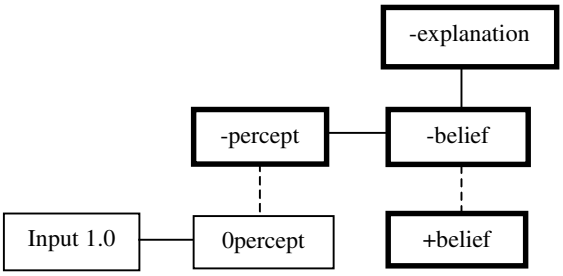

Figure 3: Network for outcome and process debriefing following negative feedback. Units that have biases from the feedback phase are indicated by bolded rectangles.

We implemented the stronger, process debriefing by multiplying bias values by a factor of 0.1. This reflects the idea that process debriefing is so thorough that it severely degrades all cognitions that were created in the preceding feedback phase. Networks in the no-debriefing condition were identical to those described in Figure 2, with no topology changes after the feedback phase. However, as in all debriefing conditions, biases of .05 of final activations were used for any units being carried over from the feedback phase. Networks were run for 120 update cycles in each of the two phases; by this time they had typically settled into stable states.

Principles of Network Design

In summary, network design can be summarized by 13 principles:

1. Units represent cognitions.
2. The principal cognitions in belief perseverance experiments are input feedback, percepts, beliefs, and explanations.
3. The sign of unit names represent the positive or negative poles of cognitions.
4. Unit activation represents strength of a cognition (or a pole of a cognition).
5. The difference between positive and negative poles of a cognition represents the net strength of the cognition.
6. Connection weights represent constant implications between cognitions.
7. Connection weights are bi-directional, allowing possible mutual influence between cognitions or poles of cognitions.

8. Cognitions whose poles are mutually exclusive have negative connections between the positive and negative poles.
9. Size of external input represents strength of environmental influence, such as evidence or feedback.
10. External inputs are connected to percepts, percepts to beliefs, and beliefs to explanations, representing the assumed chain of causation in belief perseverance experiments. That is, environmental feedback creates percepts, which in turn create beliefs, which eventually lead to explanations for the beliefs.
11. Networks settling into stable states represent a person's tendency to achieve consistency among cognitions.
12. Final unit activations from the feedback phase are converted to unit biases for the start of the debriefing phase of belief perseverance experiments, representing the participant's memory of the feedback phase.
13. Multiplying activation bias values by 0.1 represents thorough, process debriefing.

Results

We focus on the final net belief about one's ability after the debriefing phase. This is computed as activation on the +belief unit minus activation on the -belief unit. Here, we report only on the 10% randomization level, but similar results are found at each level of parameter randomization.

Net belief scores were subjected to a factorial ANOVA in which debriefing condition (none, outcome, and process) and feedback condition (success, failure) served as factors. There was a main effect of feedback, $F(1, 114) = 29619$, $p < .001$, and an interaction between debriefing and feedback, $F(2, 114) = 9102$, $p < .001$. Mean net ability scores are shown in Figure 4. For success feedback, net belief scores were higher after no debriefing than scores obtained after outcome debriefing, which were in turn higher than scores obtained after process debriefing. The opposite holds for failure feedback.

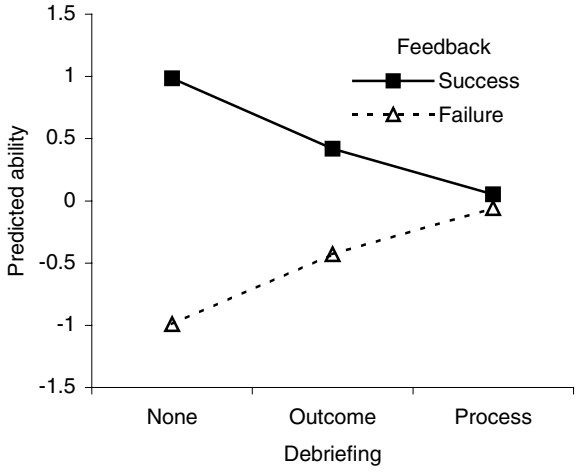

Figure 4: Mean predicted ability in the simulation after debriefing.

To assess the fit to human data, we computed a regression F with regression weights based on the pattern of the Ross et al. (1975) results. The regression weights were 2, -2, 1, -1, 0, and 0 for the no debriefing/success, no debriefing/failure, outcome debriefing/success, outcome debriefing/failure, process debriefing/success, and process debriefing/failure conditions, respectively. This produced a highly significant regression $F(1, 114) = 47558$, $p < .001$, with a much smaller residual $F(4, 114) = 67$, $p < .001$. The regression F accounts for 99% of the total variance in net belief. As with human subjects, there is a large difference between success and failure with no debriefing, a smaller but still substantial difference after outcome debriefing, and very little difference after process debriefing.

To assess the role of explanation in the simulation, we subjected activations on the explanation unit after the debriefing phase to the same ANOVA. There is a main effect of debriefing, $F(2, 114) = 3787$, $p < .001$, a much smaller main effect for feedback $F(1, 114) = 15.37$, $p < .001$, and a small interaction between them, $F(2, 114) = 6.76$, $p < .005$. The mean explanation scores are presented in Figure 5. Explanations are strong under no-debriefing, moderately strong under outcome debriefing, and weak under process debriefing. But because explanations had been strongly active in all three conditions at the end of the feedback phase, these post-debriefing results reflect relative differences in maintenance of explanations. Explanations are maintained under no debriefing, partially maintained under outcome debriefing, and eliminated in process debriefing.

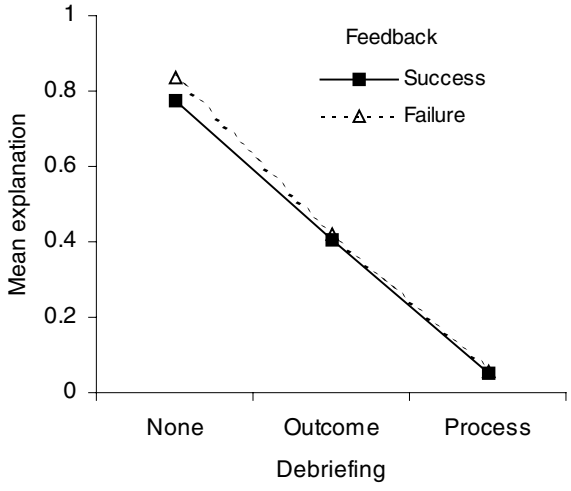

Figure 5: Mean explanation scores in the simulation after debriefing.

Discussion

The tendency for beliefs to persevere even after evidence for them has been fully invalidated challenges some basic assumptions about human rationality. If people reasonably

base their beliefs on evidence, then why is counter-evidence not sufficient to eliminate or change beliefs?

We used constraint-satisfaction neural networks to test the idea that explanation plays a key role in sustaining beliefs in these circumstances. The model provides a good fit to existing psychological data from debriefing experiments in which subjects are informed that that the principal evidence for their beliefs is no longer valid (Ross et al., 1975). Simulated beliefs remain strong without debriefing; belief strength is reduced after standard outcome debriefing, and eliminated after more thorough, process debriefing. This pattern of results matches the psychological data, with about half-strength beliefs under outcome debriefing and elimination of beliefs by process debriefing. As in our earlier simulations of cognitive dissonance phenomena, the neural constraint-satisfaction model is here shown to be robust against parameter variation. Even a high degree of parameter randomization does not change the pattern of results.

The simulations further revealed that belief perseverance is mirrored by strength of explanation. Explanations remain strong with no debriefing, and decrease progressively with more effective debriefing. Although it is obvious that debriefing reduces the strength of erroneous beliefs, the finding that it also reduces explanations is perhaps less obvious. In our simulations, explanation is reduced by effective debriefing via connections from external evidence to percepts, percepts to beliefs, and beliefs to explanations.

People spontaneously generate explanations for events as a way of understanding events, including their own beliefs (Kelley, 1967). If an explanation is generated, this explanation becomes a reason for holding an explained belief, even if the belief is eventually undercut by new evidence.

Future work in our group will extend this model to other belief perseverance phenomena and attempt to generate predictions to guide additional psychological research.

Abstract

We examined the influence of the pre-existing organization of the semantic memory on forming new episodic associations between words. Testing human subjects' performance we found that a semantic relationship between words facilitates forming episodic associations between them. Furthermore, the amount of facilitation increases linearly as a function of the number of co-occurrence of the words, up to a ceiling. Constrained by these empirical findings we developed a computational model, based on the theory of spreading activation over semantic networks. The model uses self-organizing maps to represent semantic relatedness, and lateral connections to represent the episodic associations. When two words are presented to the model, the interaction of the two activation waves is summed and added to the direct lateral connection between them. The main result is that the model is capable of replicating the empirical results. The model also makes several testable predictions: First, it should be easier to form an association from a word with few semantic neighbors to a word with many semantic neighbors than vice-versa. Second, after associating an unrelated word pair it should be easier to associate another two words each related to one of the words in the first pair. Third, a less focused activation wave, which may be the cause of schizophrenic thought disorder, should decrease the advantage in learning rate of related over unrelated pairs.

Introduction

The principles of forming associations between concepts in memory have been studied since the early days of psychological research. For example, the British empiricist school of philosophers (e.g., Hume, 1738), proposed three main principles of association: Contiguity (i.e., proximity in time and space), Similarity (or Contrast), and Cause and Effect. Fulfilling any of these conditions should be sufficient to form an association between concepts. The strength of the association is determined by the frequency at which any of the above conditions is fulfilled. An important aspect of this theory is that intentionality is not a necessary condition for the associative process to occur. Indeed, associations are frequently established without intention and without allocating attention to the learning process. We will refer to these associations as *incidental associations*. This paper presents a computational component of a larger study in which we examine characteristics of forming incidental associations between words.

Phenomenologically defined, two words are associated if the presentation of one brings the second to the perceiver's awareness. Associations between words can be formed in at least two different ways. First, *episodic associations* are formed when two words co-occur in time and space. An episodic association is therefore a subjective experience. Second, *semantic associations* are based on semantic relatedness between the words. Words are considered semantically related if they share common semantic features, for example, if they belong to the same semantic category. Although the two classes of associations are based on different properties, many associated word pairs are also semantically related, which raises the possibility of an interaction between the two types of associations.

A well-known interaction of this type is the semantic priming effect (Meyer and Schvaneveldt, 1971). The presentation of a related prime word prior to performing a lexical task, such as naming and/or lexical decision, results in faster and more accurate performance (see Neely, 1991, for a review). Ample research was aimed at isolating the types of word relations that mediate this phenomenon (e.g. Fischler, 1977; McKoon & Ratcliff, 1979; Moss et al., 1995; Shelton & Martin, 1992). More specifically, a frequently asked question was whether words that are related only in one way, either semantically or episodically, would induce effective priming and how an interaction between these to types of relations would affect priming. Although a debate still exists, it is safe to say that both types of relations prime effectively and that their combined effect is additive.

A common theory of the organization principles of the semantic system and the mechanisms underlying semantic priming is the theory of spreading activation over semantic networks (Collins & Loftus, 1975). In a semantic network, a concept is represented as a node. Semantically related nodes are connected with unidirectional weighted links. When a concept is processed,

the appropriate node is activated and the activation spreads along the connections of the network, gradually decreasing in strength. The decrease is proportional to the weights of the links in the path. In addition, the activation decays over time. Awareness of word occurs when its activation exceeds a threshold. According to this theory semantic priming occurs when activation from the prime spreads and partially pre-activates related targets so that a smaller amount of additional processing is required to bring its node activation above threshold.

An alternative and computationally more explicit modeling approach was recently proposed to explain semantic priming. Such models represent concepts in the semantic system by distributed (rather than local) representations. Concepts are not represented by single units, but rather by distinguishable patterns of activity over a large number of units (Hinton, 1990; Masson, 1995; Moss et al., 1994; Plaut, 1995). Each participating unit accounts for a specific semantic microfeature, and semantic similarity is thus expressed as overlap in activity patterns over the set of micro-features. In these models, recurrent dynamics is employed until the net settles to a stable state (an attractor). Semantic priming is explained by the fact that after settling to a prime, fewer modifications in the nodes' state are necessary for settling to a related target, making the latter settling process faster.

All the currently computational models of semantic priming have focused on processes based on existing associations. The process of acquiring new associations was abstracted in the training of the network. In the current study, we propose a computational model of forming new episodic associations between words on the basis of an already existing semantic network and show how this process is influenced by the organization of the semantic system.

Behavioral Experiments

A series of human performance experiments was conducted to supply constraints on the associating process. The following is a brief description of the relevant experiments and results (see Silberman & Bentin, submitted, for an elaborated report).

In one experiment, 10 randomly ordered Hebrew word pairs were repeated 20 times. In each trial, the two words were displayed one after the other with a Stimulus Onset Asynchronicity (SOA) of 700 ms. The subjects searched whether a letter presented 800 ms after the onset of the second word was included in the preceding word pair. Hence, proximity was achieved by having the subjects store the two words together in working memory for 800 ms. Following this "study session", the strength of the association between the words in each pair were unexpectedly tested using cued recall and a free association tests. In the cued recall test, the subjects were presented with the first words that occurred in half of the pairs, and asked to remember each word's associate. In the free association test, they were presented with the first words the other pairs, and asked to respond with their first free associate. We compared the strength of incidentally formed associations between semantically related (e.g. *milk-soup*) and semantically unrelated words (e.g. *paint-forest*). The results of this experiment, based on 64 subjects, are presented in Table 1.

Table 1: Percentage of cued recall and free association for pairs of semantically related and unrelated words.

Relatedness	Cued Recall	Free Associations
Related	38.8%	7.5%
Unrelated	19.4%	1.3%[1]

[1] Based on 16 subjects only.

As is evident in Table 1, semantic relatedness between words doubled the probability that an association would be incidentally formed between them. A between-subjects ANOVA of the cued recall performance showed that the difference between the two groups was statistically reliable [$F(1,62)=7.84$, $p<0.01$].

If semantic relationship facilitates the formation of associations by providing a higher initial linkage baseline or a smaller pool of candidates in the test phase, its effect should not interact with the number of episodic repetitions. Hence the difference between recall performance for related and unrelated word pairs should be the same, regardless the number of repetitions in the incidental learning phase (obviously, the absolute performance for both groups should positively correlate with the number of repetitions, up to a ceiling effect). To test this hypothesis, we manipulated the number of times each pair of the semantically related and unrelated pairs was repeated during the study phase.

Twenty-four Hebrew word pairs were selected for this experiment. The words in each pair were semantically related (belonged to the same semantic category) but not strongly associated (verified using free association questionnaires, in which we tested that none of the words was elicited by its pair among the first three free associates). Two study lists were prepared. Each consisted of 12 originally related pairs and 12 unrelated pairs formed by randomly pairing the other words. Pairs presented in the related condition in one list were used to form the pairs of the unrelated condition in the other list. Four groups of 24 subjects each were assigned to either 1 presentation (i.e., no repetition), 5, 10 or 20 presentations during the incidental study phase, in which subjects performed in the letter search task. The results of this experiment are presented in Figure 1.

An ANOVA showed that semantically related pairs were associated better than semantically unrelated pairs [$F(1,92)=204$, $p<0.0001$], and that the main effect of the number of repetitions was significant [$F(3,92)=25$ $p<0.0001$]. More revealing, however, was the significant interaction between the two factors [$F(3,92)=19$, $p<0.0001$], suggesting that each repetition contributed

more to related than to unrelated pairs. These results suggest that semantic information reinforces the formation of associations (at least if these are formed incidentally). The semantic effect has a ceiling at which additional repetition contributes equally to forming both related and unrelated associations.

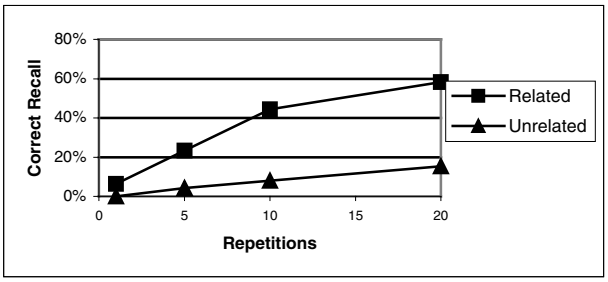

Figure 1: Percentages of correct recall for related and unrelated pairs in several learning repetition conditions. It is easier to form associations between related words.

These data demonstrated that semantic information is involved in forming episodic associations. For words that are semantically related, each learning repetition is more efficient. This facilitation is seen even if the subject's attention is not directed to the semantic level.

The aim of the present study was to develop a computational understanding of how associations are formed, including the influence of semantic factors on that process, as suggested by the above experiments.

Computational Model

Network Architecture

Our model is based on a Self-Organizing Semantic Map with lateral connections (Kohonen, 1995; Miikkulainen, 1992; Ritter & Kohonen, 1989). Semantic maps are 2-D networks that represent words by their nodes. The maps are formed by an unsupervised learning algorithm, such that words that are close in their meaning are represented by nearby nodes in the map. Hence, semantic relatedness is modeled by distance over the map. Semantic maps have been successfully used in various studies in which aspects of the semantic system were modeled, such as language acquisition (Li, 2000), semantic priming (Lowe, 1997), and semantic and episodic memory (Miikkulainen, 1992). Because self-organizing maps are based on biologically plausible Hebbian learning, and maps in general are common in many parts of the cortex (Knudsen, Lac & Esterly, 1987), self-organizing maps are most appealing as a biologically plausible analogue of classic semantic networks.

Based on a semantic map we added all-to-all unidirectional lateral connections to represent the potential associations between two words. The strength of each such connection is composed of semantic and episodic components:

$$Lat\left((i,j),(u,v)\right) = Sem\left((i,j),(u,v)\right) + Epis\left((i,j),(u,v)\right) \quad (1)$$

where $Lat\left((i,j),(u,v)\right)$ is the connection weight from node (u,v) to node (i,j). The semantic component represents the distance on the map and is given by the equation:

$$Sem\left((i,j),(u,v)\right) = 1/\left(1+e^{|w(i,j)-w(u,v)|}\right), \quad (2)$$

where $w(i,j)$ is the map's weights vector for neuron (i,j). Initially, the episodic part of all the lateral connections was set to zero. Hence, prior to any learning of associations, the lateral links only capture the topographic organization of the map, i.e. the semantic relatedness of words.

When a word is presented to the model, an activity bubble is generated surrounding the node that represents it. The activity wave then spreads according to synchronized recurrent dynamics. At each time step, the input to each neuron is the sum of the activities of all neurons in the previous time step, weighted by the lateral connections. Then, the neuron's activity is set according to a sigmoid function

$$S^{t}_{(i,j)} = \sigma\left(\sum_{(u,v)} Lat\left((i,j),(u,v)\right)\ S^{t-1}_{(u,v)}\right), \quad (3)$$

where

$$\sigma(x) = 1/\left(1+e^{-x}\right), \quad (4)$$

and $S^{t}_{(i,j)}$ is the activity of the neuron *(i, j)* at time *t*.

When two words are presented to the model (such as in the learning phase of Experiment 1 below) both activities spread independently over the map. The sum of the intersection of activation (the MIN of the two values) over all the map's neurons and over all time steps is calculated and added to the episodic component of the lateral connection between these two words. When the geometric distance between the two words is smaller (indicating stronger semantic relatedness), the resulting activity waves overlap more extensively, causing a greater amplification of the direct link between them. Thus, it is easier for the model to associate related words than unrelated words. Conceptually, this method is an abstraction of Hebbian learning of the associative links since the resulting connection strength depends on the intersection of both words' activation waves.

Input Representations

In order to organize the semantic map, we used numeric representations based on the lexical co-occurrence analysis in the Hyperspace Analogue to Language (HAL) model of Burgess and Lund (1997). These vectors have been shown to capture the semantics of words quite well (Burgess & Lund, 1997) and have been found successful in creating sensible Self-Organized Semantic Maps (Li, 2000). In the current simulations, HAL representations were based on the 3.8 million word CHILDES database, a corpus with particularly clearly defined word semantics.

The semantic map in our model consisted of 250 nouns organized on a 40 by 40 grid. We selected 48 nouns that formed 24 pairs of words, with the criterion that words in each pair belong to the same semantic category and thus are semantically related. The words were English translations of the 48 Hebrew words used in the behavioral experiment described above. In some cases, where a direct translation did not exist or the translation word did not appear in our set of HAL representations, a similar English word was selected. Another 202 nouns were selected randomly from the set of representations as "fillers" in the map, to create a richer semantic neighborhood in which the 48 words of interest could organize. See Figure 2 for the final semantic map that was used in the current simulations.

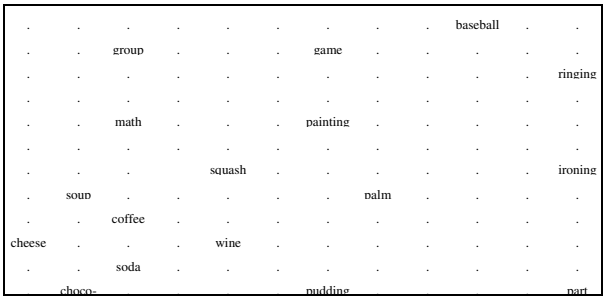

Figure 2: A section of the organized semantic map. Similar words are mapped to adjacent nodes.

Semantic Facilitation Simulation

The first simulation was aimed at replicating the empirical results of the second behavioral experiment that demonstrated semantic facilitation of associations' formation.

Experimental Setup

Out of the 24 semantically related pairs that were embedded in the semantic map, we selected 12 pairs that had numeric representations with a Euclidean distance shorter than the theoretical average (0.707) but larger then a threshold (0.5). Thus, these pairs were semantically related but not associated to each other prior to the experiment. In addition, we randomly re-matched the other 12 pairs such that 12 semantically unrelated pairs were formed as well.

Procedure

During the simulation of the learning phase of the experiment, in each trial the model was presented with two words with a certain time delay (i.e. SOA). Note that the absolute time scale of the network is arbitrary and can be adjusted to fit the data. Each of the 24 pairs (12 related and 12 unrelated) was presented once. Since during the learning phase, the episodic information does not affect the spreading activation process, the resulting association from multiple presentations was calculated simply by multiplying the result of a single presentation by the number of repetitions. The number of learning repetitions was varied from 1 to 30. During the simulation of the test phase, only one word was presented to the model. The resulting activation wave spread based on the same dynamics, except that in this phase, both the semantic and the episodic components of the lateral connections were taken into account. The activity continued to spread until the first neuron reached an activity threshold (0.98). The word represented by this node was then output as the result.

Results and Discussion

In Figure 3 the results that corresponds to the number of repetitions used in the behavioral experiment (1, 5, 10, 20) are shown. The percentages of correct recall demonstrated by the model for the related and unrelated pairs are shown for each repetition condition. As shown by the Figure, the model successfully replicates the results from the behavioral experiment. In the early stages, the learning rate of the related pairs is higher than the learning rate of the unrelated pairs. At about 10 repetitions, a ceiling effect reduces the learning rate of the related pairs, such that the advantage of these pairs over the unrelated pairs is abolished. In addition, the learning rate of the unrelated pairs is relatively constant. It is important to emphasize that non-linearity is introduced to the testing phase of the simulated experiment by the recurrent dynamics of the model. Hence, the linear way in which multiple repetitions were modeled does not dictate linearity in the output learning rate.

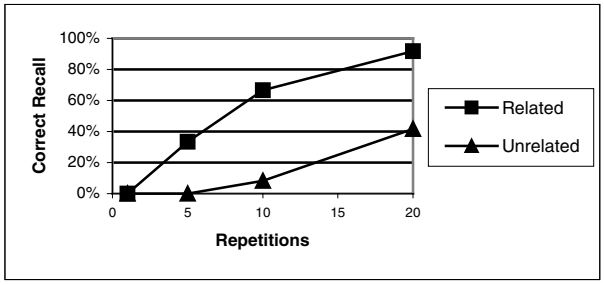

Figure 3: Percentages of correct recall demonstrated by the model, matching these obtained in the behavioral experiments (Figure 1).

Implicit Asymmetry Simulation

Associations between word pairs are directional. In free association questionnaires, for most pairs the subject would reply with word B after A with a different probability than the other way around (Koriat, 1981). In our model, this *explicit asymmetry* is achieved by the unidirectional lateral connections, which represent the association between two words in the map. However, our model demonstrates an additional asymmetry, which we call *implicit asymmetry*: it is sometimes easier to form an association between two words in one direction than in the opposite direction even before any episodic in-

formation is taken into account. The second simulation was aimed at quantifying this phenomenon.

Experimental Setup

First, we examined the density of the semantic neighborhoods of the words that were used in experiment 1. For each of the 48 words of interest we counted how many of the 250 total words in the model's semantic system were within a fixed 100-dimensional distance (0.4) according to their HAL representations. For each pair we then calculated the difference in the densities of the semantic neighborhoods of the two words and selected 3 related and 3 unrelated pairs with the greatest difference (in absolute values).

Procedure

We replicated the procedure of experiment 1 twice with the 6 pairs selected. First, the pairs were presented in the forward direction, from sparse to dense. Then, we repeated the entire procedure with the pairs presented in the opposite order (backward).

Results and Discussion

Figure 4 shows the percentages of correct recall as demonstrated by the model for pairs in the forward and backward direction in each repetition condition. Word pairs in the forward direction (sparser neighborhood → denser neighborhood) show advantage in correct recall as well as in learning speed throughout the first ten repetitions. The reason for this implicit asymmetry is the spreading of activation over a non-uniformly distributed high-dimensional space (elaborated in the General Discussion below). Although implicit asymmetry has not yet been observed experimentally, there is indirect evidence that suggests that such a process might indeed exist in the brain. Dagenbach, Horst and Carr (1990) found that it is easier to add a new word to semantic memory than to establish a link between two formerly unconnected words already in semantic memory. This result may apply to our prediction since we may assume that newly learned words were not yet well embedded into their semantic neighborhood and thus have a sparser semantic neighborhood than familiar words. In future work, we intend to test this prediction of the model with behavioral experiments.

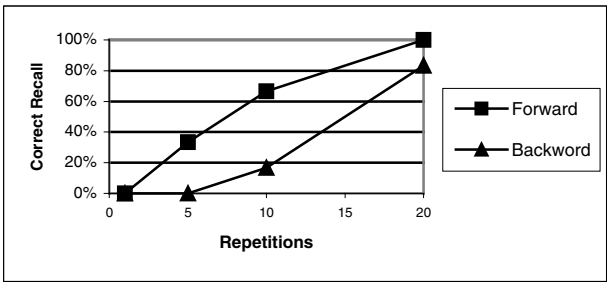

Figure 4: Percentages of correct recall demonstrated by the model for forward and backward pairs in several learning repetition conditions. The results show that learning is easier from sparse to dense neighborhoods.

General Discussion

As described in the "Behavioral Experiments" section, in a series of experiments we investigated semantic factors that affect the process of forming associations between words. The goal of this study was to present and evaluate a computational model that could account for these results and to produce further predictions regarding the process of associating words. Our model suggests that semantic relatedness between words, as well as episodic associations, could be implemented in a single structure using two distinct types of representations. On one hand, semantic relatedness is expressed as geometrical proximity in a high-dimensional (100D) feature space. On the other, episodic associations are represented by arbitrary "physical" connections between the units that represent the concepts. Both types of relations are implemented simultaneously in a semantic map with lateral connections artificial neural network.

As was demonstrated in human subjects, the model shows the facilitation semantic information has on learning new associations. This facilitation emerges in a natural, mechanistic manner, without involvement of top-down, intentional processes. It is achieved by implementing Hebbian link strengthening based on intersections of activation waves over a semantic map.

The asymmetric nature of relationships between words and more specifically of associations imposes difficulties for computational models that rely on geometric distances between high-dimensional numeric representations of words. Our model is also based on such high-dimensional vectors and the self-organization algorithm that establishes the semantic map is symmetric. Nonetheless, the model demonstrates two kinds of asymmetries. The first, explicit asymmetry is achieved by the unidirectional lateral connections that are implemented on top of the symmetric organization of the semantic map. These connections make it possible to have asymmetric associations between two words, based on the episodic experience of the two possible directions of the word pair. The second, implicit asymmetry, emerges from the non-uniform distribution of concepts in the high-dimensional space. This non-uniform distribution induces asymmetric distances in terms of spreading activation between two points in the semantic space that otherwise would have equal distance from one another in both directions.

Further empirical studies can be derived from this computational research. The model suggests that when an association is formed between two semantically distinct words, it can serve as a "pipeline" that enhances the spreading of activity from the semantic neighborhood of the first word to the semantic neighborhood of the second. Since this activity is, in turn, used to form other associations, we infer that the existence of an as-

sociation between words from distinct semantic neighborhoods (e.g. different categories) would facilitate forming other associations between unrelated pairs that belong to those semantic neighborhoods.

Another possible implication of this model is in testing one of the theories concerning *Schizophrenic Thought Disorder* (hereinafter STD) as suggested by Spitzer (1997). According to Spitzer's theory, the activation over the semantic network of STD patients spreads faster and further than that of normal subjects. This unfocused activation can explain experimental results in STD patients that show stronger semantic priming and indirect semantic priming. It may also explain the clinical STD phenomena of loose, oblique and derailed associations. By manipulating our model we can computationally test this theory. It is possible to vary the parameters of the functions that govern the spreading activation (equations 1-4) to make it less focused. By examining the resulting changes in the model's behavior, we may be able to gain insight regarding the processes that lead to this pathology.

Conclusion

We set out to study the process of creating new associations between words in human memory during incidental learning. Empirical results suggest that semantic information enhances the process of forming episodic associations. A model based on spreading activation on a laterally connected self-organizing map matches these results and leads to further insights into why such associations tend to be asymmetric. In future work, we plan to test some of the model's predictions, including implicit associations and processes of abnormal behavior.

Acknowledgements

We are grateful to Ping Li and Curt Burgess for providing the HAL vectors. This research has been supported in part by the National Science Foundation grant IIS-981147 to Dr. R. Miikkulainen, and by a German-Israeli Science Foundation grant #567 to Dr. S. Bentin.

Representation: Where Philosophy Goes When It Dies.

Peter Slezak (p.slezak@unsw.edu.au)
Program in Cognitive Science, University of New South Wales
Sydney NSW 2052 AUSTRALIA

Abstract

Robert Cummins (1996, p.1) has characterised the problem of mental representation as "*the* topic in the philosophy of mind for some time now". This remark is something of an understatement. The same topic was central to the famous controversy between Nicolas Malebranche and Antoine Arnauld in the Seventeenth Century and remained central to the entire philosophical tradition of "ideas" in the writings of Locke, Berkeley, Hume and Kant. I show that the recurrence of certain deep perplexities about the mind is a systematic and pervasive pattern, confirming Jerry Fodor's disparaging remark: "Cognitive science is where philosophy goes when it dies" (Fodor, 1994b, p. 110).

The Tripartite Schema

Recently Bechtel (1998, p. 299) states the essentials of a modern theory of representation: "There are ... three interrelated components in a representational story: what is represented, the representation, and the user of the representation".

Z: System Using Y → Y: Representation → X: Thing Represented

Among the problematic assumptions, Bechtel's diagram and discussion crucially fail to distinguish internal and external representations. Bechtel's conception in this regard is not idiosyncratic but almost universal in cognitive science (Newell 1986, p. 33). As we will note presently, in the case of pictorial images, the assimilation of internal and external representations tacitly encourages the illegitimate postulate of a user or external observer - the notorious homunculus. The same tacit assimilation of external and internal representations is at the heart of Searle's "refutation" of symbolic AI and also leads to the doctrine that we think "in" language (Carruthers 1996, Slezak forthcoming a). The assimilation just noted in Bechtel will also be seen in the seemingly unrelated problem of consciousness and the mind-body problem (Place 1956), *inter alia*.

The tripartite scheme appears obvious and innocuous enough but Bechtel's diagram (modified here) is a variant of the scheme which we see throughout the long history of the subject. Thus, for example, nothing could seem more remote from modern theories in cognitive science today than Malebranche's (1712/1997) seventeenth century doctrine of "the vision of all things in God". On the contrary, however, despite the theological trappings, it is instructive to recognize the profound affinity of Malebranche's views with those at the very forefront of theorising today in psychology and artificial intelligence: Malebranche's theory is just Bechtel's tripartite model (Nadler 1992), and the modern problem of representation is how to avoid the notorious difficulties clearly articulated by his critic Arnauld (1683/1990).

It is no accident that Gibson's 'ecological' approach involves a direct realism which has seen proposed as alternative to the representationalism of computational theories. This is merely one form in which the Malebranche-Arnauld debate is being rehearsed today. This celebrated debate is described by Nadler (1989) as a debate between an 'object theory' of ideas and an 'act theory', respectively. He explains

> ... the object theory of ideas involves a commitment to a representationalist or *indirect* realist theory of perception, such as Malebranche (and, on the traditional reading, Locke) put forth. An act theory of ideas, on the other hand, forms the core of Arnauld's perceptual direct realism. If ideas are representational mental acts [rather than entities], then they can put the mind in direct cognitive contact with the world - no intervening proxy, no *tertium quid*, gets in the way. (1989, p.6)

It is no accident that recent proponents of 'situated cognition' have been complaining of exactly the same indirect, mediated conception in computational theories of cognition. For example, J. Greeno (1989) unwittingly echoes Arnauld:

> I am persuaded ... we are connected directly with the environment, rather than connected indirectly through cognitive representations.
> ... An individual in ordinary circumstances is considered as interacting with the structures of situations directly, rather than constructing representations and interacting with the representations. (1989, p. 290)

Precursors: Pointless Exercise?

Despite the skepticism expressed by Gaukroger (1996), precursors of modern cognitive science provide an independent, extensive source of insight into contemporary issues and, conversely, are themselves elucidated in novel ways unavailable to traditional

scholarship (Yolton 1996, Slezak 1999, 2000). The possibility of two-way elucidation arises from the extraordinary persistence of the seemingly simple problem of saying "in some illuminating way, what it is for something in the mind to represent something" (Cummins 1996, p.1). From Yolton's (1984, 1996) statement of earlier concerns we see their parallel with the contemporary problem: Scholastics' notions of 'intelligible species' and Cartesian talk of ideas were striving for some way to explain the conformity or agreement between ideas and objects.

If Malebranche and Arnauld anticipated contemporary concerns about representation in cognitive science, then it is clear that the current theoretical problem has nothing to do with the theoretical framework of symbolic, computational approaches as universally assumed. Indeed, the recurrence of essentially the same dispute in widely varying contexts today suggests that the underlying problem does not arise essentially from the special features of any one of them. I suggest that we may discern the same underlying problem at the heart of notorious disputes such as 'The Imagery Debate', Searle's Chinese Room conundrum, the thinking-in-language debate, 'situated cognition' and a number of others which have been prominent and recalcitrant.

No Representations?

The 'Cognitive Revolution' was characterized by a re-discovery of the indispensability of internal representations following their repudiation by Skinnerian behaviourism. There is considerable irony in recent approaches which appear to reject internal representations once again (Brooks 1991, Freeman and Skarda 1990, Clark and Toribio 1994, Greeno 1989, van Gelder, 1998). Notwithstanding Eliasmith's (1996) claim, these views are not plausibly seen as a return to behaviourism, but they are symptoms of the profound difficulties posed by the phenomena. It is sobering to notice that Arnauld's critique of Malebranche exactly prefigures these recent attacks on representational theories. Arnauld's treatise *On True and False Ideas* is concerned to repudiate what he describes as "imaginary representations", saying "I can, I believe, show the falsity of the hypothesis of *representations*" (1683/1990, p.77) for "one must not make use of alleged *entities* of which we have no clear and distinct idea in order to explain the effects of nature, whether corporeal or spiritual" (1683/1990, p. 65).

Tables & Chairs: Bumping Into Things

Fodor (1985a) joked that philosophers are notorious for having been prey to absurd, eccentric worries such as the "fear that there is something fundamentally unsound about tables and chairs". Nevertheless, he optimistically opined that sometimes "mere" philosophical worries turn out to be *real* as in the case of the representational character of cognition. However, far from being a *contrast* with the traditional anxiety about tables and chairs, modern scientific disputes concerning representations appear to be *identical* with this notorious worry!

Thus, it is surely no accident that, reflecting upon Fodor's (1980) 'methodological solipsism', Jackendoff (1992, 161) asks facetiously "Why, if our understanding has no direct access to the real world, aren't we always bumping into things?" Though intending a mild parody, Jackendoff captures precisely the paradox charged against Locke and also Malebranche, who Nadler (1992, p. 7) says "is often portrayed ... as enclosing the mind in a "palace of ideas," forever cut off from any kind of cognitive or perceptual contact with the material world". Thus, Jackendoff's satire is evocative of Samuel Johnson's famous refutation of Berkeley's "ingenious sophistry" by kicking a stone. Of course, Berkeley's "sophistry" is just the worry about the reality of tables and chairs.

Imagery: The Pictorial Theory

The 'Imagery Debate' is perhaps the most remarkable modern duplication of seventeenth century controversies. In this re-enactment, among the *dramatis personae* Pylyshyn plays Arnauld against Kosslyn's Malebranche. Significantly, the central error identified by Arnauld of ascribing corporeal properties to mental ones exactly the one charged by Pylyshyn (1973, 1981) against Kosslyn and related to Cummins' (1996) point that internal representations do not function by being understood".

Kosslyn's (1994) pictorial account of imagery takes mental images to represent by virtue of a relation of resemblance to their objects and by virtue of actually *having* spatial properties which they represent. Furthermore, "depictive" representations in a "visual buffer" are taken to have the specific function of permitting a re-inspection of images by the higher visual apparatus. Not surprisingly, this "quasi-perceptual" model has been repeatedly charged with the error of importing an 'homunculus'. The charge is vigorously rejected on the grounds that "the theory is realized in a computer program" (Kosslyn, Pinker, Smith & Schwartz, 1979, p. 574), but undischarged homunculi can lurk in computational models just as easily as in traditional discursive theories (see Slezak 1992, 1994, 1995, 1999). Thus, Kosslyn, Sokolov and Chen (1989) offer a diagram of the visual imagery system which is a profusion of inter-connected boxes and arrows. The box labeled "visual buffer" contains another box labeled "attention window" which is left unexplained. This box is, in fact, the observer in the 'theater' which is the source of the traditional problem. The elaborate diagram is reducible to the same tripartite schema we have seen in Malebranche. Significantly, following Descartes, Arnauld explicitly pointed to the seductive error of taking pictures as an appropriate model of mental representation (Arnauld 1683/1990, p.

67) and he cites the *camera obscura* as an erroneous model for imagery. Thus, retinotopic maps on the visual cortex cited by Kosslyn (1994), p. 14) as vindicating the pictorial theory are pictures alright, but only for the *theorist.*

Descartes Déjà Vu.

A related unlikely indication of the relevance of early philosophy to current problems is seen in Edelman's (1998) work on perception. Despite its concern with the latest theories of perception, the central problem is stated in terms identical with that of the entire tradition of writers on 'ideas'. Edelman writes: "Advanced perceptual systems are faced with the problem of securing a principled (ideally, veridical) relationship between the world and its internal representation." Edelman's solution "is a call for the representation of similarity instead of representation by similarity". This might have been taken verbatim from Descartes's *Treatise of Man* or *Dioptrics* where he said "the problem is to know simply how [images] can enable the soul to have sensory perceptions of all the various qualities of the objects to which they correspond - not to know how they can resemble these objects" (Descartes 1985, 1, 165).

Mind-Body Problem

The pervasive error seen starkly in Kosslyn's TV screen metaphor reveals the link between the various problems in cognitive science and the traditional mind-body problem. In the classic statement of materialism, U.T. Place (1956) argued that the rejection of materialism is based on the qualitative features of subjective experience. Although these features have recently been supposed to constitute the "hard" problem of consciousness (Chalmers 1996), Place suggested that they are the source of the 'phenomenological fallacy'. This is "the mistake of supposing that when the subject describes his experience, how things look, sound, smell, taste, or feel to him, he is describing the literal properties of objects and events on a particular sort of internal cinema or television screen." Place's diagnosis has been revived and given prominence by Dennett (1991), however the fallacy would be more aptly named the 'Malebranchean Theater'.

Thinking In Language

Just as we seem to be looking at pictures when we imagine visually, so we appear to talk to ourselves when we think. Indeed, Carruthers (1996) who seeks to revive what he acknowledges to be an unfashionable doctrine explicitly bases his argument on such evidence of introspection. This is the evidence that we sometimes find ourselves in a silent monologue, talking to ourselves *sotto voce*, as it were.

However, in a neglected article, Ryle (1968) suggested that the very idea that we might think "in" language is unintelligible, and the undeniable experience of talking to ourselves cannot support any claim about the vehicles of thought. It is significant that Ryle mentions *en passant* among the equally problematical cases, that in which we claim to see things in our 'mind's eye' - taken to involve mental pictures of some kind. Ryle's comparison and his warning is unwittingly confirmed by Carruthers (1996, 1998) who explicitly invokes Kosslyn's pictorial account of imagery as support for his own analogous theory. In doing so, however, Carruthers only brings into relief the notorious difficulties of his own model which relies on representations - sentences of natural language - which are, like pictures, paradigmatically the kind requiring an external intelligent observer.

Connectionism & Cognitive Architecture

The crucial difference between symbolic and connectionist architectures is said to be the absence of *explicit* representations with constituent structure (Fodor & Pylyshyn 1988, Fodor & McLaughlin 1990). This issue may turn precisely on the same question we have seen. Specifically, the distinction between explicit and implicit representation appears to be based on a tacit appeal to the criterion of intelligibility or discernability to an external observer. D. Kirsh (1990, p. 340) points out that in connectionist systems, "it is becoming increasingly difficult … to track the trajectory of informational states these mechanisms generate. There is no doubt that we must find some method of tracking them; otherwise there is no reason to think of them as more than complex causal systems." Explicitness is characterised as a matter of "directly reading off" information from "visible structures" and the "immediate grasp" of information which is "directly available" or "immediately readable" (1990, p. 356), but the obvious question is: By whom? In an influential article Ramsey, Stich and Garon (1991) question traditional folk psychology because "in many connectionist networks it is not possible to localize propositional representation beyond the input layer" (1991, p. 209). Again we may ask, By whom? Significantly, Ramsey et al. imply that the difficulty of identifying representations in a neural net is "a real inconvenience to the connectionist model builder" (1991, p. 209). However, as Cummins' (1996, p.102) warns, "Internal representations are not exploited by being understood" by the programmer".

Symbols & Searle

Searle's (1980) Chinese Room conundrum appears to have an identical logical structure to those I have noted. In this case, a crucial equivocation on distinct meanings of 'meaning' has led to the postulation of symbols having meaning in an *observer-relative* sense in which a representation is necessarily apprehended and understood by someone. However, intelligibility *to the theorist* must be irrelevant to Searle's question of whether a

system has genuine, 'original' intentionality (see Slezak 1994, 1999). As before, rejecting this inappropriate criterion of meaning actually amounts to rejecting a certain conception of representations or, equivalently, rejecting the *agent* as homunculus in the system. Intentionality and the directness of cognition is achieved, following Arnauld, by eliminating a conception of symbols as intermediate objects to be apprehended as if they were external representations.

Searle's (1980) criterion for judging intentionality in his Chinese Room amounts to Carruthers' (1996) claim that the language of thought or 'mentalese' must be English, since the symbols are to be understood by a fully comprehending intelligent person. Accordingly, the much-discussed conundrum is best understood, not as a challenge to 'strong AI' as such, but as a *reductio ad absurdum* of symbols conceived as being intelligible to an observer. It is significant that this mistake is not Searle's alone, for it is implicit in the orthodox computational view of cognitive science which sees its origin in Frege-Russell formal symbols requiring an interpretation (Newell and Simon 1976, Newell, 1986). In AI, too, this conception has been explicitly embraced by Nilsson (1987, 1991) and embodied in the CYC program of Lenat and Feigenbaum which has been caricatured by Smith (1991) as the 'Electric Encyclopedia'. In these cases the question of meaning of mental representations is confused between whether representations are *intelligible* and whether they are *explainable*.

Searle's conundrum is evoked by Glanvill's response in 1661 to Descartes' coding theory of perception. "But how is it, and by what Art doth the soul read that such an image or stroke in matter … signifies such an object? Did we learn such an Alphabet in our Embryo-state?" (quoted in Yolton 1984, p. 28). Echoing Searle, Glanvill suggests that the "motions of the filaments of nerves" learn the quality of objects by analogy with the way in which a person learns to understand a language, for otherwise "the soul would be like an infant who hears sounds or sees lips move but has no understanding of what the sounds or movements signify, or like an illiterate person who sees letters but 'knows not what they mean' "(1984, p. 28).

Logicism & Observer Attribution

Within AI, an independent, though parallel, debate has been proceeding about the classical symbolic conception, the "logicist' view, according to which an abstract formal system gets its meaning from a model theory - that is, the intended interpretations of the designer (Newell and Simon 1976, Nilsson 1987, 1991). Woods (1987), Smith (1987), Rosenschein (1985) and others have argued that this classical logical view is fundamentally misguided in its conception of the way in which a system gets to relate to the external world by embracing the specific conception of "observer attribution" (see Hadley 1995). Birnbaum (1991, p. 62) says that AI mistakenly adopts a theory from logic which is quite inappropriate to capture what it means for a system to have beliefs.

Misrepresentation

The problem of misrepresentation has arisen for causal or co-variation theories of intentional content (Dretske 1996, Fodor 1994a) since these theories seem to be unable to capture the way a mismatch might arise between a representation and the world. If a mentalese token 'mouse' might be caused not only by mice but also by shrews, then the symbol must *ipso facto* mean 'shrew' and cannot be in error.

The puzzle might be accounted for by noting that it arises from tacitly adopting the stance of external interpreter: The very problem itself cannot be coherently formulated except in terms of judgements which are not part of the scientific, explanatory enterprise. The veridicality of representations is not a property which can play any role in the functioning of representations or the explanation of them. Like the picture on a jig-saw puzzle, the meaning of representations conceived as semantically evaluable in this way is for our own benefit and not intrinsic to the arrangements of inter-locking components.

The very concern with misrepresentation arises from tacitly adopting a questionable assumption endorsed by Davidson (1975) that having a belief requires also having the *concept* of belief, including the concept of error. However, it seems that animals might have beliefs even if they are unable to know that they have them and reflect on their truth value. A cat can surely be correct in thinking that a mouse is in a certain hole without having the *concepts* of belief and truth.

Argument From Illusion

The modern problem of misrepresentation is a variant of the classical 'argument from illusion' employed in support of Locke's 'ideas' and A.J. Ayer's (1940) sense-data as the immediate objects of perception. The parallel should not be surprising since an illusion in the relevant sense is precisely a misrepresentation. The traditional argument, just like Dretske's and Fodor's, turns on the possibility of a mismatch between mental representations and their referents in the external world.

Responding to Ayer, Austin (1962, p.61) remarked on the "curious" and "melancholy fact" that Ayer's position echoes that of Berkeley. Of course, this is the same melancholy fact that Fodor's "real" problems of representation are identical with the traditional concerns about the reality of tables and chairs. Questions of veridicality for ideas and sense-data arose from precisely the same assumptions as Fodor's - namely, the spurious possibility of a comparison between representations and the world. Twin Earth puzzles, too, seem to be an unnoticed variant on the problem of misrepresentation (Slezak, forthcoming b).

It should be less surprising that the classical arguments for 'ideas' should be akin to the modern case for representations when it is noticed that the 'argument from illusion' is effectively an 'argument from imagery'. The proverbial illusory pink elephant as the immediate object of perception is a visual image *par excellence*.

Illusion of the Intelligent Reader

We might expect a compelling kind of error to emerge in unrelated domains of theorising about the mind. Chomsky has drawn attention to the way in which traditional grammars produce an illusion of explanatory completeness while, in fact, they have "serious limitations so far as linguistic science is concerned" (Chomsky 1962, p 528). The success of the grammar depends on being "paired with an intelligent and comprehending reader". Here we see an entirely different version of the homunculus problem. Chomsky notes that in judging the adequacy of traditional grammars the unnoticed reliance on the user's linguistic ability is illegitimate because it is just what the theory is supposed to explain (Chomsky, 1962, p.528). Evidently, this is just the issue captured in Cummins' distinction, in a different context, between 'meaning' and 'meaningfor' (1996, p. 86) and is evidently the problem also for pictorial images or thinking in natural language.

Conclusion

Fodor (1968, p. vii) once remarked: "I think many philosophers secretly harbor the view that there is something deeply (ie. conceptually) wrong with psychology, but that a philosopher with a little training in the techniques of linguistic analysis and a free afternoon could straighten it out." Thirty years later, the suspicion of deep conceptual problems at the heart of philosophy and psychology is more clearly justified. By adopting a broader perspective we may see why the sorry fortunes of the two disciplines have been inextricably linked.

Abstract

This paper examines the process of categorization in young children, and tests predictions derived from a model of young children's similarity judgment. The model suggests that linguistic labels might have greater contribution to similarity judgment for younger children than do other attributes. It is argued that because categorization is based on similarity, the model predicting similarity judgment should also predict categorization. Predictions of the model were tested in the experiment where 4-6 year-olds were asked to perform a categorization task. Results of the experiment demonstrate that young children perform categorization in a similarity-based manner, and support both qualitative and quantitative predictions of the label-as-attribute model.

Introduction

The ability to group things together is an important component of human cognition: stimuli (i.e., objects, scenes, situations, or problems) rarely recur exactly, and, as a result, records of specific stimuli would be of little help. Therefore, the ability to form categories and store stimuli as members of these categories is a critical component of learning, memory, and thinking. Furthermore, it has been demonstrated that even infants are capable of forming categories (e.g., Balaban & Waxman, 1997; Quinn & Eimas, 1998; Mandler, 1997). It is less clear, however, how people form categories and include novel instances into a category. Several theories have emerged in an attempt to answer these questions (e.g., Lamberts & Shanks, 1997; Smith & Medin, 1984, for reviews).

The general question of how people form categories and add new instances to these categories consists of three more specific questions: (1) How do people decide whether or not a novel entity is a member of an existing category? (2) How do people form a category when presented with a large number of positive and negative instances of the category? And (3) how do people decide whether or not two novel entities are members of the same novel category? While much theoretical and empirical work on categorization has focused on the first two questions (see Lamberts & Shanks, 1997; Smith & Medin, 1984, for reviews), the third question has remained largely under-researched. At the same time, answers to this question are important for understanding of the "first step" in the process of categorization – forming a new category and including some novel entities as its members, while excluding others.

The current research attempts to examine the third question. As a first approximation, it appears plausible that, if no information about the entities is available, the entities would be grouped together on the basis of their perceptual similarity. If, in addition to perceptual information, there is also linguistic information (e.g., "*Look, here is an X*"), then there are at least two possibilities for grouping. If the label *X* is familiar, then the object denoted as *X* could be included into all categories that include *X* as its member. However, if label *X* is novel, it seems likely that categorization should be performed on the basis of similarity. In this case, a model predicting similarity judgment should also predict categorization. One such model, the label-as-attribute model suggests that young children consider linguistic labels as attributes of compared entities (Sloutsky & Lo, 1999). The model predicts that both perceptual and linguistic cues should contribute to comparison-based processes, such as similarity judgment. These predictions have been confirmed in a number of studies examining contribution of perceptual and linguistic factors to similarity judgment (Sloutsky & Lo, 1999) and inductive inference (Sloutsky & Lo, 2000; Sloutsky, Lo, & Fisher, in press). It was found that young children aggregate perceptual and linguistic cues when computing overall similarity among compared entities.

We can predict, therefore, categorization should be a function of similarity computed over perceptual and

linguistic cues. In what follows, we specify the model and its predictions, and present experiments designed to test predictions of the model.

The model is based on the product-rule model of similarity (Estes, 1994; Medin, 1975) that specifies similarity among non-labeled feature patterns. In the product-rule model, similarity is computed using Equation 1:

$$Sim(i, j) = S^{N-k} \qquad \mathbf{1}$$

where N denotes the total number of relevant attributes, k denotes the number of matches, and S ($0 \leq S \leq 1$) denotes values (weights) of a mismatch. For example, suppose that one is presented with two schematic faces A and B. Further suppose that these faces consist of four distinct features (i.e., the shape of the face, eyes, nose, and the size of ears), that they share two of these features (i.e., the shape of the face and eyes), and differ on the other two. Finally, suppose that $S = 0.5$, the value frequently derived empirically in past research (Estes, 1994). In this case, similarity between A and B would be equal to 0.25 (i.e., 0.5^2). Note that similarity between entities decreases very rapidly with a decrease in the number of mismatches, approximating the exponential decay function discussed elsewhere (Nosofsky, 1984). For example, if the faces share only one of the four features, their similarity would be equal to 0.125 (i.e., 0.5^3). On the other hand, if the faces share all four features, they would be identical, and their similarity would be equal to 1 (i.e., 0.5^0).

The label-as-attribute model suggest that linguistic labels might have greater contribution to similarity judgment for younger children than do other attributes, and there is evidence supporting this suggestion (see Sloutsky & Lo, 1999). Why would labels weigh more for younger children and what might be a mechanism underlying the greater weight of labels at earlier age? One possible explanation is that labels have larger weights because they are presented auditorily, and the auditory system matures earlier than the visual system. In particular, the auditory system starts functioning during the last trimester of gestation (Birnholz & Benaceraff, 1983; see also Jusczyk, 1998, for a review), whereas the visual system does not start functioning until after the birth. As a result, even though the neural bases of visual perception are fully developed at quite a young age (e.g., Aslin & Smith, 1988), auditory stimuli may still have a privileged processing status for younger children, thus resulting in larger weights of auditory stimuli (Napolitano, Sloutsky, & Boysen, 2001). In fact, it has been demonstrated that 15-months-olds grouped objects together when the objects shared an auditory input (either a label or a non-linguistic instrumental music input) if the input perfectly correlated with an infant's fixation of an object (Roberts, 1995; Roberts & Jacob, 1991, but see Balaban & Waxman, 1997).

According to the label-as-attribute model, similarity of labeled feature patterns could be calculated using Equation 2:

$$Sim(i, j) = S_{Label}^{1-L} S_{Vis.attr}^{N-k} \qquad \mathbf{2}$$

where N denotes the total number of visual attributes, k denotes the number of matches, $S_{vis.attr.}$ denotes values (attentional weights) of a mismatch on a visual attribute, S_{Label} denotes values of label mismatches, and L denotes a label match. When there is a label match, $L = 1$, and $S_{Label} = 1$; when there is a label mismatch, $L = 0$, and $S_{Label} < 1$. Note that S ($0 \leq S \leq 1$) denotes attentional weights of mismatches and the contribution of S is large if S is close to 0 and is small if S is close to 1. This is because the closer the value of S to 1, the smaller the contribution of a mismatch to the detection of difference, while the closer the value of S to 0, the greater its contribution to the detection of difference. When two entities are identical on all dimensions (i.e., there are no mismatches), their similarity should be equal to 1; otherwise, it is smaller than 1. Note that according to the model, when neither entity is labeled (i.e., $S_{Label} = 1$), similarity between entities is determined by the number of overlapping visual attributes, thus conforming to Equation 1. Labels are presented as a separate term in the equation because they are expected to have larger attentional weights than most visual attributes, an assumption that was borne out in previous research (Sloutsky & Lo, 1999). In the case that the weight of a label does not differ from that of other attributes, the label will become one of the attributes in the computation of similarity, and Equation 2 turns into Equation 1.

Finally, the model suggests that if the child is presented with a Target feature pattern (T) and Test feature patterns (A and B) and asked which of the Test patterns is more similar to the Target, the child's choices could be predicted using Equation 3:

$$P(B) = \frac{Sim(T, B)}{Sim(T, B) + Sim(T, A)} \qquad \mathbf{3}$$

In short, we argue that if categorization in young children is indeed similarity-based, then the same model that predicts similarity judgment in young children (e.g., Sloutsky & Lo, 1999) should be able to predict their categorization.

Simple derivations from Equation 3 allow us to predict categorization as a function of feature overlap. First, consider the case when entities are not labeled. Substituting *Sim (T,A)* and *Sim (T,B)* by their equivalents in Equation 1, we get Equation 4:

$$P(B) = S^x/(S^x + S^y) = S^x/[S^x(1 + S^{y-x})] = 1/(1 + S^y/S^x) \quad \mathbf{4}$$

For the labeled entities, derivations remain essentially the same, except for the S_{Label} parameter. The parameter equals to 1, if there is a label match, otherwise it equals to λ ($0 < \lambda < 1$). Therefore, in the case of labeled entities, the probability of selecting the item that shared the same label (say item B) could be derived according to Equation 5:

$$P(B) = S^x/(S^x + \lambda S^y) = S^x/[S^x(1 + \lambda S^{y-x})] = 1/(1 + \lambda S^y/S^x) \quad \mathbf{5}$$

In short, in the no-label condition, the probability of categorizing Test B and the Target together should be a function of the ratio of S^y/S^x (i.e., the ratio of similarity of Test A and Test B to the Target), whereas in the label condition such categorization should be a joint function of S^y/S^x and λ (i.e., attentional weight of label). Because we can estimate λ from our prior research, we can use Equations 4 and 5 for estimating specific probabilities of categorization. One important (and testable) consequence of this proposal is that because linguistic labels contribute to similarity in a quantitative manner rather than in a qualitative "all-or-nothing" manner, they should also make a quantitative contribution to categorization.

When stimuli consist of a small number of easily distinguishable and countable features (e.g., schematic faces or dot patterns), *N* and *K* (Equations 1 and 2) and subsequently *X* and *Y* (Equations 4 and 5) could be computed directly. However, if stimuli are perceptually rich, the task of determining *N*, *K*, and subsequently *X* and *Y* is complicated, if not impossible. One possible solution to this problem is to conduct a calibration study estimating similarity of each of the Test stimuli to the Target. Because similarity of each of the two Test stimuli to the Target is equivalent to S^y and S^x, ratios of similarity (i.e., S^y/S^x) could be easily computed, and therefore could be used to test the model.

The overall experimental idea was as follows. Participants were presented with triads of stimuli, with each triad consisting of Test stimuli A and B and Target T. In order to use perceptually rich stimuli and to quantify perceptual similarity, the stimuli were selected from sequences of images, in which one animal was "morphed" into another in a fixed number of steps. An example of a morphed sequence is presented in Figure 1. Multiple triads were formed from these sequences. These triads were subjected to a preliminary "calibration" study, in which participants were asked to estimate similarity of each of the Test stimuli to the Target. Those triads that gave the ratios of .5/.5, .4/.6, .3/.7, and .1/.9 were selected for the major study. An example of a .3/.7 triad is presented in Figure 2.

In addition to the quantitative predictions of Equations 4 and 5, we can formulate two qualitative predictions:

(1) When entities are not labeled, the probability of categorizing of Test stimulus together with the Target is a function of the ratio of perceptual similarity of this Test stimulus and the competing test stimulus to the Target.

(2) When entities are labeled, linguistic labels should affect categorization in a quantitative manner rather than in a qualitative "all-or-nothing" manner. Categorization should be a function of two variables – the weight of linguistic label and the similarity ratios – and not of linguistic labels alone.

Method

Participants

Participants were 37 preschool children recruited from daycare centers located in middle class suburbs of Columbus, Ohio (19 girls and 18 boys, $M = 5.4$ years; $SD = 0.82$ years).

Materials and Design

The experiment had a mixed design with a labeling condition (label vs. no-label) as a between-subject variable and similarity ratio as a within-subject variable. At both levels of the labeling condition participants were presented with the same triads of animal faces, one of which was a Target and two of which were Test stimuli. The only difference between the levels of the labeling condition was that in the label condition all stimuli were labeled, whereas in the no-label condition these stimuli were not labeled.

Materials consisted of triads of 4" × 4" pictures of animal faces selected to represent four levels of the stimulus pattern condition. Selection was made on the basis of results obtained in the calibration study. Each triad of pictures included a Target and two Test stimuli. The Target was located at the center above the Test stimuli.

These stimuli were selected by conducting a calibration experiment, in which 19 4–5 year-old children were presented with triads of pictures of animals (similar to those in Figure2) and asked which of the Test stimuli was more similar to the Target. 16 triads were selected on the basis of this calibration, representing four similarity ratios of (e.g., *Sim* (A, Target)/ *Sim* (B, Target): (1) .5/.5 = 1, (2) .4/.6 = 1.5, (3) .3/.7 = 2.33, and (4) .1/.9 = 9. Each of the four ratios included 4 triads. These four levels of perceptual similarity were included in the design.

Sim to the Target = .3

Procedure

Triads of pictures were presented to each participant on a computer screen. A female researcher interviewed each child individually in a quiet room in their schools. Before the experimental task participants were introduced to two warm-up trials. Questions asked during the warm-up trials were identical to the questions asked during the experimental trials. No feedback was given to the participants on their performance on the warm-up or experimental trials, and no participant was eliminated from the study on basis of his/her performance in the warm-up. The sole purpose of the warm-up was to illustrate to children the nature of the task they were to perform.

Experimental trials were identical to warm-up trials. In the label condition participants were first introduced to the labels for the Target and Test stimuli and asked to repeat them. All the labels used were two-syllable artificial count nouns (e.g. a Bala, a Guga). No labels were introduced in the no-label condition. Then, children were asked whether the Target was the same kind of animal as Test 1 or Test 2. Positions of two Test stimuli were randomized across trials. In both conditions participants had 16 experimental trials (four trials each of the four within-subject stimulus patterns). The order of trials was randomized for each participant.

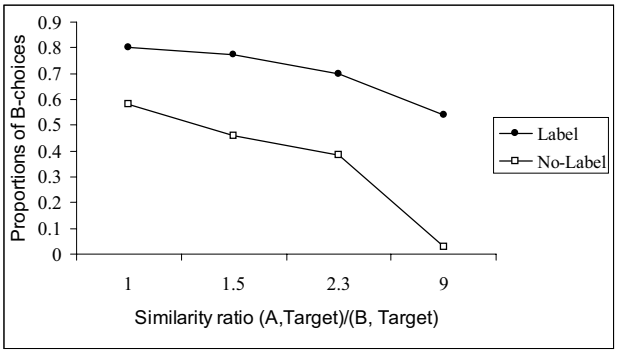
The important part of the instruction for preschool participants read: *Now we are going to play a game about animals from other planets. I am going to show you pictures of those alien animals, tell you their names, ask you to remember their names, and repeat them to me. Then I will ask you one question about those animals. Are you ready to start? I will show you something like this* (a warm-up triad was introduced at this point). *Look at them: this is a Guga* (points to the Target). *This is a Bala* (points to Test A). *This is a Guga* (points to Test B). *Could you please repeat their names? Do you think that this Guga* (points to the Target) *is the same kind as this Bala* (points to Test A) *or this Guga* (points to Test B)?

Note that in the no-label condition all stimuli were referred to as "this one." The order of introduction of the Test stimuli and their location relative to the target were randomized.

Results and Discussion

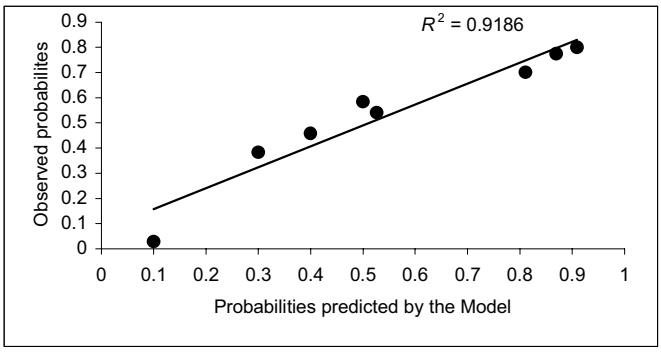
Proportions of B-choices by levels of the similarity ratio and labeling condition are presented in Figure 3 (recall that in the Label condition, Test B always shared the label with the Target). These proportions were averaged across the four trials for each level of the ratio and then averaged across subjects. Proportions averaged across trials were then subjected to a two-way (Labeling condition by Similarity ratio) mixed ANOVA with levels of similarity ratio as a repeated measure. The analyses indicated a significant main effect of labeling ($M_{\text{Label}} = .70 > M_{\text{No-Label}} = .36$), $F(1,35) = 30$, $MSE = 0.15$, $p < .0001$, and a significant main effect of the similarity ratio, $F(3,105) = 22.9$, $MSE = 0.06$, $p < .0001$, with no significant interaction. Planned comparisons of the levels of similarity ratio pointed to the following direction P(1) > P(1.5) = P(2.33) > P(9), all ts > 2, ps < .05. These results support the qualitative predictions, indicating that (a) when entities are not labeled, categorization is a function of perceptual similarity; (b) when entities are labeled, categorization is a function of similarity computed over perceptual and linguistic cues, and (c) labels contribute quantitatively to similarity among entities.

Figure 3. Proportions of B-choices by similarity ratio and labeling condition.



Quantitative predictions of the model are presented in Figure 4, where predicted probabilities of B-choices are plotted against observed probabilities. For the no-label condition, these probabilities were derived from Equation 4, whereas for the label condition they were derived from Equation 5 ($\lambda = .1$ was estimated from previous Sloutsky & Lo's data sets). Results indicate a good fit between predicted and observed probabilities ($r = .95$) with approximately 92% of variance explained by the model. These results indicating that similarity predicts much of categorization in young children support the hypothesis that, at least when labels are novel, categorization in young children is a function of similarity.

Figure 4. Overall fit of the model.



Several issues, however, would require further research. In particular, it remains unclear whether or not adults exhibit the same pattern of categorization as children. On the one hand, if entities are novel, it seems likely that adults should also use similarity as a basis of their categorization. On the other hand, there is evidence (Sloutsky, Lo, & Fisher, in press; Yamauchi & Markman, 2000) that adults are more likely than children to consider linguistic labels as category markers. There is also evidence that under different conditions adults may either rely on similarity for categorization (Smith & Sloman, 1994), or ignore it (Rips, 1989).

In short, the reported results support both quantitative and qualitative predictions of the model of label-as-attribute. As predicted, categorization appeared to be a function of two variables – the weight of linguistic label and the similarity ratios – and not of linguistic labels alone. These results also support the contention of the model that for young children linguistic labels are distinct attributes of entities. High correlations between the probabilities predicted by the model of similarity and the observed categorization frequencies support the hypothesis that categorization in young children is a similarity-based process.

The Interaction of Explicit and Implicit Learning: An Integrated Model

Abstract

This paper explicates the interaction between the implicit and explicit learning processes in skill acquisition, contrary to the common tendency in the literature of studying each type of learning in isolation. It highlights the interaction between the two types of processes and its various effects on learning, including the synergy effect. This work advocates an integrated model of skill learning that takes into account both implicit and explicit processes; moreover, it embodies a bottom-up approach (first learning implicit knowledge and then explicit knowledge on its basis) towards skill learning. The paper shows that this approach accounts for various effects in the process control task data, in addition to accounting for other data reported elsewhere.

Introduction

The role of implicit learning in skill acquisition and the distinction between implicit and explicit learning have been widely recognized in recent years (see, e.g., Reber 1989, Stanley et al 1989, Willingham et al 1989, Proctor and Dutta 1995, Anderson 1993), Although implicit learning has been actively investigated, complex and multifaceted interaction between the implicit and the explicit and the importance of this interaction have not been universally recognized; to a large extent, such interaction has been downplayed or ignored, with only a few notable exceptions. Research has been focused on showing the *lack* of explicit learning in various learning settings (see especially Lewicki et al 1987) and on the controversies stemming from such claims. Similar oversight is also evident in computational simulation models of implicit learning (with few exceptions such as Cleeremans 1994).

Despite the lack of studies of interaction, it has been gaining recognition that it is difficult, if not impossible, to find a situation in which only one type of learning is engaged (Reber 1989, Seger 1994, but see Lewicki et al 1987). Our review of existing data (see Sun et al 2001) has indicated that, while one can manipulate conditions to emphasize one or the other type, in most situations, both types of learning are involved, with varying amounts of contributions from each (see, e.g., Sun et al 2001; see also Stanley et al 1989, Willingham et al 1989).

Likewise, in the development of cognitive architectures (e.g., Rosenbloom et al 1993, Anderson 1993), the distinction between procedural and declarative knowledge has been proposed for a long time, and advocated or adopted by many in the field (see especially Anderson 1993). The distinction maps roughly onto the distinction between the explicit and implicit knowledge, because procedural knowledge is generally inaccessible while declarative knowledge is generally accessible and thus explicit. However, in work on cognitive architectures, focus has been almost exclusively on "top-down" models (that is, learning first explicit knowledge and then implicit knowledge on the basis of the former), the bottom-up direction (that is, learning first implicit knowledge and then explicit knowledge, or learning both in parallel) has been largely ignored, paralleling and reflecting the related neglect of the interaction of explicit and implicit processes in the skill learning literature. However, there are a few scattered pieces of work that did demonstrate the parallel development of the two types of knowledge or the extraction of explicit knowledge from implicit knowledge (e.g, Rabinowitz and Goldberg 1995, Willingham et al 1989, Stanley et al 1989), contrary to usual top-down approaches in developing cognitive architectures.

Many issues arise with regard to the interaction between implicit and explicit processes: (1) How can we best capture implicit and explicit processes computationally? (2) How do the two types of knowledge develop along side each other and influence each other's development? (3) How is bottom-up learning possible and how can it be realized computationally? (4) How do the two types of knowledge interact during skilled performance and what is the impact of that interaction on performance? For example, the synergy of the two may be produced, as in Sun et al (2001). In this paper, we will focus on the interaction and the synergy resulting from the interaction.

A Model

Let us look into a model that incorporates both implicit and explicit processes.

Representation. The inaccessible nature of implicit knowledge may be captured by subsymbolic distributed representations provided by a backpropagation network (Rumelhart et al 1986). This is because representational units in a distributed representation are capable of accomplishing tasks but are subsymbolic and generally not

individually meaningful (see Rumelhart et al 1986, Sun 1995); that is, they generally do not have an associated semantic label. This characteristic of distributed representation accords well with the inaccessibility of implicit knowledge. [1] In contrast, explicit knowledge may be captured in computational modeling by a symbolic or localist representations (Clark and Karmiloff-Smith 1993), in which each unit is easily interpretable and has a clear conceptual meaning, i.e., a semantic label. This characteristic captures the property of explicit knowledge being accessible and manipulable (Smolensky 1988, Sun 1995). This radical difference in the representations of the two types of knowledge leads to a two-level model CLARION (which stands for *Connectionist Learning with Adaptive Rule Induction ON-line*; proposed in Sun 1997), whereby each level using one kind of representation captures one corresponding type of process (either implicit or explicit). [2]

Learning. The learning of implicit action-centered knowledge at the bottom level can be done in a variety of ways consistent with the nature of distributed representations. In the learning settings where correct input/output mappings are available, straight backpropagation (a supervised learning algorithm) can be used for the network (Rumelhart et al 1986). Such supervised learning procedures require the a priori determination of a uniquely correct output for each input. In the learning settings where there is no input/output mapping externally provided, reinforcement learning can be used (Watkins 1989), especially Q-learning (Watkins 1989) implemented using backpropagation networks. Such learning methods are cognitively justified: e.g., Shanks (1993) showed that human instrumental conditioning (a simple type of skill learning) was best captured by associative models (i.e., neural networks), when compared with a variety of rule-based models. Cleeremans (1997) argued that implicit learning could not be captured by symbolic models.

Specifically, $Q(x,a)$ is the "quality value" of action a in state x, output from a backpropagation network. Actions can be selected based on Q values, for example, using the Boltzmann distribution (Watkins 1989).

We learn the Q value function as follows:

$$\Delta Q(x,a) = \alpha(r \quad \gamma \max_b Q(y,b) - Q(x,a)) = \alpha(r - Q(x,a))$$

where x is the current state, a is one of the action. r is the immediate reward, and $\gamma \max_b Q(y,b)$ is set to zero for the process control task we tackle in this paper, because we rely on immediate reward in this particular task (details below). $\Delta Q(x,a)$ provides the error signal needed by the backpropagation algorithm and then backpropagation takes place. That is, learning is based on minimizing the following error at each step:

$$err_i = \begin{cases} r - Q(x,a) & \text{if } a_i = a \\ 0 & \text{otherwise} \end{cases}$$

where i is the index for an output node representing the action a_i. Based on the above error measure, the backpropagation algorithm is applied to adjust internal weights (which are randomly initialized before training).

The action-centered explicit knowledge at the top level can also be learned in a variety of ways in accordance with the localist representations used. Because of the representational characteristics, one-shot learning based on hypothesis testing (Nosofsky et al 1994, Sun 1997) is needed. With such learning, individuals explore the world, and dynamically acquire representations and modify them as needed, reflecting the dynamic (on-going) nature of skill learning (Sun 1997, Sun et al 2001). The implicit knowledge already acquired in the bottom level can be utilized in learning explicit knowledge (through *bottom-up* learning; Sun et al 2001).

Initially, we hypothesize rules of a certain form to be tested (Dienes and Fahey 1995, Nosofsky et al 1994). When a measure of a rule (the IG measure) falls below the deletion threshold, we delete the rule. Whenever all the rules of a certain form are deleted, a new set of rules of a different form are hypothesized, and the cycle repeats itself. In hypothesizing rules, we progress from the simplest rule form to the most complex, in the order as shown in Figure 1, in accordance with those numerical relations used in human experiments (Berry and Broadbent 1988, Stanley et al 1989). (Other rule forms can be easily added to the hypothesis testing process. Since rules are tested in a parallel fashion, adding more rules will not drastically change the working of the model.)

The IG measure of a rule is calculated (in this process control task) based on the immediate reward at every step when the rule is applied. The inequality, $r > threshold$, determines the positivity/negativity of a step and of the rule matching this step. [3] Then, PM (positive match) and NM (negative match) counts of the matching rules are updated. IG is then calculated based on PM and NM:

$$IG(C) = log_2 \frac{PM(C) \quad c_1}{PM(C) \quad NM(C) \quad c_2}$$

where C is the current rule and c_1 and c_2 (where $2 \quad c_1 = c_2$) are Laplace estimation parameters. Thus, IG essentially measures the positive match ratio of a rule.

Simulation of human skill learning data

Simulation Focus. A number of well known skill learning tasks that involve both implicit and explicit processes were chosen to be simulated that span the spectrum ranging from simple reactive skills to more complex cognitive skills. The tasks include serial reaction time tasks,

[1] However, it is generally not the case that distributed representations are not accessible at all but they are definitely less accessible, not as direct and immediate as localist representations. Distributed representations may be accessed through indirect, transformational processes.

[2] Sun (1995, 1997), and Smolensky (1988) contain more theoretical arguments for such two-level models (which we will not get into here).

[3] In the process control task, $r = 1$ if *process-outcome* = *target+/-1* and $r = 0$ otherwise, and $threshold = 0.9$.

$P = aW$	b
$P = aW_1$	b
$P = aW$	cP_1
$P = aW_1$	bP_2

Figure 1: The order of rules to be tested. $a = 1, 2$, $b = -1, -2, 0, 1, 2$, $c = -1, -2, 1, 2$, P is the desired system output level (the goal), W is the current input to the system (to be determined), W_1 is the previous input to the system, P_1 is the previous system output level (under W_1), and P_2 is the system output level at the time step before P_1.

process control tasks, the Tower of Hanoi task, and the minefield navigation task.

We focus on simulating process control tasks in this paper. We are especially interested in capturing the interaction of the two levels in the human data, whereby the respective contributions of the two levels are discernible through various experimental manipulations of learning settings that place differential emphases on the two levels. These data can be captured using the two-level interactive perspective.

We aim to capture (1) the verbalization effect, (2) the explicit (how-to) instruction effect, and (3) the explicit search effect. Through the simulations, it will be shown that the division of labor between, and the interaction of, the two levels is important.

To capture each individual manipulation, we do the following: (1) The explicit (how-to) instructions condition is modeled using the explicit encoding of the given knowledge at the top level (prior to training). (2) The verbalization condition (in which subjects are asked to explain their thinking while or between performing the task) is captured in simulation through changes in parameter values that encourage more top-level activities, consistent with the existing understanding of the effect of verbalization (that is, subjects become more explicit; Stanley et al 1989, Sun et al 1998). (3) The explicit search condition (in which subjects are told to perform an explicit search for regularities in stimuli) is captured through relying more on the (increased) top-level rule learning, in correspondence with what we normally observe in subjects under the kind of instruction. (4) Many of these afore-enumerated manipulations lead to what we called the synergy effect between implicit and explicit processes: that is, the co-existence and interaction of the two types of processes leads to better performance than either one alone (Sun et al 2001). By modeling these manipulations, we at the same time capture the synergy effect as well.

General Model Setup. Many parameters in the model were set uniformly as follows: Network weights were randomly initialized between -0.01 and 0.01. Percentage combination of the two levels (through a weighted sum) is used: that is, if the top level indicates that action a has an activation value l_a (which should be 0 or 1 as rules are binary) and the bottom level indicates that a has an activation value q_a (the Q-value), then the final outcome is $v_a = w_1 \quad l_a \quad w_2 \quad q_a$. The combination weights of the two levels were set at $w_1 = 0.2$ and $w_2 = 0.8$. Stochastic decision making with the Boltzmann distribution (based on the weighted sums) is then performed to select an action out of all the possible actions. The Boltzmann distribution is as follows:

$$p(a\ x) = \frac{e^{v_a\ \alpha}}{\sum_i e^{v_{a_i}\ \alpha}}$$

Here α controls the degree of randomness (temperature) of the decision-making process. It was set at 0.01. (This method is also known as Luce's choice axiom.) Other parameters include numbers of input, output, and hidden units, the external reward, the rule deletion threshold, the backpropagation learning rate, and the momentum. Most of these parameters were not free parameters, because they were set in an a priori manner (based on our previous work), and not varied to match the human data.

For modeling each of these manipulations, usually only one or a few parameter values are changed. These parameters are changed as follows. To capture the verbalization effect, we raise the rule deletion threshold at the top level. The hypothesis is that, as explained earlier, verbalization tends to increase top-level activities, especially rule learning activities. To capture the explicit search effect, we increase the weighting of the top level in addition to raising the rule deletion threshold. The hypothesis is that explicit search instructions tend to increase the reliance on top-level rule learning. To capture the explicit instruction effect, we simply wire up explicit a priori knowledge at the top level.

Simulating Stanley et al (1989)

The task. Two versions of the process control task were used in Stanley et al (1989). In the "person" version, subjects were to interact with a computer simulated "person" whose behavior ranged from "very rude" to "loving" (over a total of 12 levels) and the task was to maintain the behavior at "very friendly" by controlling his/her own behavior (which could also range over the 12 levels, from "very rude" to "loving"). In the sugar production factory version, subjects were to interact with a simulated factory to maintain a particular production level (out of a total of 12 possible production levels), through adjusting the size of the workforce (which has 12 levels). In either case, the behavior of the simulated system was determined by $P = 2 \quad W - P_1 \quad N$, where P was the current system output, P_1 was the previous system output, W was the subjects' input to the system, and N was noise. Noise (N) was added to the output of the system, so that there was a chance of being up or down one level (a 33% chance respectively).

There were four groups of subjects. The control group was not given any explicit how-to instruction and not asked to verbalize. The "original" group was required to verbalize: Subjects were asked to verbalize after each block of 10 trials. Other groups of subjects were

human data

model data

	sugar task	person task
control	2.276	2.610
original	2.952	4.187
memory training	4.089	5.425
simple rule	4.073	5.073

Figure 3: The model data for the task of Stanley et al (1989).

given explicit instructions in various forms, for example, "memory training", in which a series of 12 correct input/output pairs was presented to subjects, or "simple rules", in which a simple heuristic rule ("always select the response level half way between the current production level and the target level") was given to subjects. The numbers of subjects varied across groups. 12 to 31 subjects were tested in each group. All the subjects were trained for 200 trials (20 blocks of 10 trials).

The data. The exact target value plus/minus one level (that is, "friendly", "very friendly", or "affectionate") was considered on target. The mean scores (numbers of on-target responses) per trial block for all groups were calculated. Analysis showed the verbalization effect: The score for the original group was significantly higher than the control group ($F(1,73) = 5.20, p < 0.05$). Analysis also showed the explicit instruction effect: The scores for the memory training group and for the simple rule group were also significantly higher than the control group. See Figure 2.

The model setup. The model was set up as described earlier. We used 168 input units, 40 hidden units, and 12 output units. There were 7 groups of input units, each for a particular (past) time step, constituting a moving time window. Each group of input units contained 24 units, in which half of them encoded 12 system output levels and the other half encoded 12 system input levels at a particular step. The 12 output units indicated 12 levels of subjects' input to the system. The learning rate was 0.1. The momentum was 0.1.

The rule deletion threshold was set at 0.15 for simulating control subjects. To capture the verbalization condition, the rule deletion threshold was raised to 0.35 (to encourage more rule learning activities). To capture the explicit instruction conditions, in the "memory training" condition, each of the 12 examples was wired up at the top level as simple rules (in the form of $P_1 - \quad W$); in the "simple rule" condition, the simple rule (as described earlier) was wired up at the top level. A reward of 1 was given when the system output was within the target range. In simulating the person task (a common, everyday task), we used pre-training of 10 blocks before data collection, to capture prior knowledge subjects likely had in this type of task.

The match. Our simulation captured the verbalization effect in the human data well. See Figures 2 and 3. We used a t test to compare the "original" group with the control group in the model data, which showed a significant improvement of the original group over the control group ($p <$ 01), the same as the human data.

Our simulation also captured the explicit instruction effect, as shown in Figure 3. We used pair-wise t tests to compare the "memory training" and "simple rule" groups with the control group in the model data, which showed significant improvements of these two groups over the control group, respectively ($p <$ 01).

Both effects point to the positive role of the top level. When the top level is enhanced, either through verbalization or through externally given explicit instructions, performance is improved, although such improvement is not universal (Sun et al 2001). They both showed synergy between the top-level explicit processes and the bottom-level implicit processes.

Simulating Berry and Broadbent (1988)

The task. The task was similar to the computer "person" task in Stanley et al (1989). Subjects were to interact with a computer simulated "person" whose behavior ranged from "very rude" to "loving" and the task was to maintain the behavior at "very friendly" by controlling his/her own behavior (which could also range from "very rude" to "loving"). In the salient version of the task, the behavior of the computer "person" was determined by the immediately preceding input of the subject: It was usually two levels lower than the input ($P = W - 2 \quad N$). In the non-salient version, it was determined by the input before that and was again two levels lower than that input ($P = W_1 - 2 \quad N$). Noise (N) was added to the output of the computer "person" so that there was a chance of being up or down one level (a 33% chance respectively).

Four groups of subjects were used: salient experimental, salient control, non-salient experimental, and non-salient control. The experimental groups were given explicit search instructions after the first set of 20 trials, and after the second set of 20 trials were given explicit instructions in the form of indicating the relevant input that determined the computer responses (W or W_1). 12 subjects per group were tested.

The data. The exact target value plus/minus one level (that is, "friendly", "very friendly", or "affectionate") was considered on target. The average number of trials on target was recorded for each subject for each set of 20 trials. Figure 4 shows the data for the four groups of subjects for the three sets of trials. Analysis showed that on the first set, neither of the two experimental groups differed significantly from their respective control groups.

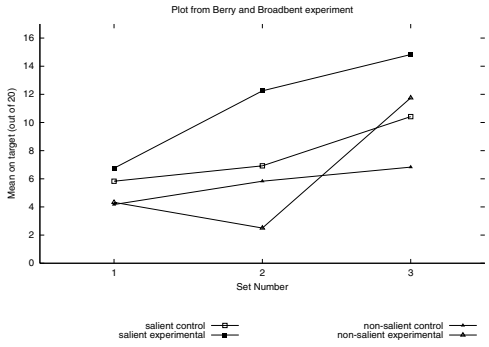

Figure 4: The data of Berry and Broadbent (1988).

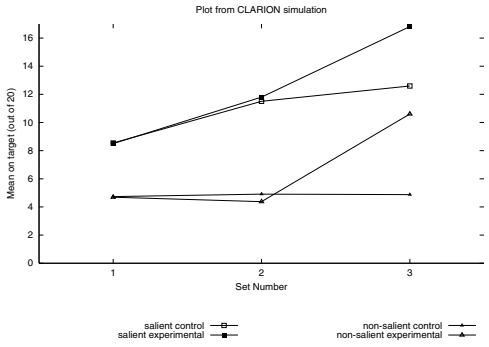

Figure 5: The simulation of Berry and Broadbent (1988).

However, on the second set, the salient experimental group scored significantly higher than the salient control group ($p < 0.01$), but the non-salient experimental group scored significantly less than the non-salient control group ($p < 0.05$). On the third set, both experimental groups scored significantly higher than their respective control groups ($p < 0.01$). The data clearly showed (1) the explicit search effect: improving performance in the salient condition and worsening performance in the non-salient condition; (2) the explicit instruction effect: improving performance in all conditions; as well as (3) the salience difference effect (during the 2nd set, under the explicit search condition).

The model setup. The model was set up similarly as described earlier for simulating Stanley et al (1989), except the following differences. The rule deletion threshold was set at 0.1 initially. To capture the explicit search effect (during the second training set), the rule deletion threshold was raised to 0.5 (for increased learning activities in the top level), and the weighting of the two levels was changed to 0.5/0.5 (for more reliance on the top level). To capture the explicit instructions given in this task (during the third training set), only rules that related the given critical variable to the system output were hypothesized and tested at the top level thereafter, in correspondence with the instructions (that is, $P = aW \quad b$, where W is the critical variable indicated by the instructions). The learning rate was 0.04. The momentum was 0.

The match. We captured in our simulation of this task the following effects exhibited in the human data: the salience difference effect, the explicit search effect, and the explicit instruction effect. The results of the simulation are shown in Figure 5. On the first set, neither of the two experimental groups differed significantly from their respective control groups; however, on the second set, the salient experimental group scored slightly higher than the salient control group, but the non-salient experimental group scored slightly less than the non-salient control group. On the third set, both experimental groups scored significantly higher than their respective control groups ($p < 0.01$).

The data demonstrated clearly the explicit instruction effect (improving performance in all conditions), and showed to some extent the explicit search effect (improving performance in the salient condition and worsening performance in the non-salient condition), as well as the salience difference effect along with the explicit search effect. The data showed the extent and the limit of the synergy effect (in that the non-salient condition discouraged synergy).

General Discussions

Although implicit learning is a controversial topic, the existence of implicit processes in skill learning is not in question — what is in question is their extent and importance. We allow for the possibility that both types of processes and both types of knowledge coexist and interact with each other to shape learning and performance, so we go beyond the controversies and the studies that focused mostly on the minute details of implicit learning (Gibson et al 1997).

The incorporation of both processes allows us to ask the question of how synergy is generated between the two separate, interacting components of the mind (the two types of processes). The model may shed some light on this issue. Sun and Peterson (1998) did a thorough computational analysis of the source of the synergy between the two levels of CLARION in learning and in performance. The conclusion, based on the systematic anaylsis, was that the explanation of the synergy between the two levels rests on the following factors: (1) the complementary representations of the two levels: discrete vs. continuous; (2) the complementary learning processes: one-shot rule learning vs. gradual Q-value approximation; and (3) the bottom-up rule learning criterion used in CLARION. [4] It is very likely, in view of the match between the model and human data as detailed in this paper, that the corresponding synergy in human performance results also from these same factors (in the main).

[4]Due to lengths, we will not repeat the analysis here. See Sun and Peterson (1998) for details.

As a result of its distinct emphasis, CLARION is clearly distinguishable from existing unified theories/architectures of cognition, such as SOAR, ACT, and EPIC. For example, SOAR (Rosenbloom et al 1993) is different from CLARION, because SOAR makes no distinction between explicit and implicit learning, and is based on specialization, using only symbolic forms of knowledge. Although ACT (Anderson 1993) makes the distinction, it is different from CLARION because traditionally it focuses mainly on top-down learning (from declarative to procedural knowledge).

Concluding Remarks

This work highlights the importance of the interaction of implicit and explicit processes in skill learning. It captures the interaction through a model that includes both types of processes. This modeling work reveals something new in the existing data (cf. Gibson et al 1997, Lebiere et al 1998). The contribution of this model lies in capturing human data in skill learning through the interaction of the two types of processes, and also in demonstrating the computational feasibility and psychological plausibility of bottom-up learning (Sun et al 2001).

Abstract

Thirteen non-demented patients with Parkinson's disease (PD) were compared with age matched controls on two standard tests of implicit learning. A verbal version of the Serial Reaction Time (SRT) task was used to assess sequence learning and an artificial grammar (AG) task assessed perceptual learning. It was predicted that PD patients would show implicit learning on the AG task but not the SRT task, as motor sequence learning is thought to be reliant upon the basal ganglia which is damaged in PD. Patients with PD demonstrated implicit learning on both tasks. In light of these unexpected results the research on SRT learning in PD is reconsidered, and some possible explanations for the sometimes conflicting results of PD patient samples on the SRT task are considered. Factors which merit further study in this regard are: The degree to which the SRT task relies on overt motor responses; the effects of frontal lobe dysfunction upon implicit sequence learning; and the degree to which the illness itself has advanced.

Current theoretical accounts of human memory draw an important distinction between implicit and explicit learning processes (e.g., Squire, 1994; Squire & Zola, 1996). Explicit (or declarative) learning and memory is characterized by the acquisition and retrieval of information accompanied by awareness of the learned information and its influence. Implicit learning refers to similar acquisition without awareness of the learned information or its influence. Such learning occurs in situations and tasks whereby the ability to consciously or deliberately recall the episode in which learning took place, or to describe the rules underlying the task, typically fall well behind the level of performance. It is thought that explicit learning is dependent upon medial temporal lobe and diencephalic brain structures, while habit learning and implicit skill learning is closely associated with neostriatal structures such as the basal ganglia (Squire, 1994; Squire & Zola, 1996).

One striking characteristic of implicit learning has been its demonstrable robustness even in the face of quite major brain damage. For example, using the serial reaction time (SRT) task researchers have shown implicit learning to be preserved in normal ageing (Howard & Howard, 1989), Korsakoff patients (Nissen & Bullemer, 1987), closed head injury patients (McDowall & Martin, 1996) and Alzheimer's disease (Knopman & Nissen, 1987). However, the fact that the very brain structures thought to be closely associated with certain forms of implicit learning are the most impaired by Parkinson's disease (PD), makes PD of special interest for implicit learning researchers. The characteristic neuropathology of PD includes marked degeneration and atrophy of the basal ganglia and substantia nigra, particularly the caudate nucleus or the neostriatum (Knight, 1992). In the present study we were interested to compare the performance of PD patients with controls on two tests of implicit learning: the serial reaction time (SRT) task and the artificial grammar (AG) task.

In the SRT task participants respond as quickly as possible to the presentation of an asterisk on a computer monitor. The asterisk can appear at any one of several different locations and participants must respond by pressing a key which corresponds to the spatial location of the asterisk. Unknown to the participants, the location of the stimulus follows a sequence which is repeated over a number of trials. Sequence learning is assumed to occur when, over the course of successive trials, the reaction times (RT) of participants decrease significantly and when there is a significant increase in the RT of participants upon the

administration of a block of trials where the position of the asterisk is random. Of particular interest, is that while participants display significant learning over trials, they are often unaware that such learning has occurred and mostly unable to correctly report the actual sequence followed (Nissen & Bullemer, 1987).

In the first study of PD patients using the SRT task Ferraro, Balota and Connor (1993) reported that non-demented individuals with PD showed less sequence specific learning than healthy controls. Similarly, Pascual-Leone et al. (1993) found patients with PD acquired some SRT procedural knowledge although its degree was less than in healthy volunteers. However, perhaps the clearest evidence for an implicit visuomotor learning deficit in patients with basal ganglia dysfunction comes from a study by Jackson et al. (1995). The authors found no significant SRT learning in PD patients and concluded that the results suggest a role for the basal ganglia in SRT learning or the expression of serially-ordered action. Westwater et al. (1998) employed a verbal version of the SRT task, designed to minimize the influence of the motor symptoms of PD, and reported similar results. In summary, there is a growing number of studies suggesting that implicit learning in PD, at least as measured by the SRT task, is reduced or impaired in people with PD.

AG learning involves presenting participants with a set of rule-governed stimuli (typically cards consisting of letter strings belonging to a finite-state grammar) for observation, and asking them to commit the letter strings to memory. The set of stimuli typically consists of exemplars which cover the entire range of transitions of the grammar, providing exposure to all the rules of the grammar albeit in an indirect fashion. On completion of the orientation task, participants are informed of the existence of a complex grammatical system governing the stimuli presented. Participants are then shown a new set of cards, only half of which conform to the grammar, and asked to decide whether each item conforms to the structure of the grammar. The assumption behind this paradigm is that tacit knowledge, which is abstract and representative of a complex grammar system, can be learnt independently of conscious efforts (Reber, 1989).

One important theoretical issue for the study of implicit learning concerns the degree to which different types of implicit learning are separate or dissociable both functionally and at an anatomical level. For instance, while formally similar to habit learning paradigms such as the SRT task, AG participants typically evidence abstract knowledge about a complex rule system on grammaticality tests, while the measure used in SRT tasks is reaction time, which is more likely to tap visuomotor knowledge (Seger, 1998). The examination of abstract judgment-linked learning (e.g., AG learning) and visuomotor learning in a group such as PD patients, where brain structures assumed to be involved in implicit learning processes are damaged, provides a method to investigate the possibility that these forms of implicit learning may be independent.

While several studies have examined the performance of PD patients on the SRT task (and generally found deficits or impairments), to our knowledge only two published studies have reported using the AG task with PD patients. Thierry, Peigneux and Van der Linen (1998) observed the same level of performance in controls and patients with PD on initial trials which suggested preserved AG learning in PD, and more broadly, that the basal ganglia may not be crucially involved in the rule-extraction mechanisms engaged in AG learning. Recently, Reber and Squire (1999) investigated the ability of patients with PD to learn AG in both a standard condition and a letterset transfer version of the task. They observed learning under both conditions and concluded that the learning of AGs appeared not to depend on the integrity of the neostriatum. They also commented that the dissociation between SRT and AG performance in patients with PD relies upon comparisons across studies, and that a dissociation within the same group of patients would be even stronger evidence.

The finding that patients with PD exhibit intact AG learning but show impairment on SRT tasks suggests implicit learning is not a single entity and that different neural systems may mediate performance on particular implicit learning tasks. In the present study we set out to compare the performance of a group of patients with PD on the SRT task with their performance on an AG task. The verbal version of the SRT task replaced the standard button-pressing response with a vocal response in an attempt to reduce the motor component of the task. We hypothesized that patients with PD would show impaired performance on the SRT task but not on the AG task in comparison to healthy controls.

Method

Participants

Participants consisted of 14 patients with PD recruited from the Neurology outpatients' service of Wellington Hospital, and 14 volunteers from the community who served as healthy controls. The diagnosis of PD was confirmed by a senior staff neurologist. One member of the PD group scored below the standard cut-off of 24 points on the Mini-Mental Status Examination (MMSE; Folstein, Folstein, & McHugh, 1975), used as a screening measure for abnormal cognitive decline, and was excluded from further analyses.

The PD group comprised eight males and five females, with a mean age of 66.42 years (range = 37 to 79 years). In the control group, eight were male and six were female, and the mean age was 68.36 years (range = 53 to 74 years). Each of the patients with PD in the present study fell within the early to middle/late stages of severity as assessed by the Hoehn and Yahr (1967) degree of clinical disability scale. Ten of the patients were in Stage Two (bilateral midline involvement without loss of balance), two were in Stage Three (first signs of impairment in equilibrium, significant slowing of body movements), and one was in Stage Four (fully developed PD, still able to stand and walk, but markedly incapacitated). At the time of testing all patients with PD were under the care of a neurologist and all but two were receiving anti-Parkinsonian medication. None had a history of head injury within the preceding ten years, or had a history of alcohol abuse, stroke or epilepsy, and all

subjects had normal or corrected to normal vision. The administration of a standardized measure of depression indicated an absence of depression for all participants.

Materials

All participants were administered the National Adult Reading Test (NART; Nelson & Willeson, 1991) to compare performance on intellectual ability. Additionally, the Controlled Oral Word Association Test (COWAT; Benton & Hamsher, 1976) was administered in order to assess verbal fluency. There were no significant group differences on variables of age, gender, or number of years spent in formal education. A summary of the group demographics is displayed in Table 1.

Table 1. Demographic Data.

Measure	PD M (SD)	Controls M (SD)
Age (yrs)	66.4 (11.0)	68.3 (8.4)
Education (yrs)	12.2 (2.7)	12.3 (2.6)
MMSE	27.3 (2.0)	29.0 (1.3)
COWAT	33.6 (12.2)	47.6 (2.1)*
NART	116.5 (5.0)	122.0(10)*

* $p<.05$

Note: MMSE = Mini Mental Status Examination; COWAT = Controlled Oral Word Association Test - age corrected scores: NART = National Adult Reading Test, expressed as a Wechler Adult Intelligence Scale - Revised full scale equivalent.

Apparatus and Procedure

All participants were tested individually beginning with the NART, followed by the MMSE. Following this participants either completed the SRT, the COWAT, and then the AG task, or performed these three tasks in reverse order. The ordering of these three tasks was counterbalanced within both the PD patient group and the control participant group.

SRT Task. The SRT task was a verbal version of the classic SRT task, as devised by Nissen and Bullemer (1987), replicating the SRT task used by Westwater et al. (1998) (refer to Westwater et al. for a more detailed description of the procedure). Briefly, all participants completed five blocks of trials, each consisting of 100 trials. In each trial a stimulus (an asterisk) appeared in one of four positions along the bottom of a computer monitor. In the first four blocks the asterisk appeared in a sequential manner (the 10-item sequence used in Nissen and Bullemer (1987)). In the fifth block the location of the asterisk was determined pseudorandomly. All participants were asked to respond as quickly as possible to the location of each stimulus by saying aloud the number corresponding to its location. Upon a response the stimulus disappeared and 400ms later the next stimulus appeared in one of the other locations. At the conclusion of the task all participants were asked whether they noticed anything about the nature of the stimuli. Although some participants reported being aware of some form of pattern to the stimuli, none were able to correctly reproduce it when asked to do so.

Artificial grammar task. Grammatical letter strings were generated from a finite-state Markovian rule system identical to that used by Dienes, Broadbent, and Berry (1991). This structure was used to generate both 23 training and 23 test items, each three to six letters in length. Twenty-three non-grammatical test items were also generated from the rule system by substituting an inappropriate letter for an appropriate letter in an otherwise grammatical string. Each letter string was presented on a 7.5 x 12.7 cm index card.

The procedure for the training and testing phases closely followed the standard AG procedure and is fully described by Dienes et al. (1991: Experiment 1., "grammatical" participants). At the conclusion of the task, participants were asked: "What were the grammatical rules or strategies on which you were basing your judgments of grammaticality or classification". No participant was able to accurately identify the rules with any significant success.

Results

SRT task. The results of one patient with PD were omitted from SRT data analyses because of a technical problem with the microphone and the voicebox, which led to invalid data. Error rates were defined as verbal responses which were incorrect with regard to the position of the stimuli, as well as any omissions. Both groups averaged well below a 5% error rate across blocks and did not differ significantly in total error rate, $t(24) = -1.22$, $p>.05$. Incorrect responses were not included in the RT analyses. For each set of 10 trials (the sequence pattern in blocks 1 to 4), each participant's median RT of correct responses was computed. Figure 1. shows the mean of those median scores for each block (ten repetitions of 10 trials) for the PD and control groups. All analyses involved a mixed Group x Block ANOVA with Block as a within-group factor. A 2 (Group) x 5 (Block) mixed factor ANOVA showed a significant Group effect, $F(1,24) = 6.34$, $p<.05$, and a significant effect of Block $F(4,96) = 11.75$, $p<.0001$. There was no significant Group x Block interaction, $F(4,96) = 0.56$, $p>.05$.

In order to examine both sequence learning and non-specific practice effects a 2 (Group) x 4 (Block) ANOVA with repeated measures on the last factor was computed over the first four blocks. This revealed a significant main effect for Block, $F(3,72) = 15.89$, $p<.0001$, and a significant main effect for Group, $F(1,24) = 6.02$, $p<.05$. There was no Group x Block interaction, $F(3,72) = 0.45$, $p>.05$.

Decreased RT over the first four blocks can result from both sequence learning and non-specific practice effects. To examine sequence-specific learning, a 2 (Group) by 2 (Block) mixed factor ANOVA was computed for Block 4 and Block 5. This resulted in main effects for Group, $F(1,24) = 7.72$, $p<.05$, and Block, $F(1,24) = 24.21$, $p<.0001$. There was no Group x Block interaction, $F(1,24) = 0.01$, $p>.05$.

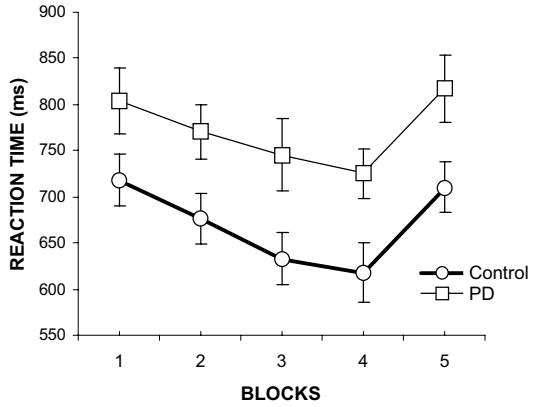

Figure 1. Mean RT across blocks for PD and Control groups.

A preliminary inspection of the effects of disease severity on sequence learning was performed by dividing patients into two groups according to their Hoehn and Yahr scores: Stage 2 (n=9) and Stage 3-4 (n=3). However, the data suggested there was no effect of severity of disease on SRT performance. These results have to be interpreted with caution because of the small number of patients especially in the severe group. A similar pattern of results emerged using both the COWAT and NART as covariates.

Frontal lobe dysfunction has also been associated with impairment in performance on a visuomotor sequence learning task (Beldarrain et al., 1999). However, correlation analysis failed to show a significant association between performance on the COWAT (a test that has been associated with frontal lobe functioning) and sequence specific learning (as measured by the increase in mean reaction time from trial 4 to 5) for patients with PD, $r = -0.56$, $p>.05$. Once again, small numbers preclude any serious conclusions on this matter.

Artificial grammar task. Participants' scores were calculated firstly, by the percentage of grammatical strings classified correctly and the percentage of ungrammatical strings classified correctly, and secondly, by the percentage of grammatical strings classified as grammatical relative to the percentage of grammatical strings classified as ungrammatical.

Average percentage correct for making grammaticality judgments for the patients with PD was 55.9% (standard error of the mean (SEM) = 2.1%), a performance significantly better than chance, $t(12) = 2.85$, $p<.01$. Controls obtained 57.9% (SEM = 1.9%) correct for grammaticality judgments, and also performed better than chance, $t(13) = 4.32$, $p<.001$. There was no significant difference in classification performance between the groups, $t(25) = 0.75$, $p>.05$.

Patients with PD classified as grammatical 61.2% (SEM = 3.4%) of the grammatical strings and 49.5% (SEM = 4.7%) of the ungrammatical strings. Control participants classified as grammatical 63.4% (SEM = 3.9%) of the grammatical strings and 47.5% (SEM = 3.7%) of the ungrammatical strings. A two-way ANOVA revealed a significant effect of the Grammaticality variable, $F(1,25)= 25.24$, $p<.0001$, but no significant Group effect, $F(1,25)= 0.0003$, $p>.05$. There was no significant Group x Grammaticality variable interaction, $F(1,25)= 0.57$, $p>.05$.

Discussion

The present study compared the performance of patients with PD with matched controls on two distinct tests of implicit learning, a verbal version of the SRT task and an AG task. Contrary to our first hypothesis the participants with PD demonstrated implicit learning on the SRT task. As predicted, they also showed implicit learning on the AG task. The control group also demonstrated implicit learning on both tasks. These results are further testimony to the robustness of implicit learning in the face of both age (given the mean ages of both groups) and neurological damage. At the same time the failure to observe impaired learning on the SRT task, by the PD participants, is inconsistent with other recent studies (e.g., Jackson et al., 1995; Westwater et al., 1998).

Perhaps the first point to consider is that findings regarding implicit learning and PD have been quite diverse and sometimes conflicting. For example, findings of deficits in performance of patients with PD on rotor-pursuit tasks (Harrington et al., 1990; Heindel et al., 1989) and mirror reading skill acquisition tasks (Allain et al., 1995; Yamadori et al., 1996) are tempered by findings of preserved learning on both the former (Bondi & Kasniak, 1991), and the latter (Bondi & Kasniak, 1991; Harrington et al., 1990). Moreover, attempts to relate findings at a behavioral or cognitive level, with likely neuroanatomical substrates have also produced a complex picture. For example, some authors attribute performance deficits to the disrupted basal ganglia in PD, or argue for a more specific emphasis on brain stem structures of the basal ganglia such as the substantia nigra, or other basal nuclei including the caudate nucleus or the putamen (e.g., Doyon et al., 1997). Others attribute the primary role to impaired neuroanatomical circuitry in PD (e.g., Bondi & Kaszniak, 1991; Heindel et al., 1989; Taylor, Saint-Cyr, & Lang, 1986), or more specifically the “complex loop” (e.g., Bondi & Kaszniak, 1991), whereas some authors have emphasized the importance of disturbed striatofrontal or caudate outflow in PD (e.g., Saint-Cyr, Taylor, & Lang, 1988). In summary, research on implicit learning in PD has produced conflicting results and also a wide range of possible explanations at the anatomical level.

However, studies employing the SRT task have been generally more consistent. Jackson et al. (1995) reported impairments on a variant of the SRT task in a group of 10 non-demented PD patients compared with healthy controls. Pascual-Leone et al. (1993) reported that patients with PD “achieved procedural knowledge” on the SRT task but at a slower rate than healthy controls. Ferraro et al. (1993) concluded that “there does appear to be some breakdown in implicit learning in non-demented PD individuals....” (p.175). Doyon et al. (1997) observed an impairment late in the sequence acquisition process on a version of the SRT for PD patients with a bilateral striatal-dysfunction. Finally,

Westwater et al. (1998) using a verbal version of the SRT task found implicit learning was impaired in PD. In summary, the evidence that procedural learning is impaired in PD, at least as measured by the SRT task, is generally more consistent that for other dimensions of implicit learning. In light of the SRT studies reviewed above, it is interesting to speculate as to why the PD patients in the present study demonstrated preserved implicit learning.

One possible explanation for this discrepancy then concerns the verbal version of the SRT task adopted for this experiment. Specifically, the current investigation was structured as to minimize the extent to which deficits displayed by the patient group could be artifacts of bradykinesia, akinesia, and/or motor arrests (symptoms commonly associated with PD), rather than failure to demonstrate implicit learning per se. The present findings suggest that difficulties in executing a motor response may be responsible for the impairment in implicit learning of patients with PD, as gauged by the standard SRT tasks which include an overt motor component in the method of response (e.g., Ferraro et al., 1993, Jackson et al., 1995; Pascal-Leone et al., 1993). However, this line of thought must be viewed with some reservations. Firstly, the SRT task used here replicated that of Westwater et al. (1998) who obtained results which conflict with this study. Secondly, findings of impaired PD patient performance on habit learning tasks that do not include a motor component (Knowlton, Mangels, & Squire, 1996) strongly suggest that the neostriatum is important not just for motor learning but also for acquiring non-motor dispositions that depend on new associations. Finally, the verbal response retains a motor element in which the deficiency is a salient feature of PD. For instance, bradykinesia has been associated with inappropriate and/or lengthy hesitations and a softening of the voice (becoming less audible), often accompanied by monotonous and hurried speech sounds (Knight, 1992). Therefore, while the exclusion of an overt motor component in the SRT task is useful in light of the motor difficulties experienced by patients with PD, it is by itself unlikely to account for the unexpected preserved learning exhibited by patients with PD in the current investigation.

A second reason that could account for the inconsistent SRT performance of PD patient samples observed in studies involves the possible role played by the frontal lobes in visuomotor sequence learning. Jackson et al. (1995) reported evidence for a procedural learning deficit in PD patients on the SRT task. However, when they compared PD patients who scored poorly on the Wisconsin Card Sorting Test (WCST) (suggesting a degree of frontal lobe dysfunction), with patients who scored normally on this test, the "frontal" group appeared to perform considerably worse than either the "non-frontal" group or the healthy controls. Unfortunately, their small sample size (11 PD patients) precluded a meaningful statistical comparison of these sub-groups. Beldarrain et al. (1999) examined SRT learning in 22 (non-PD) patients with unilateral prefrontal lesions and observed that learning was impaired in patients with lesions greater than 2cm in diameter. In concluding they argued for the "crucial role of the prefrontal cortex in procedural implicit learning" (p.1859). By contrast, Doyon et al. (1997), who studied PD patients specifically, concluded that implicit learning depended upon the "integrity of both the striatum and the cerebellum, but not of the frontal lobes" (p.219). In the present study, pairwise correlations between COWAT performance and sequence specific learning on the SRT failed to reach significance supporting Doyon and colleagues' findings. However, these results must be interpreted with caution given that numbers were small and the COWAT is a measure of verbal fluency and not frontal lobe integrity per se. Future research would be advised to adopt more precise measures of frontal lobe functioning such as the WCST. In summary, there is some evidence, although far from unequivocal, that the intact functioning of the prefrontal cortex may be important for procedural learning. If this can be substantiated, then it has obvious relevance for clarifying the performance of PD patients on the SRT task, given that "frontal dysfunction" is such a common symptom of PD (Taylor et al., 1986).

A third possible explanation for the inconsistent findings in this area concerns the stage of the disease. Presumably, if the implicit learning deficit is related to damage to the basal ganglia, then this will become increasingly obvious as the disease advances. In support of this Doyon et al. (1997) found that "only PD patients in more advanced stages of the disease showed an impairment in acquiring the repeating sequence" (p.235). Similarly, on the rotary pursuit task, also an example of implicit motor skill learning, Harrington et al. (1990) reported that procedural learning was impaired but only in patients with more advanced symptoms of PD. Interestingly, in the present study, a preliminary analysis of severity did not show any effect, although as 9 of the 12 patients were in Stage 2 on the Hoehn and Yahr scale, this is perhaps not surprising. Another, preferably continuous, measure of motor function or severity that allowed for a more even distribution of the subjects into two groups would have perhaps been more useful given the small number of patients.

Finally, it is important to note that implicit learning on the AG task was also preserved among the PD patients. Overall, both groups classified strings according to their grammatical status at a level above chance, demonstrating learning for the AG system, learning that could not be consciously articulated by participants in either group. These findings are consistent with those of both Reber and Squire (1999) and Thierry et al. (1998) who also observed preserved AG learning in patients with PD and is in accord with current notions that such learning of perceptual knowledge is more cortically mediated and less reliant upon subcortical structures (Reber & Squire, 1999). Though we have devoted most of the discussion to considering explanations for the unpredicted results on the SRT task, the results on the AG task are also important, as this is only the third published study to date reporting preserved implicit learning on this task in PD patients. As such it adds to the growing body of evidence for the robustness of this dimension of implicit learning even in the face of neurological illness.

Abstract

Two striking contrasts currently exist in the sentence processing literature. First, whereas adult reading studies indicate an important role for verb biases in the initial consideration of syntactic alternatives (Britt, 1994), studies of adult listeners in world-situated eye-gaze studies suggest an almost exclusive role for referential cues in determining initial syntactic choices (Tanenhaus et al., 1995). Second, in contrast to adults, children in similar listening studies fail to take into account this referential information and instead appear to rely exclusively on verb biases or perhaps syntactically-based parsing principles (Trueswell et al., 1999). The current paper seeks to understand better these surprising contrasts by fully crossing verb bias and referential manipulations within a single experimental design, while using the eye-gaze listening technique. The full pattern is examined in adults (Exp. 1) and children (Exp. 2). Results indicate that adults combine both verb bias and referential information to determine syntactic choice, but children rely exclusively on verb bias. We discuss the implications for current theories of sentence processing as well as prior interpretations of world-situated listening studies.

Introduction

A central interest in the study of human language comprehension has been to understand the role that context plays in resolving linguistic ambiguities. In particular, can readers and listeners take into account extra-sentential information (i.e., information about the current situation or discourse) when making initial decisions about how to structure an incoming utterance? Or, do constraints on the organization of the comprehension system force it to exclude these non-linguistic factors during the early stages of processing?

These questions have played themselves out in the sentence processing literature in a series of studies examining how the referential context of a sentence affects the way readers initially interpret syntactically ambiguous phrases. To illustrate these findings, consider sentence fragment 1. The prepositional phrase (PP) beginning with *with* is temporarily ambiguous because it could be linked to the verb *hit* (verb phrase (VP)-attachment), indicating an Instrument (e.g., *with the stick*); or it could be linked to the definite noun phrase *the thief* (noun phrase (NP)-attachment) indicating a Modifier (e.g., *with the wart*).

1. The store owner hit the thief with the…

Crain and Steedman (1985) hypothesized that ambiguities involving this structure, and others, are initially resolved by taking into account the referential presuppositions of the syntactic analyses, with readers pursuing the analysis that has the fewest presuppositions. In short, if one assumes that a definite NP like *the thief* requires a unique referent, a restrictive modifier analysis of *with the wart* would presuppose the presence of two or more thieves, one of which has a wart. An Instrument analysis makes no such presupposition. Hence, it is predicted that in a context containing two possible referents (two-referent contexts) readers should pursue a modifier (NP-attachment) analysis, but in a one-referent context, or even a null context, readers should erroneously pursue an Instrument (VP-attachment) analysis.

Indeed several studies have found that readers in a two-referent context pursue a modifier analysis for ambiguous phrases of this sort (e.g., Altmann & Steedman, 1988; van Berkum, Brown & Hagoort, 1999, among many). However, several studies have failed to find such affects (e.g., Ferreira & Clifton, 1986; Rayner, Garrod & Perfetti, 1992).

An account of these conflicting findings comes from constraint-satisfaction theories of parsing that propose a role for verb biases in parsing preferences (e.g., MacDonald et al., 1994; Trueswell & Tanenhaus, 1994). These theories predict that referential effects should be weakened or eliminated when lexically specific constraints are strong. Thus, differences in the materials that were used in these prior studies may account for the conflicting findings.

Indeed, studies that have manipulated both referential context and verb bias have found that effects of referential factors disappear when a verb strongly prefers a single analysis (e.g., Britt, 1994; Spivey-Knowlton & Sedivy, 1995). Using materials like "*Susan put/dropped the book on the civil war onto the table"* Britt (1994) found that 2-book vs. 1-book contexts failed to guide parsing preferences when the verb required a PP argument. That is, for verbs like *put*, readers initially pursued VP-attachment regardless of context but for verbs like *dropped*, context guided parsing. These reading studies suggest that context only has an influence in the absence of strong lexical constraints, leading some researchers to contend that verb information plays the privileged role of proposing syntactic structures, which are only compared against context at a later stage (Boland & Cutler, 1996; Britt, 1994).

Recent work on syntactic ambiguity resolution in spoken language comprehension however has raised questions about the relative contributions of context and verb information. Tanenhaus, Spivey and colleagues (Tanenhaus et al., 1995;

Spivey et al., 2001) have found that under the right conditions situation-specific contextual information can completely override strong verb biases that support a competing syntactic alternative. In their studies, participants were given spoken instructions to move objects about on a table while their eye movements were recorded. Target instructions, like 2 below, contained a temporary PP-attachment ambiguity, in which the verb's argument preferences strongly supported an initial VP-attachment analysis of *on the napkin*.

2. Put the apple on the napkin into the box.

Even though the verb *put* requires a destination role, usually a PP, the two-referent context was sufficient to allow listeners to override the strong bias for VP-attachment. In particular, scenes containing two apples, one of which was on a napkin, eliminated early and late looks to an incorrect destination object (e.g., an empty napkin). Similar scenes with one apple resulted in large numbers of early and late looks to the incorrect destination. The authors concluded that when referential cues to attachment are salient, co-present with the linguistic utterance, and hence easy to maintain in memory, they can prevail over even the strongest of verb biases. However, they also noted that such strong effects of context are unexpected under most views of constraint-satisfaction, given the overwhelming structural bias of *put*.

Trueswell, Sekerina, Hill & Logrip (1999) replicated the findings of Tanenhaus et al. (1995) using essentially the same auditory eye-gaze task. In addition, they tested children, ages 4 and 5 , with the same materials. The children pursued the VP-attachment analysis, ignoring referential constraints even for the purpose of reanalysis. In particular, both two-referent and one-referent scenes showed early and late eye movements to the incorrect destination. Moreover, children's actions frequently involved the incorrect destination (e.g., moving an object to the empty napkin). By age eight, children acted like adults in this task, using referential context to guide parsing commitments. The authors concluded that the child parsing system relies heavily on verb-argument preferences to assign structure, and that processing demands prevented any use of the referential facts.[1] This developmental shift is surprising and a bit mysterious. How and why would lexicalist children become referentially-driven adults?

The current paper explores the striking and somewhat puzzling contrasts that we have outlined above. First, we wish to better understand the differences between adult reading and auditory studies, which paradoxically suggest that verb-specific preferences play little or no role in world-situated syntactic ambiguity resolution. Second, we wish to better understand the developmental change that occurs in sentence processing, to discover whether the parsing strategies of children and adults are as incommensurable as they appear.

To achieve these goals, we follow the lead of the prior reading studies that have, in a single experiment, fully crossed verb bias preferences with manipulations of referential context, except we now perform these manipulations in the world-situated eye-gaze task of Tanenhaus and colleagues. Such manipulations should reveal the relative contributions of these factors under all possible combinations. Second, we collected similar observations in five year olds, to observe the full pattern of information combination in this age group.

Experiment 1

In this experiment adults heard instruction containing a PP-attachment ambiguity (e.g., "Feel the frog with the feather") in both two-referent and one-referent contexts. For some subjects the target sentence contained a verb that typically uses an instrument phrase. Others heard instructions containing verbs that rarely use instruments. A third group was given instructions with equi-biased verbs.

The target instructions were globally ambiguous sentences rather than the temporarily ambiguous sentences typically used in comprehension studies. This was done for two reasons. First, we wanted to use the simplest sentences possible (i.e., ones without a second preposition) to avoid confusing children with uncommon sentence types (Exp. 2). Second, we were concerned that the previous listening studies (Tanenhaus et al., 1995; Trueswell et al., 1999) may have failed to find evidence that a VP-analysis was being considered in two-referent contexts because the disambiguating preposition occurred so soon after the introduction of the ambiguous phrase (see MacDonald, 1994, for the effects for post-ambiguity cues on parallel processing).

Because the sentences used in this study are never definitively disambiguated, we should expect continuity between the listeners' online attachment preferences and their ultimate interpretations. If listeners rely entirely on the visual context, then in two referent contexts they should interpret the ambiguous phrase as a modifier, regardless of verb bias. This preference should be reflected in both their eye movements and their actions. In contrast, if listeners simultaneously consider both lexical and contextual information then we would expect to find: 1) an effect of verb bias in both the one- and two-referent contexts and 2) an effect of referential context in some or all of the verb classes.

Methods

Participants Thirty-six students at the University of Pennsylvania volunteered for the experiment (twelve in each of the verb bias conditions). They received extra course credit or were paid for their participation. Twelve of the participants were males and all were native speakers of English.

Procedure The adult subjects were told that they were going to listen to and follow prerecorded instructions and that their responses would serve as a point of comparison for a study of how children follow directions. The subject sat in front of an inclined podium. At the center of the podium was a hole for a camera that focused on the subject's face. In each quadrant of the podium was a shelf where one of the props

[1] The children's parsing pattern might instead be attributable to the use of a syntactically-based parsing strategy (e.g., Minimal Attachment, Frazier & Fodor, 1978). This will be addressed in Experiment 2.

could be placed. At the beginning of each trial one experimenter laid out the props and introduced each one using indefinite noun phrases (e.g., *This bag contains a dog, a fan…*).

A second experimenter then played three prerecorded sound files from a laptop computer connected to external speakers. The first sound file was the same on every trial and simply told the subject to look at a fixation point at the center of the display. The second and third sound files were single sentence commands involving the props. The subject heard the first command, performed that action, and then heard the second command. Subjects signaled that an action was completed by saying "done". A second camera, placed behind the subject, recorded their actions and the locations of the props.

Stimuli On the critical trials, the first command contained an ambiguous Prepositional Phrase attachment, as in (3 a-c) below. The scene that accompanied these sentences contained the following objects: 1) a Target Instrument, a full scale object that could be used to carry out the action (e.g., for 3b a large feather); 2) a Target Animal, a stuffed animal carrying a small replica of the Target Instrument (e.g., a frog holding a little feather); 3) a Distractor Instrument; a second full scale object (e.g., a candle); and 4) A Distractor Animal, a stuffed animal carrying a replica of the Distractor Instrument. For Two Referent Trials the Distractor Animal and Target Animal were of the same kind (e.g., both frogs) for the One Referent Trials the Distractor Animal was of a different kind (e.g., a leopard carrying a candle).

3a. Choose the cow with the stick. (Modifier Bias)
3b. Feel the frog with the feather (Equi Bias)
3c. Tickle the pig with the fan. (Instrument Bias)

Examples of the three different types of verbs were used in this study are given in (3a-c). The verbs were identified in an earlier sentence completion study (see Snedeker, Dardick & Trueswell, 1999). In that experiment, adult subjects were asked to complete sentence fragments that ended with the ambiguously attached preposition (e.g., "Touch the teddy bear with…"). The verbs in the Modifier Bias condition were ones for which modifier completions (e.g., "the big brown eyes") were at least three times as frequent as Instrument completions (e.g., "your toes"). For the Instrument Bias verbs the opposite rule applied. Equi Bias verbs were those that fell somewhere in between.

The Target Instruments for each sentence were also chosen on the basis of a prior norming study (Snedeker et al., 1999). Subjects were shown several objects for each verb and asked to rate them as instruments for performing that action on a seven-point scale. We selected objects with mean ratings between 2 and 5 and balanced the ratings across the three Verb Bias conditions (M = 3.60, 3.65, and 3.64 for Modifier, Equi, and Instrument Biased respectively, $p > .9$).

Two presentation lists were constructed for each Verb Bias condition, so that each of the 8 target trials appeared in only one of the conditions on a given list but appeared in both conditions across lists (resulting in four target trials in each condition per subject). Thus Verb Bias was manipulated between subjects. This was done to minimize the number of trials per participant to ensure that children could complete the same study. Referential Context was manipulated within subjects but blocked. The first half of one list contained all One Referent Contexts while the first half of the other list contained just Two Referent Contexts. The critical trials were interspersed with twenty-four filler trials. The prop sets for the filler trials were similar to those used in the target trials: the attributes of the animals were matched to the large objects and animals of the same kind were used in half of the filler prop sets. Each list was presented in two orders (forward and reverse).

Coding Trained coders watched the videotape of the subject's actions and judged whether they made an Instrument response (performed the target action using the Target Instrument or the miniature instrument). A different coder viewed the videotape of the subject's face and recorded the onset of the target sentence and the onset and location of each fixation that occurred from the beginning of the instruction up until the subject began the action.

Results

Eye Movements For each trial we determined whether the subject looked at the Target Instrument during the time between the onset of the direct-object noun and the beginning of the action.[2] Figure 1 shows the proportion of trials with Instrument Fixations in each of the six conditions.

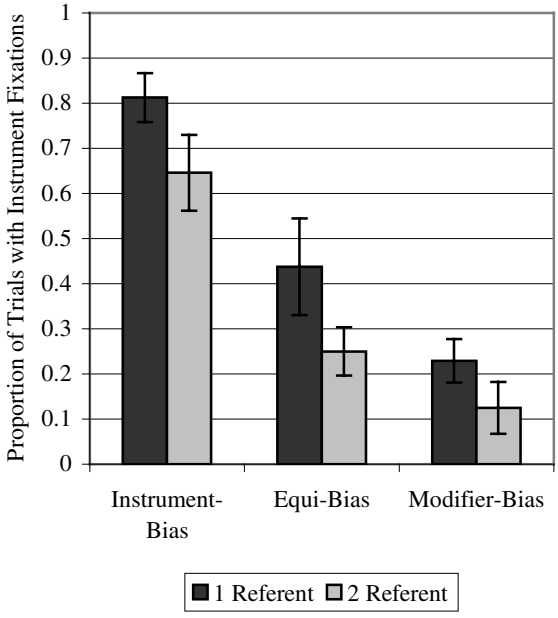

Figure 1: Proportion of Instrument Fixations for Adults (Experiment 1)

[2] This is essentially the same measure used by Tanenhaus et al., 1995. More fine-grained analyses of the pattern of fixations over time, indicate an early use of verb information even in Two Referent contexts.

Subjects' fixations during the ambiguous instructions were strongly affected by the type of verb in the sentence ($F1(2,24) = 27.71$, $p < .001$; $F2(2,18) = 35.01$, $p < .001$). Subjects who heard Instrument Biased verbs looked at the Target Instrument on 73% of the trials, indicating that they were considering the VP-attachment. Those who were given Modifier Biased verbs looked at the Target Instrument on only 18% of the trials.

Referential Context also had a strong and reliable effect on performance ($F1(1,24) = 10.52$, $p < .005$; $F2(1,18) = 11.90$, $p < .005$). When the ambiguous sentence occurred in a Two Referent Context only 34% of the trials included an Instrument Fixation, while in One Referent Contexts 49% of the trials did so. There was no significant interaction between Verb Type and Referential Context ($F1(2,24) > 1$, $p > .5$; $F2(2,18) > 1$, $p > .5$).

Actions The analysis of the Actions closely paralleled the analysis of the Instrument Fixations. Subjects tended to look at the Target Instrument when they were going to use it to perform the action but seldom fixated on it otherwise. The proportion of Instrument responses in each of the six conditions is presented in Figure 2.

Again there was a large and reliable effect of Verb Type ($F1(2,24) = 36.54$, $p < .001$; $F2(2,18) = 69.99$, $p < .001$). When the subjects heard an Instrument Biased verb, they produced Instrument actions 77% of the time. When they heard a Modifier Biased verb, they produced Instrument actions only 7% of the time.

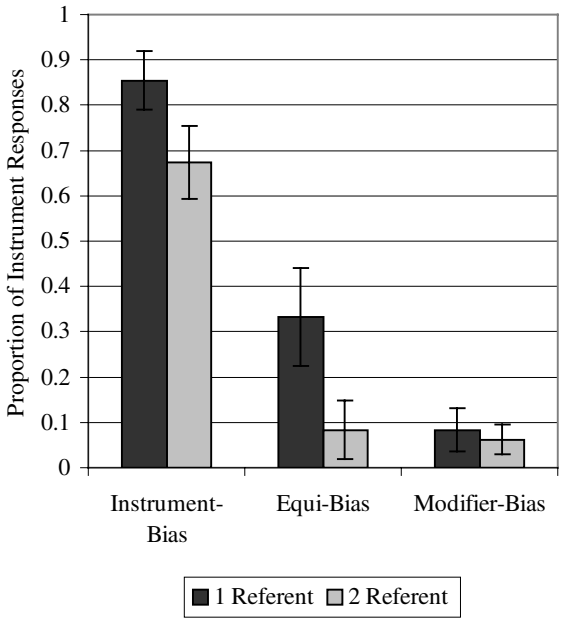

Figure 2: Proportion of Instrument Actions for Adults (Experiment 1).

Referential Context also had a strong effect on performance ($F1(1,24) = 10.81$, $p < .005$; $F2(1,18) = 15.99$, $p < .001$). In One Referent Contexts 42% of the responses involved the Target Instrument, in Two Referent Contexts only 27% did. Although the interaction between Verb Type and Referential Context was not reliable ($F1(2,24) = 2.20$, $p < .2$; $F2(2,18) = 3.28$, $p = .06$), the effect of context appeared to be isolated to the Equi Biased Verbs ($F1(1,8) = 5.33$, $p < .05$; $F2(1,6) = 11.39$, $p < .05$) and Instrument Biased Verbs ($F1(1,8) = 5.59$, $p < .05$; $F2(1,6) = 4.74$, $p = .07$). There was no significant effect of Referential Context for the Modifier Biased Verbs ($F1(1,8) < 1$, $p > .5$; $F2(1,6) = 1.00$, $p > .3$).

Experiment 2

A very similar experiment was conducted with five-year old children. Recall that Trueswell et al (1999) found an overwhelming VP-attachment bias in children of this age. As mentioned above this finding could be the result of the strong attachment bias of *put* or it could be evidence that children use a general structural parsing principle (e.g., minimal attachment). This experiment gives us the opportunity to distinguish between these explanations. A lexically based theory would predict that attachment preferences would be guided by verb information. A minimal attachment explanation would predict that children would show a VP-attachment preference independent of verb type. In addition, manipulating verb type allows us to see whether children's failure to use referential context is limited to strongly biased verbs (ala, Britt, 1994). We reasoned that children might prove to be sensitive to context for the Equi Biased verbs.

Methods

Participants Thirty-six children between 4;6 and 5;10 participated in the study ($M = 5;1$). Parents were contacted from Philadelphia area preschools and a commercial mailing list. Four additional children participated but were not included in the analyses because they refused to cooperate (1) were bilingual (1), or had been identified as developmentally delayed (2). Half of the children were male. Sex and age were balanced across the Verb Bias conditions and Lists.

Procedure and Stimuli The procedure was identical to Experiment 1 with the following exceptions. First, the children were told the names of each object twice. Second, the children were not asked to tell us when they had finished performing each action. Instead the experimenter who introduced the toys waited until the child finished moving the toys or looked at her and then praised the child for her response regardless of his or her action. Third, the number of filler trials was reduced from 24 to 10.

Results

Eye Movements Figure 3 shows the proportion of trials with Instrument Fixations in each of the six conditions. An Instrument Fixation was defined as any fixation to the Target Instrument that occurred between the onset of the direct object noun and the initiation of the action.

Like the adults, the children's fixations were strongly affected by the type of verb in the sentence ($F1(2,24) = 43.49$, $p < .001$; $F2(2,18) = 18.60$, $p < .001$). Subjects who heard Instrument Biased verbs looked to the Target Instrument on

82% of the trials, while those who heard the Modifier Biased verbs looked at the Target Instrument on only 21% of the trials. In contrast, Referential Context had no significant effect on the children's Instrument Fixations ($F1(1,24) < 1$, $p > .5$; $F2(1,18) = 1.41$, $p > .25$). There was no significant interaction between Verb Type and Referential Context ($F1(2,24) > 1$, $p > .5$; $F2(2,18) > 1$, $p > .5$). The children's fixations suggest that in all three Verb Bias Conditions, Referential Context played no role in determining the attachment of the ambiguous phrase.[3]

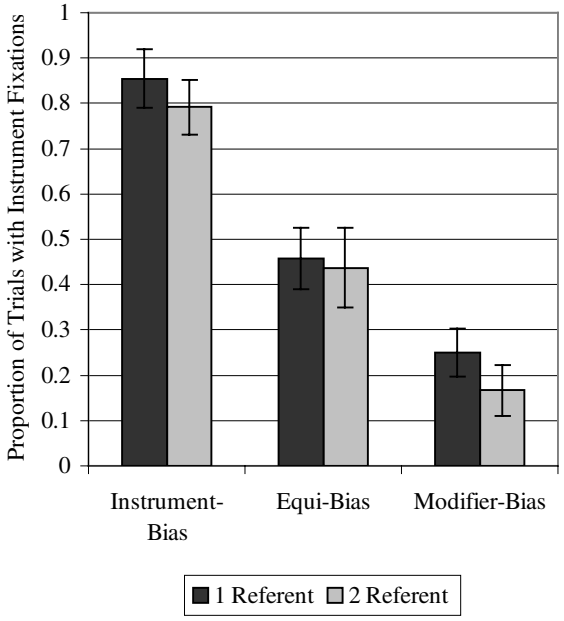

Figure 3: Proportion of Instrument Fixations for Five-Year Olds (Experiment 2)

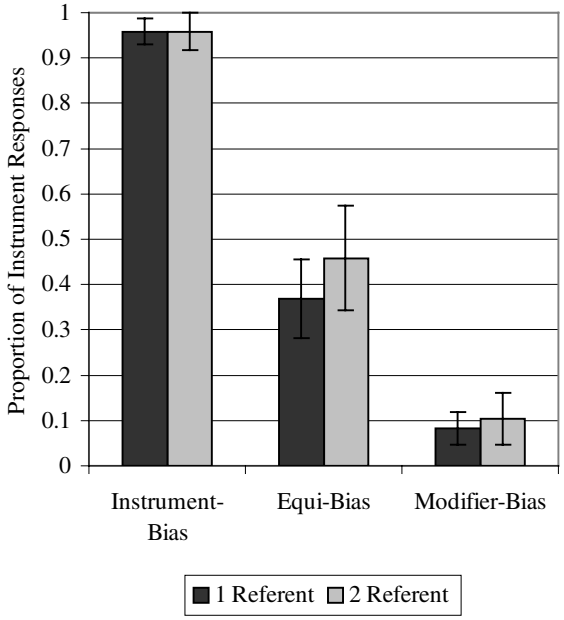
Actions The proportion of Instrument responses in each condition is presented in Figure 4. Here again the offline actions and the online eye movements provide convergent evidence of the children's interpretation of the *with*-phrase.

Verb Bias had a striking effect on the children's actions ($F1(2,24) = 58.21$, $p < .001$; $F2(2,18) = 309.47$, $p < .001$). When the Subjects heard an Instrument Biased verb, they produced Instrument Actions 96% of the time. When they heard a Modifier Biased verb, they produced Instrument actions only 9% of the time. In contrast Referential Context appeared to have no effect on the children's actions ($F1(1,24) = 1.15$, $p > .2$; $F2(1,18) = 1.46$, $p > .2$). In One Referent Contexts instruments were used on 47% of the trials, in Two Referent Contexts they were used on 51% of the trials. There was no significant interaction between Referential Context and Verb Bias ($F1(2,24) < 1$, $p > .5$; $F2(2,18) < 1$, $p > .4$).

A direct comparison of the data from the two experiments revealed a main effect of Age Group ($F1(1,66) = 9.57$, $p < .005$; $F2(1,21) = 17.32$, $p < .001$) and an Age Group by Referential Context interaction ($F1(1,66) = 7.66$, $p < .01$; $F2(1,21) = 9.79$, $p < .005$). Five-year-old children produce



more Instrument responses than adults but this difference is limited to the Two Referent Condition.

Figure 4: Proportion of Instrument Actions for Five-Year Olds (Experiment 2)

In the One Referent Context, there was no effect of Age Group nor an Age Group by Verb Bias interaction (all Fs < 1, all p's > .3), indicating that the children and adults were equally responsive to the combinatorial properties of the verbs. In the Two Referent Contexts, there was both an effect of Age Group ($F1(1,66) = 16.54$, $p < .001$; $F2(1,21) = 26.93$, $p < .001$) and a marginal Age Group by Verb Bias interaction ($F1(2,66) = 3.00$, $p = .06$; $F2(2,21) = 4.90$, $p < .05$). Children gave more Instrument Responses, especially in the Instrument Biased and Equi Biased Conditions.

General Discussion

Two important findings emerge from this work. First, we observe that lexical biases do play an important role in adult parsing preferences in a world-situated task. Even when there is a rich and potentially constraining context that is co-present with the utterance, verb bias and referential cues combine to determine adult listeners' parsing preferences. Second, children show a complete inability to use referential information to inform parsing decisions, and instead reveal detailed sensitivity to verb biases. The implications of the adult and child data are considered separately below.

The data from our adult study indicate a greater continuity between the reading and listening than previous studies would suggest. Like Britt (1994), we observe contributions of both factors in on-line parsing commitments. This pattern is consistent either with a constraint-satisfaction approach that weighs both sources of evidence (e.g., Trueswell & Tanenhaus, 1994) or a 'propose-and-select' model which gives

[3]More detailed analyses of the time course of the eye movements support these claims. Verb Bias has an early effect on fixations but Referential Context does not.

a privileged status to lexical items in computing syntactic alternatives (e.g., Boland & Cutler, 1996).

Why then did the previous *put* studies show no consideration of the VP-attachment analysis? We speculate that two additional sources of information present in those studies may have further reduced consideration of VP-attachment. First, the appearance of a second prepositional phrase (*into the box*) right at the very moment that eye movements should show consideration of VP-attachment may have served as a post-ambiguity cue that squelched consideration of this parse. Second, prosodic cues may have provided evidence during the first PP that a second potential argument was forthcoming. Prosody was held constant across conditions in these studies, but the neutral prosody that the experimenters aimed for may have revealed that the utterance would continue. Indeed, our own studies of prosody, which used a similar task and measure, suggest that differences of this kind can influence parsing as rapidly as lexical information (Snedeker et al, 2001). These additional cues may not have been enough to completely eliminate the VP-attachment analysis in the one referent condition but may have been adequate to eliminate it in the two referent condition where context also supports a modifier analysis.

Implications from the child data are clear. First, children are not 'miniature minimal attachers'. The lack of a general VP-attachment bias, and a clear sensitivity to verb information speaks to this issue. Second, children seem instead to have formed parsing strategies that derive from their syntactic/semantic knowledge of individual verbs, lending further support to constraint-based lexicalist models of parsing.

An issue that remains less understood is why children fail to use referential specificity to guide their parsing commitments (i.e., the Referential Principle). This failure occurs even verbs that have no strong attachment preferences, which might override the effects of context. We strongly suspect that the failure to employ the referential principle is not due to a general lack of knowledge about specificity or the proper use of modification—our own studies show a clear talent in children's utterances for specifying a referent via locative modification (e.g., Hurewitz et al., 2001).

A controversial position, which our current data cannot rule out, is that children show a degree of bottom-up priority for lexically-based cues to syntax, perhaps because of the architectural configuration of the system. If children have memory limitations that prevent them from considering improbable syntactic alternatives, and probability is determined solely by distributional facts gleaned from utterances, then such a pattern might emerge. Only after the processing system gains the ability to maintain parallel parses over numerous words may the contextual facts further drive processing decisions. Indeed, this may also explain the inability of children in the Trueswell et al. study to revise initial commitments. It remains to be seen however, whether other contextual factors (e.g., related to conversational goals of a discourse) might better guide parsing preferences in children.

Synfire Chains and Catastrophic Interference

Jacques P. Sougné and Robert M. French {J.Sougne, rfrench}@ulg.ac.be
Department of Psychology, University of Liège
4000 Liège, Belgium

Abstract

The brain must be capable of achieving extraordinarily precise sub-millisecond timing with imprecise neural hardware. We discuss how this might be possible using synfire chains (Abeles, 1991) and present a synfire chain learning algorithm for a sparsely-distributed network of spiking neurons (Sougné, 1999). Surprisingly, we show that this learning is not subject to catastrophic interference, a problem that plagues many standard connectionist networks. We show that the forgetting of synfire chains in this type of network closely resembles the classic forgetting pattern described by Barnes & Underwood (1959).

Introduction

A professional pitcher can send a baseball hurtling towards a batter at speeds approaching 100 miles an hour. In a mere 2 milliseconds the ball moves three inches, more than the width of a baseball bat. Given the long chain of neurons that must fire sequentially with incredible precision in order for the bat to connect with the ball, how could anyone ever hit a baseball? Consider gymnastics. The landing of a skilled gymnast dismounting from the high bar with a triple somersault is completely determined by the millisecond-precise instant he releases the bar. How is it possible to achieve the extraordinary timing accuracy necessary to consistently hit this beautiful landing correctly?

The problem is to find a way to make imprecise neurons act in an extremely precise manner. Nature has clearly found a way to circumvent the imprecision of individual neuron firings. The solution seems to rely on the presence of large *populations* of interacting neurons. In this paper we will discuss a mechanism for achieving precise timing, *synfire chains* (Abeles, 1991), that has received considerable empirical support. We will consider how the brain might learn these synfire chains and will present a neurobiologically plausibly computer simulation of synfire chain learning (see Sougné, 2001). Most importantly, we will show that the problem of catastrophic interference, a problem that plagues many types of neural networks (see French, 1999, for a review), does not seem to be a problem for synfire chains implemented in a sparsely-distributed network of spiking neurons. We simulate the classic forgetting experiment of Barnes & Underwood (1959) on a network designed to learn synfire chains and show that forgetting of information encoded in these simulated synfire chains very closely resembles the forgetting patterns of humans, as demonstrated by Barnes & Underwood. This leads to the prediction that real neural synfire chains will be forgotten gradually, rather than catastrophically.

Synfire Chains

Empirical data demonstrate the existence of very precise temporal behavior in neuron firings. For example, researchers have recorded spike timing of different cortical cells in monkeys (Abeles, 1991, Prut & al, 1998) and have observed the following stimulus-dependent pattern: when an initial neuron, A, fired, a second neuron, B, would fire 151ms later, followed by a third neuron, C, that would fire 289ms later *with a precision across trials of 1 ms*! Intervals of this duration require dozens of transmission delays from neuron A to neuron *C*. One of the major hypotheses about how this phenomenon could occur involves so-called "synfire chains." Abeles (1991). The other hypothesis is based on an increase in a population rate, which builds excitation in a downstream population, which, in turn, increases its firing rate, etc. (see Shadlen & Newsome, 1994). According to Abeles' hypothesis, since cortical synapses are relatively weak, many inputs to cells must arrive at the same time for them to fire. Consequently, each step in the synfire chain requires a significant pool of neurons whose simultaneous firing raises the potential of the next pool of neurons to allow them to fire. Recent experiments (Prut & al, 1998) indicate that these precise temporal firing sequences correlate more to behavior than to rate modulation and do not seem to be a byproduct of rate modulation. This would seem to buttress the synfire chain hypothesis.

Previous work on synfire chain learning has focused on how they can develop from a chaotic net with an unsupervised Hebbian learning rule (Bienenstock, 1995; Hertz & Prügel-Bennet, 1996). These studies involved an external stimulus which makes a large pool of neurons fire simultaneously at a particular instant. Subsequently, a sequence of successive large pools of simultaneous neuron firings occurs, produced by the random connection weights of the network. A given neuron will only fire if a large enough number of its presynaptic neurons provoke an increase of postsynaptic potential *simultaneously*. Connections are modified by a Hebbian learning rule. After learning, when the previously learned stimulus is presented again, the same chain fire, thereby constituting a synfire chain. These studies show that these chains are stable,

noise tolerant and that one network can store many different chains. Formal analysis showed that there is a relation between network size and the length of learnable synfire chains (Bienenstock, 1995), and that the recall speed should be faster than the training speed of the sequence (Sterratt, 1999).

In previous modeling work (Sougn□, 2001), it has been shown how a synfire chain can develop, thereby linking two pools of neuron firings caused by two sequential external stimuli. After learning, the first external stimulus will reactivate the stored synfire chain. It was also shown that synfire chain learning depends on the size of the network, the presence of long term depression (LTD) and the sparseness of connections. It turns out, surprisingly, that these synfire chains are not subject to catastrophic interference.

Catastrophic Interference

Gradual forgetting is one of the fundamental facts of cognition, which means that plausible models of human cognition must exhibit progressive forgetting of old information as new information is acquired. Only rarely does new learning in natural cognitive systems *completely* (or □catastrophically□) interfere with previously learned information (see, for example, French & Ferrara, 1999). However, it turns out that for a very large class of commonly used connectionist models □ those with a single set of shared (or partially shared) multiplicative weights (and most notably, standard feedforward backpropagation networks) □ learning new information can quite easily completely destroy all traces of previously learned information (McCloskey & Cohen, 1989; Ratcliff, 1990). In fact, the very features that give these connectionist models of memory their much-touted abilities to generalize, to function in the presence of degraded input, etc., are the root cause of catastrophic forgetting (See French, 1999, for a review of research on catastrophic interference).

Catastrophic interference is a radical manifestation of a more general problem for connectionist models of memory □ in fact, for *any* model of memory □, the so-called □stability-plasticity□ problem (Grossberg, 1982). The problem is how to design a system that is simultaneously sensitive to, but not radically disrupted by, new input.

A number of ways have been proposed to avoid the problem of catastrophic interference in connectionist networks. In the connectionist network that is our brain, McClelland, McNaughton & O□Reilly (1995) proposed that the dual memory system consisting of our hippocampus and neocortex evolved, at least in part, in order to overcome the problem of catastrophic interference (see also French, 1997).

In what follows, however, we hope to show that, rather unexpectedly, there is no catastrophic interference in the implemented network of old information from newly learned precise firing sequence. We will begin by considering a now classic experiment on human forgetting by Barnes & Underwood (1959). We will then show that when this experiment is simulated for synfire chains in a sparsely distributed network of spiking neurons, the forgetting curves observed during new learning are largely the same as those observed in Barnes & Underwood.

Forgetting Caused by New Learning

Barnes & Underwood (1959) conducted a series of experiments that measured the extent of retroactive interference in human learning. We will consider two of their experiments in this paper. In the first, subjects first learned a set of paired associates (A-B) consisting of a nonsense syllable and an adjective (e.g. *dax* paired with *regal*, etc.) and then were asked to learn a new set of paired associates (A-C) consisting of the same nonsense syllables associated with a new set of adjectives (e.g. *dax* paired with *dirty*, etc.). (This was called the A-B/A-C paradigm.) The forgetting curve for the A-B associate pairs produced by interference from the learning of the new A-C pairs was relatively gradual (Figure 1a).

In a second experiment, participants first learned a list of paired associates A-B, as above. Then they were asked to learn a series of paired associate where the second word was very semantically close to the original I word in the A-B pairs. They called this paradigm the A-B/A-B′ paradigm. See Figure 1b for the results of this second experiment.

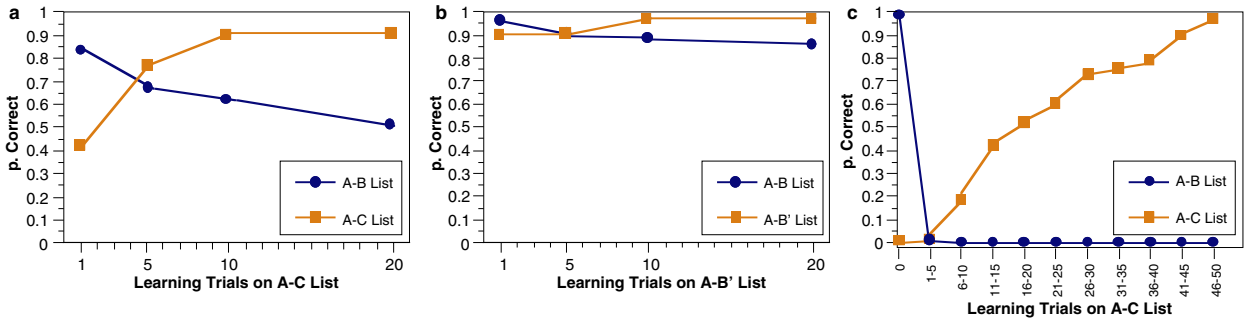

Figure 1, a: Gradual forgetting of previously learned information in Barnes & Underwood's (1959) A-B/A-C. b: Results of the same experiment when the C list closely resembles the original B list (A-B/A-B′ paradigm). c: McCloskey & Cohen's (1989) results showing the network's catastrophic forgetting A-B/A-C paradigm.

When connectionist networks began to become widely used as models of human memory, McCloskey & Cohen (1989) used the Barnes & Underwood A-B/A-C paradigm to test forgetting in these networks. It came as a considerable surprise to most researchers in the field that, at least under certain circumstances, McCloskey & Cohen were able to show that forgetting in a standard backpropagation network was anything but gradual. In one set of experiments, for example, a standard backpropagation network thoroughly learned a set of "one's addition facts" (i.e., the 17 sums 1+1 through 9+1 and 1+2 through 1+9). Then the network learned the 17 "two's addition facts" (i.e., 2+1 through 2+9 and 1+2 through 9+2). Recall performance on the originally learned one's facts plummeted as soon as the network began learning the new two's addition facts. Within 1-5 two's learning trials, the number of correct responses on the one's facts had dropped from 100% to 20%. In five more learning trials, the one's knowledge was at 1%, by 15 trials, no correct answers from the previous one's problems could be produced by the network. The network had "catastrophically" forgotten its one's sums. (See Figure 1c).

Networks of Spiking Neurons

In a network of spiking neurons (Maass & Bishop, 1999), nodes can be in two different states: they can fire (on), or they can be at rest (off). A node fires at a precise moment and transmits activation to other connected nodes with some time course. When a node activation or potential $V_i^{(t)}$ reaches a threshold, it emits a spike. After firing, the potential is reset to some resting value V_r. Inputs increase the node potential, but some part of the node potential is lost at each time step. Spiking neuron models, and in particular, INFERNET, the network discussed here, use a quite realistic post synaptic potential (PSP) function.

INFERNET is not a fully connected network; its structure is organized by clusters of nodes which constitute subnets. Each subnet is fully connected. From each node of a subnet there is a connection to every other node within that subnet. Some subnet nodes have connections to external subnet nodes. This not only reduces the computational demands of the program, but also better corresponds to the actual organization of the brain.

Two variables affect each connection: weight and delay. Each weight corresponds to the synaptic strength between a presynaptic and postsynaptic cell. The weight between a presynaptic node *j* and a postsynaptic node *i* is designated by w_{ij}. Noise is added to this value and the resulting noisy connection is denoted by $\hat{w}_{ij}$. The delay *d* of a connection determines when the effect of the presynaptic node firing will be maximum on the postsynaptic node. There is also a noise factor on the delay. This delay corresponds to the axonal, synaptic and dendritic delays of real neurons.

A signal, whether excitatory or inhibitory, will be affected by a leakage factor. When the signal has reached its maximum, at each following step of 1 ms, the signal will be divided by 2. Delays and leakage factors define the Post Synaptic Potential function $\varepsilon_{ij}(x)$:

$$\varepsilon_{ij}(x) = \frac{1}{2^x} H(x) \qquad (1)$$

$$\text{where: } H(x) = \begin{cases} 1 \text{ if } x \geq 0 \\ 0 \text{ if } x < 0 \end{cases}$$

and x is the difference between the time t, the time of the presynaptic node firing, and the noisy delay on the connection: $x = t - t_j^{(f)} - d$.

When a node potential V_i reaches a threshold θ, it emits a spike. Thereafter, the potential is reset to its resting value. After emitting a spike, a node enters a refractory period. This corresponds to the membrane resistance of real neurons which increases after a spike. In INFERNET, the refractory state of node *i* depends only on the last spike of the node *i*: $t_i^{(f)}$. A value dependent on the refractory state is subtracted from the node state value V_i. This value is denoted by $\eta_i(u)$, where u is the difference between the current time t and the time of the last spike of node *i*: $u = t - t_i^{(f)}$, and where a and b are constants

$$\eta_i(u) = \left[1 + e^{-\left(u^a - b\right)}\right] \vartheta(u)\theta \qquad (2)$$

$$\text{where: } \vartheta(u) = \begin{cases} +\infty, & \text{if } u < 1 \\ 1, & \text{otherwise} \end{cases}$$

Variables affecting the potential of a node have now been defined. Equation (3) express how $V_i^{(t)}$ is calculated at each time step.

$$V_i^{(t)} = \left[\sum_{j \in \Gamma_i} \sum_{t_j^{(f)} \in F_j} \hat{w}_{ij}\, \varepsilon_{ij}(x) \right] - \eta_i(u) \qquad (3)$$

Node *i* fires when its potential $V_i(t)$ reaches the threshold Θ. This potential is affected by connection weights $\hat{w}_{ij}$ coming from each presynaptic node *j*. The set of presynaptic connections to node *i* is given by $\Gamma_i = \{j | j \text{ is presynaptic to } i\}$. F_j is the set of all firing times of presynaptic nodes *j*: $t_j^{(f)}$. Noisy connection weights linking *j* node to *i* node are $\hat{w}_{ij}$.

Learning

Long term potentiation (LTP) and depression (LTD) are the basic mechanisms of long-lasting modifications of synaptic efficiency. Hebb (1949) postulated that when presynaptic activity coincides with postsynaptic activity, the connection between both neurons is strengthened. According to recent experiments, the modification of synaptic efficiency depends on precise timing of afferent signals (neurotransmitters binding to

receptors) and the postsynaptic neuron spike. LTP seems to require that postsynaptic action potential be simultaneous or subsequent to postsynaptic currents (Markram et al., 1997; Zhang et al., 1998). In short, when the signal from the presynaptic neuron firing arrives before, or during the spike of postsynaptic neuron, the synapse is strengthened (LTP). When the signal from the presynaptic neuron arrives after the spike of postsynaptic neuron, the synapse is depressed (LTD).

In the present model, the plasticity of a synapse w_{ij} is a function of three parameters: the firing time of the presynaptic neuron: $t_j^{(f)}$, the transmission delay between this firing and its effect on the postsynaptic neuron (d_{ij}), and the firing time of postsynaptic neuron $t_i^{(f)}$. Learning in INFERNET consists of modifying the weights of connections between nodes w_{ij} by a value $\check{}\, w_{ij}$ (weights are all short integers from -32767 to 32767, which explains why the weight change values run from –1024 to 1024). The Hebbian learning function used is shown in Figure 2. This function follows empirical studies (Markram et al., 1997; Zhang et al., 1998). Similar functions have been used in various simulations by others (Levy & Horn, 1999; Munro & Hernandez, 1999).

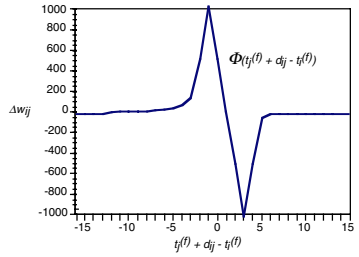

Figure 2: INFERNET's Hebbian learning function: when the signal from the presynaptic neuron arrives before or during the spike of the postsynaptic neuron, the synapse is strengthened (LTP); when the signal arrives after this spike, the synapse is depressed (LTD).

The learning algorithm attempts to reproduce the temporal relation between two successive inputs. This is particularly difficult because two successive inputs can be separated by several tenths of a second and a single connection cannot alone be responsible for such long delays. A long chain of successive pools of node firings is therefore required. This problem is illustrated in Figure 3. The problem is linking nodes *a* and *a´* that fire at time 0 with node *g* firing at time 49. In the learning phase, only nodes *a* and *a´* and *g*, 49 ms later, are externally stimulated. The system has to find a chain of node-firings that makes the target node *g* fire at time 49 when the probe nodes *a* and *a´* fire at time 0. The levels shown in Figure 3 are defined by the pools of firing nodes that separate the nodes firing in response to the input probe and the nodes responding to the target. Note that when simultaneous input from enough afferent neurons does not occur, the node will not fire. There is therefore a phenomenon of selection of only those nodes that have fired due to simultaneous inputs. This requires a large fan out of connections at all levels between the probe nodes and the target nodes.

The refractory state indicates when a particular node fired. We also know the delay of signal propagation from a presynaptic node to a postsynaptic node. From these two values we can, therefore, detect which synapse can contribute to a node firing at the right moment. In Figure 3, one can detect which nodes contribute to the firing of node *g* i.e., *e* and *f*, whose signals arrive at *g* virtually simultaneously. If *f* fired 9 ms before *g*, and *e* fired 11 ms. before *g*, their respective connections will be strengthened. Similarly, one can also determine which nodes contributed to the firing of *f* (i.e., *d* and *d´*), if *d* fired 7 ms before *f*, their connection will be strengthened (to a somewhat lesser extent because we are farther down the chain). This chaining rule acts as if a signal was going backwards from the target node to the probe nodes, losing a bit of its strength at each step. In order to reduce combinatorial explosion, only the *n* best contributing nodes are selected for the next level in this chaining rule. Connections between nodes will be modified according to equation (4):

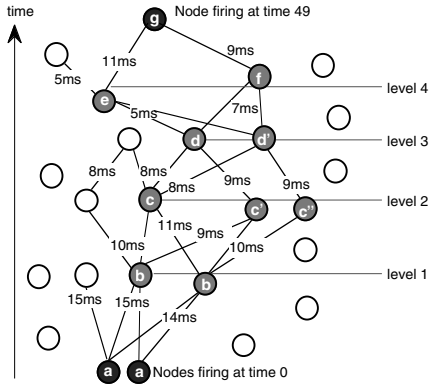

Figure 3: The chaining rule problem: Learning a path of neural firings that makes node *g* fire exactly 49 ms after nodes *a* and *a´*.

$$\Delta w_{ij} = \Phi\left(t_j^{(f)} + d_{ij} - t_i^{(f)}\right) - \lambda \qquad (4)$$

$$where \quad \lambda = \left\{ \begin{array}{c} -level \ if \ \Phi\left(t_j^{(f)} + d_{ij} - t_i^{(f)}\right) is \ negative \\ level \ otherwise \end{array} \right\}$$

This rule is based on the history of node firing and has neurobiological justification. For example, Markram, et al. (1998) show that the state of a synapse is indicative of its past activity. Moreover, empirical studies (Engert & Bonhoeffer, 1997) show that LTP also propagates from the originating synapse to neighboring synapses, lending further plausibility to the present chaining rule. In addition, each connection has a small decay factor (of –10 by epoch).

The learning algorithm is triggered only when external input is presented. We can imagine that

external input provides a strong signal that triggers the chaining rule. Note that Hebbian learning does not seem to be dependent on this kind of signal and affects probably all synapses downstream from an action potential. Here, it is the target input that is the signal to launch the chaining rule. The objective is to link the probe nodes firing to the target nodes firing and to avoid reinforcing other irrelevant firings.

Simulation 1

In general, motor forgetting occurs more slowly than cognitive forgetting (Globerson, Nahumi, Ellis, 1998). By testing the present synfire chain algorithm for cognitive forgetting,, we reasoned that if catastrophic interference disappeared for this paradigm, the same algorithm would eliminate it for precise motor learning.

The following simulation is based on the original AB-AC paradigm used in Barnes & Underwood (1959). As in the original experiment, we created a list of non-words (A) and two associated lists of words (B and C). Each B and C word was coded over 6 nodes (out of 800 possible nodes) and each non-word A was coded over 16 nodes. Although the selection of nodes was made randomly, we ensured that there was very little overlap among the items in the A-list and among the items in the B-list. All lists consisted of eight items.

Each temporal firing sequence consisted of 16 nodes firing at time 0, corresponding to a presentation of a non-word from list A in the Barnes & Underwood experiments. Six nodes fired at time 60, triggered by the associated word from the B wordlist.

Once the network had learned to associate the items in list A with those in list B, the network then had to associate the node-firings associated with the items in the A-list with those of the C-list. As in Barnes & Underwood, we kept the similarity very low between the corresponding words in the B and C lists. This meant that very few nodes overlapped in the encoding of the corresponding words from the two lists. As the network learned the new set of associations, we tracked how fast new learning was taking place (i.e., how close the output of the network was to the desired word in List C) and, at the same, time, how far the output was from the originally learned word in List B.

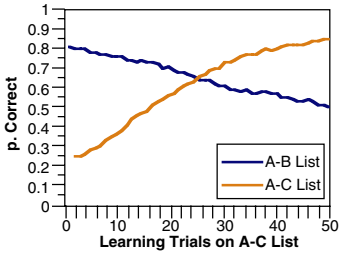

Figure 4: INFERNET performing AB-AC learning.

The results, based on 20 runs of the program, are shown in Figure 4. The Y axis indicates the proportion of correct node firings, i.e. the number of B and C node-firings within a –2ms window divided by the total number of nodes in B and C words. It is clear that, unlike the catastrophic interference observed in standard backpropagation networks (see Figure 1c), this sparsely-distributed network of spiking neurons can learn the second set of associations without catastrophically forgetting the previously learned list. These results are strikingly similar to those of Barnes & Underwood (Figure 1a).

Simulation 2

All of the model parameters for this simulation were identical to those of the preceding simulation, with the exception that wordlist C was replaced by a wordlist B′. All words in the B′ List were very similar to the corresponding words in the B list. Of the 6 nodes used by the representation of each B′ word, 4 of them were shared by the corresponding word in the B List.

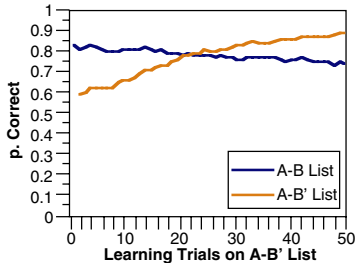

Figure 5: INFERNET performing AB-AB′ learning.

The results, based on 20 runs of the program, are shown in Figure 5. Again, this simulation closely reproduced the experimental results of Barnes & Underwood's second experiment (see Figure 1b). The results indicate the second associations are learned more quickly and the first associations are almost not forgotten, as for humans.

Conclusions

Human learning involves relating two signals separated in time, or linking a signal, an action and a subsequent effect. On occasion, the precise timing of these signals is of critical importance. A millisecond inaccuracy can mean that the spear thrown by the hunter will miss its target, that the gymnast will miss her landing, etc. Events may often be separated in time, but nonetheless, humans can link them, if necessary, with extraordinary accuracy, thereby allowing them to correctly perform a particular action at precisely the right moment. We have explored one major hypotheses concerning how the brain might achieve this namely, synfire chains.

Clearly people are not born with encodings of this timing information. Hunters *learn* to throw projectiles accurately, gymnasts *learn* to land correctly. Precise temporal firing sequences must be learnable and permit the linking of two events with extreme precision.

A learning algorithm based on a Hebbian learning rule has been presented in this paper. We have briefly explored the ability of a sparsely-distributed network of spiking neurons, INFERNET, to learn synfire chains and, most importantly, we studied forgetting in this network of these chains. Unlike many current connectionist networks, we found that the forgetting of synfire chains is not subject to catastrophic interference, but rather, closely resembles the gradual forgetting curves exhibited in Barnes & Underwood's (1959) paper on human forgetting. This is due to the sparseness of the number of paths (compared to the very large number of possible paths) from probe to target created by the learning algorithm. We hope to have demonstrated the importance of synfire chains for human cognition and to have shown an implementation in a network of spiking neurons. Finally, and crucially, our simulations indicate that synfire chains, so necessary for precision actions in the real world, may not be affected by catastrophic forgetting.

Abstract

It will be shown that whilst a popular connectionist model, the simple recurrent network (SRN) as introduced by Elman (1990), is a very good first approximation in modeling human sequence learning, it is not, in itself, sufficient. At CogSci 2000, all five papers referring to the SRN tried to provide evidence that it is an adequate model of human performance. We will take on a more moderate position. The results of a human experiment followed by a structured interview reveal that human sequence learning is not always the kind of statistical process captured by the SRN alone.

Introduction

In cognitive science, there is an ongoing debate whether human learning should be modeled by the explicit use of rules or by figuring out statistical regularities. In addition, it has been emphasized that human learning consists of both rule and associatively-based processes (e.g. Jones & McLaren, 1999; McLaren et al. 1994).

Perhaps the most popular connectionist model used to study sequence learning is the previously mentioned SRN developed by Elman, which has become ubiquitous in the literature (Cleeremans, 1993; Elman, 1990; Elman et al. 1996; McLeod et al. 1998). A diagram of the SRN is shown in Figure 1.

The SRN is capable of learning any sequence, even sentences with hierarchical structure (McLeod et al. 1998). However, as will be seen later, this is not to be confused with learning to master any kind of sequential problem. Among other connectionist models, the SRN does not implement rules and therefore learns sequences in an associative way. Therefore, the results of the SRN should resemble human learning if humans also learn sequences associatively. In contrast, the results of the SRN might differ from human performance either if human sequence learning incorporates something more than an associative process, or if the associative mechanisms used in human sequence learning are not those employed in the SRN.

In the SRN, the network receives input from the input units and is made to predict the next step of the sequence at the output level. The SRN has connections from the hidden units to the so-called context units, which are exact copies of the hidden units one time step ago. All other connections in the network are adjustable. The context units provide the SRN with a dynamic memory, i.e. depending on the sequence position, the very same inputs can result in different predictions of the network. Each time step, the network is trained by adjusting the weights on the connections according to the backpropagation learning algorithm (first introduced by Werbos, Le Cun, Amari, Parker and now most widely accessible in Rumelhart et al. 1986). The SRN with a supervised learning algorithm was chosen for this paper, because it was considered appropriate in modeling the human experiment (as will be seen later, the subjects in the human experiment received a signal if they had made an error and no signal if they had made the correct response).

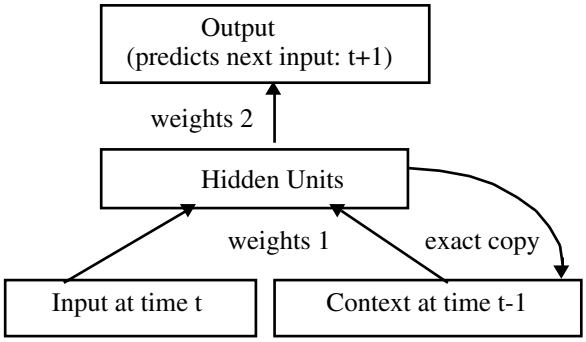

Figure 1: The simple recurrent network (SRN).

The serial reaction time task (Nissen & Bullemer, 1987) is a particularly successful paradigm used to test human sequence learning. In this type of task, the subject sits in front of a screen on which one of a number of lights flashes on at different locations. The subject is asked to press the key below the flashing light as fast as possible and the reaction time of each response is measured. While the subjects are not informed about any sequence in the stimulus material, the lights flash in a particular order. Therefore, there is a contingency in the way that the preceding stimuli

predict the current one. If subjects speed up their reaction times on the sequences but are not able to provide verbal information concerning the contingencies, then their learning could be considered associative. If subjects can verbalize the contingencies, their behavior can be seen as cognitive and/or associative, depending on the degree to which subjects are able to state the underlying rules governing the sequences. A particular advantage of the task is that the stimuli of the sequence are presented one after another and as a result, the reaction times to each separate stimulus can be measured. Consequently, it can be compared to each separate output activation of the SRN used to model the task. Another advantage is that there are lights flashing on at different screen locations rather than symbols. Symbols would have a semantic meaning for subjects, which would have the consequence that subjects would probably not start the experiment without preconceptions.

Simulation studies with the SRN

The SRN has been assumed to be able to learn any kind of sequence learning task with the exception of the catastrophic interference problem, i.e. when the SRN learns a set of sequences and is then trained on a new set of sequences similar to the old ones and tested again on the old sequences, its performance is very poor. The reason for this problem, however, seems to lie in the fact that the SRN uses backpropagation as the learning algorithm which does not have an adaptive learning rate. However, McLaren (1993) has shown that an adaptively parametrised error correcting system (APECS) can avoid catastophic interference. As a result, there seems to be some chance that all sequential problems could possibly be modeled successfully with neural networks employing the SRN architecture. Although there is published work about weaknesses of the SRN (Servan-Schreiber et al., 1991; Cleeremans, 1993; Maskara & Noetzel, 1993; Timmermans & Cleeremans, 2000), those and other reported failures did not turn out to be due to the SRN architecture *per se* (Spiegel, Jones & McLaren, 2001; Spiegel & McLaren, 2001). Our new papers may lead some connectionists to argue that the SRN models human performance entirely. In order to prevent this seemingly wrong conclusion from happening, we present a sequential problem that can be solved by humans, but not by the SRN. Furthermore, a detailed network analysis about how the SRN tackles the task will be necessary to prove that this problem cannot be completely solved by the SRN. We start with an analysis of SRN performance on the task that we eventually settled on.

Procedure

The SRN was implemented using the C programming language. The task can be represented by the following grammar: (ab(c*1 ^ 3)ba) ^ (abb(c*1 ^ 3)bba). Here, the symbol ^ stands for the word *or*. For connectionist models, those letters have no semantic meaning. Expressed in words, those grammars mean: The sequence starts with the letter A. After that, the letter B follows either once or twice. Then, the letter C follows either once or three times, before the letter B appears the same number of times it had appeared earlier (once or twice) and finally, the sequence ends with the letter A. The input and output layers have a local representation for each symbol in the sequence, i.e. a = (1,0,0), b = (0,1,0) and c = (0,0,1). The network is trained with a learning rate of 0.1 and 300 hidden units.

Results

As it turned out, the network could learn this problem, a not inconsiderable achievement as there had been claims that it could not (for an overview, see Spiegel et al. 2001), but never generalized to both novel sequences with the same structure, but two c's, i.e. (abccb**a**) ^ (abbccb**b**a). It failed to predict an a after the final b in the first sequence type and failed to predict the second b after the second last b in the second sequence type (the bold letters). An entire simulation experiment with eight networks having been trained for at least half a million trials never resulted in the case where the SRN generalized to both novel sequences, even when the lowest stringent criterion was set, i.e. best match.

Modifying network parameters After this simulation experiment, 300 other SRNs were run with different numbers of hidden units (ranging from 5 to 500) on the same problem, but none of them reached sufficient generalization performance. Moreover, with less than 6 and more than 450 hidden units, the network completely lost the ability to learn the task.

Network analysis A separate network analysis focused on the ability to generalize to varying numbers of c fillers in the range between two and eleven. An interesting discovery was made: the SRN would never stabilize in generalizing to any even number of c fillers in both sequence types of the grammar displayed earlier, but it would generalize after an odd number of c fillers. In essence, the network appeared to exploit the fact that it was only trained on an odd number of c filler items by adopting cyclical patterns of activity tuned to the 1 and 3 c cases. These would also apply to other odd numbers of c items (e.g. 101), but never to even numbers of the c fillers. Moreover, whilst the performance on the trained patterns would remain stable, the ability to generalize to novel patterns would fluctuate over training trials.

The possibility of generalization during transitions between these stable states remains, however, so further tests were carried out. To assess this possibility, a very sensitive network session had to be run, with different

numbers of hidden units and a test of generalization performance after each single trial. As a consequence, an SRN was implemented that would do 100,000 generalization tests during 100,000 training trials. Finally, two cases were found: after trial 39956 a 400 hidden units SRN fulfilled the best match criterion on generalizing to both two c sequences while also mastering the sequences it had been trained on. One trial later, it had lost its ability to generalize. On trial 39967 it regained this ability for one single trial, but lost it immediately from the next trial onwards and never regained it. Hence, we thought this was enough evidence to state that the SRN does not stabilize in generalizing to the sequences with two c's. Based on those findings, an experiment with human subjects was carried out to explore whether they were able to generalize to the two c case.

Human Experiment

The experiment comprised a three choice serial reaction time task. The stimulus was a circle flashing in different locations on a computer screen. The circles were arranged as a triangle, i.e. lower left corner, upper middle corner, lower right corner. The subjects were asked to press the key that corresponded to the stimulus location as fast and as accurately as possible. They were divided into an Experimental and a Control group. In both groups the order of presentation during training blocks as well as during testing followed a sequence. The sequences for the Experimental group were the same as those that the SRN had been trained on. They shall be called *consistent* sequences from now on:

(ab (c*1 ^ 3) b**a**) ^ (abb (c*1 ^ 3) b**b**a)

In the human experiment, all three letters corresponded to a particular circle, i.e. circle flashes were what the subjects saw, not letters. In the first sequence type, subjects should learn to predict the final a (bold letter) once the c had stopped and the letter b had appeared. In the second sequence type, subjects should be able to predict the second b (bold letter) once the letter c had stopped and the first b had appeared. The Control group received the same sequences as the Experimental group in 50 percent of the cases, and the following ones in the other 50 percent of the cases. They shall be called *inconsistent* sequences from now on:

(ab (c*1 ^ 3) b**b**) ^ (abb (c*1 ^ 3) b**a**a)

Because the final letter in the first sequence type and the letter before the final letter in the second sequence type had an alternative letter in 50 percent of the cases, the Control group should never be able to predict the location of the last circle in the single b case and the location of the circle before the last circle in the double b case. There were four training sessions of equal length for both Experimental and Control groups. Following that, there were two testing sessions of equal length in which both groups received 50 percent of the following consistent sequences:

(ab (c*1 ^ 2 ^ 3) b**a**) ^ (abb (c*1 ^ 2 ^ 3) b**b**a)

In addition, both groups received 50 percent of the following inconsistent sequences:

(ab (c*1 ^ 2 ^ 3) b**b**) ^ (abb (c*1 ^ 2 ^ 3) b**a**a)

The difference between the training trials and the testing trials lies in the fact that both groups receive the same sequences during testing and both groups receive the two c case which is used to test their performance to generalize to novel sequences.

The experiment aimed to investigate the following hypotheses: subjects in the Experimental group should perform faster on the critical positions (=bold letters) in the consistent sequences than in the inconsistent sequences and they should generalize to the novel sequences, because they were constructed according to the same underlying grammar. On the other hand, subjects in the Control group should show no real difference between the reaction times on consistent and inconsistent sequences. The same holds for accuracy. Subjects in the Experimental group should be more accurate on the critical positions of the consistent sequences, whereas subjects in the Control group should show more or less equal accuracy on consistent and inconsistent sequences. As a result, the (RTinconsistent-RTconsistent) differences as well as the (Errors_inconsistent-Errors_consistent) differences should be significantly higher in the Experimental group than in the Control group.

Method

Subjects The experiment comprised 30 subjects aged 18 to 40 years who were either graduate or undergraduate students at the University of Cambridge. The subjects were randomly assigned to each condition.

Apparatus The experiment was run on a Macintosh Quadra 630 computer. The subjects were seated approximately 80cm from the screen, which was roughly at eye level. The diagonal of the screen was 30cm in size. The light in the room was dimmed to a constant level.

Procedure After detailed instructions, the circles appeared on the screen. The display consisted of white outlines of three triangularly placed circles in the middle of a black background. They were two centimeters in diameter and the centers of the circles on the bottom of the triangle were approximately 5.5cm

apart. The center of the upper circle was approximately 4cm apart from the centers of the two other circles. Each trial, one of the outlines would flash in such a way that it would become a solid white circle that remained on the screen until the subject responded or had not pressed a key within 4.25 seconds of the stimulus onset. After each response or after 4.25 seconds the solid circle was immediately cleared leaving only the outlines remaining. The response keys were arranged in the following way: the lower left circle corresponded to the 'v' key, the upper middle circle to the 'b' key and the lower right circle to the 'n' key. Subjects were requested to use their index-, middle-, and right finger of their preferred hand. If subjects took longer than 4.25 seconds, pressed the wrong key or a different key than the three designated, an acoustic signal indicated that the subject had made an error. Reaction time was measured in milliseconds from the stimulus onset until the key press, and the interval between a response and the onset of the next stimulus was 180ms. When one sequence finished, the screen was cleared (to the black background) and then the three outlines reappeared for 600ms until the first circle filled with white.

Block characteristics Both Experimental and Control group started with one block of 9 random circle locations in order to assess the subjects' baseline reaction time and accuracy. Then both Experimental group and Control group received 78 sequences in each of the six following blocks. Out of those six blocks, the first four blocks comprised the training trials and the last two blocks comprised the testing trials. Out of the 78 sequences in both training and testing phase, the first six of each block were not taken into the final analysis because concentration at the beginning of each block may be influenced by the preceding pause. Of the remaining 72 sequences in each block of the training phase, the Experimental group randomly received eighteen of all possible combinations of the consistent sequences (see above). The Control group randomly received nine of all possible combinations of both consistent and inconsistent sequences.

Of the 72 sequences in the testing phase, both Experimental and Control group received six of all possible combinations of the earlier mentioned consistent and inconsistent sequences per block, i.e. 12 as a whole (in order to determine the average reaction time, only the reaction times where the subjects made a correct response were counted):

The difference between these trials and those of the Control group in the training phase was that it tested whether the subjects were able to generalize to novel sequences, i.e. the ones containing the letter c twice.

Interview A structured questionnaire immediately followed the last block of the experiment. In this questionnaire, subjects were asked whether the circles had flashed on in a particular sequential order, and if so, what they can tell about the sequences.

Results

It was necessary to assess both average reaction time and number of error differences because a significant result for one of the measures does not necessarily mean much, as there could be a significant opposite trend in the other. If this was the case, the significant result in the expected direction would not reveal evidence for learning. This effect is called speed-accuracy tradeoff.

Reaction times The results of the average reaction times are considered first, i.e. the dependent variable was: inconsistent minus consistent average reaction time. An analysis of variance was carried out with the between subjects factor *group* (Experimental vs. Control group) and the within subjects factors *type* (single vs. double b case) and *number of c's* (one vs. two vs. three). Before this analysis was carried out, we tested whether the underlying assumptions for an analysis of variance with repeated measurements were met. Cochran's C test to check the equality of variances as well as the Mauchly test of sphericity (Norusis, 1994) revealed that the assumptions were entirely fulfilled. The analysis of variance revealed a significant main effect for the between subjects factor *group*, $F(1,28)=9.35$, $p<.01$, $f=.57$. The Experimental group ($M_e=34.71$, $\pm SE_e=7.58$) reveals a significantly higher reaction time difference when compared with the Control group ($M_c=1.49$, $\pm SE_c=7.79$). The size of this effect is expressed in terms of the index f (Cohen, 1988). Because f-values greater than .4 are considered large, this effect can be regarded as very strong. Cohen's f can be set in relation to more traditional effect size measures, such as the amount of variance explained by this effect ($\eta^2=.25$).

Thereafter, it was crucial to know whether subjects show a reliable effect on the one c case and the three c case and in particular whether they are able to generalize to the novel sequences with two Cs. This last will form the basis for the critical comparison with the SRN. In this experiment, the two c case showed a result on the borderline between significant and marginally significant, $F(1,28)=2.82$, $p=.05$, ($M_{e\_2c}=21.65$, $\pm SE_{e\_2c}=9.22$ vs. $M_{c\_2c}=-4.0$, $\pm SE_{c\_2c}=12.14$), providing some evidence that people do generalize to novel sequences. It is interesting to note that the sequences the subjects had been trained on obviously show larger effects, which is partly reflected in the strong main effect of the ANOVA. In order to provide a better comparison between trained and novel sequences, here are the results for the sequences the subjects were trained on:

The one c case revealed a significant effect in favor of the Experimental Group, $F(1,28)=5.29$, $p=.01$,

(M_{e_1c}=47.23, ±SE_{e_1c}=15.77 vs. M_{c_1c}=-4.75, ±SE_{c_1c}=16.24). Similarly, the three c case showed a significant effect in the same direction $F(1,28)=4.62$, $p=.02$, (M_{e_3c}=35.26, ±SE_{e_3c}=7.84 vs. M_{c_3c}=13.22, ±SE_{c_3c}=6.61). The full results are displayed in Figure 2.

Number of Errors So far, however, it could still be that the effects on the reaction times are due to a speed-accuracy tradeoff. Therefore, it was necessary to focus on the second performance measurement, i.e. the *number of errors* subjects made with consistent and inconsistent sequences. The same kind of ANOVA with the dependent variable *error differences* revealed no significant difference between Experimental and Control group, $F(1,28)=2.28$, ns., nor did any of the individual comparisons for all three numbers of c even show a descriptive trend in the opposite direction, which entirely excludes the possibility of a speed-accuracy tradeoff.

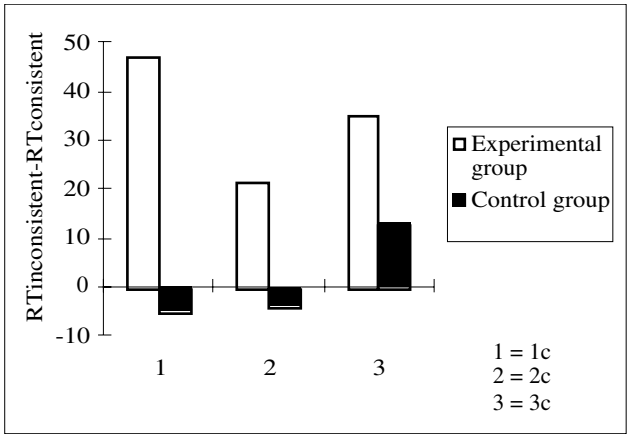

Figure 2: Average reaction time differences in humans.

Computational Model The Experimental SRN was trained with the same sequences as the Experimental group until it first reached the earlier defined performance criteria. The Control SRN was trained for 40,000 trials on the same sequences as the Control group. Both SRN's were trained with a learning rate of .1 and had 300 hidden units. The results of the network performance are displayed in Figure 3.

As can be seen in terms of the output activation differences (activation corresponding to the critical target value of the consistent sequences minus activation corresponding to the critical target value of the inconsistent sequences), the Experimental SRN has learned the task, but is not able to generalize to the two c case in any way. The Control SRN more or less resembles the human Control group in a way that it is not able to predict the next position, because it equally favors consistent and inconsistent sequences.

Structured Interview In order to get a better idea of how people solved this task, it was necessary to find out to what extent subjects verbalize the sequences. Here it was crucial to find out how many people in the Experimental group verbalized the rule that the number of b's after the c's was dependent on the number of b's before the c's. Only fourteen out of fifteen subjects in the Experimental group were able to take part in the interview. All fifteen subjects in the Control group answered the questions.

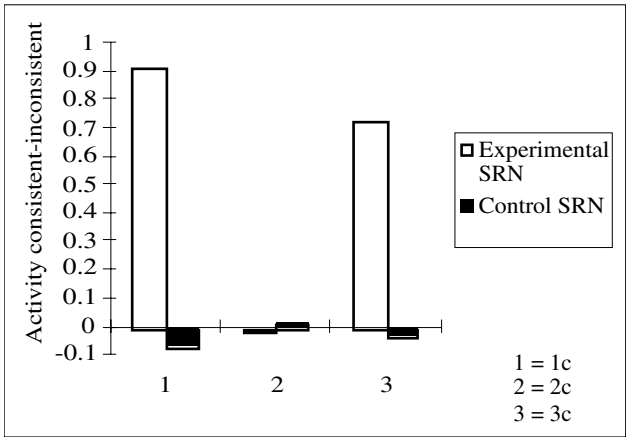

Figure 3: Activity differences between consistent and inconsistent output units on the critical letters.

Almost all of the subjects in the Experimental as well as the Control group verbalized that the circles flashed in a sequential order, while none of the subjects in either group was able to verbalize how many times a circle flash corresponding to the grammatical letter C had appeared.

None of the subjects in the Control group verbalized any dependency between the b flashes before and after the c flashes, which was expected, because they were independent of each other in the Control group. In the Experimental group, two out of fourteen subjects verbalized this dependency. A close look at the reaction time differences of those two subjects revealed that their reaction time differences were more pronounced in their effect (1c=107.32, 2c=51.37, 3c=82.55) than the average RT-differences of the remaining twelve subjects in the Experimental group (1c=32.56, 2c=16.72, 3c=25.12) and none of the error differences point in the wrong direction, which excludes the possibility of a speed-accuracy tradeoff. Interestingly, when performing the same ANOVA with the exception of the two subjects who verbalized the rule, there is still evidence of learning the trained sequences: $F(1,25)=4.71$, $p<.05$, $f=.43$, $\eta^2=.16$, but no longer evidence for generalization to the novel sequences, of $F(1,25)=1.54$, ns., (M_{e_2c}=16.71, ±SE_{e_2c}=10.91 vs. M_{c_2c}=-4.0, ±SE_{c_2c}=12.14). In other words: Successful learning but generalization failure occurs when the subjects who represented the rule are left out of the analysis, which corresponds to the results of the

associative SRN. As a result, one tentative conclusion is possible here: the human ability to represent the rule (which is absent in the SRN) may have led to successful generalization in humans. There is, of course, another equally valid interpretation of this finding, however, and that is that those subjects who had learned the sequences (associatively) best were the ones who subsequently became aware of them and were able to induce the rules governing them.

Discussion

This experiment provides evidence that humans and the SRN may differ when dealing with a particular sequential problem. Whilst the SRN is capable of learning all of the sequences presented in the training set, it cannot generalize to particular sequences that were constructed according to the same underlying grammar. Furthermore, a logical analysis of the inner representations of the network revealed the reason why it does not learn the problem: the way the network represents the temporal order of the sequences in its context layer makes it impossible to solve the complete generalization problem.

There is some evidence that humans approach the problem in a different way. The structured interview suggested that some humans can induce the underlying rules of the sequences and the results of those subjects in the experiment provide evidence that they may make explicit use of them when generalizing to novel sequences.

However, it would be hard, and possibly premature to uncouple the rule-based and the associative component of humans who have participated in this task. Those two subjects who represented the task in a rule-based way have probably started with associative learning and later somehow induced the rule. The suggestion here is that there is a real possibility that there are associative mechanisms available to humans which interact with cognitive processing to determine task performance. On the basis of our results, we consider the purely associative SRN a very powerful model that may be able to learn many kinds of sequence, but does *not* simulate the human ability to generalize in this experiment.

Abstract

Current models of decision making under risk assume access to the absolute magnitudes of gamble attributes. The two experiments presented here provide evidence that decisions under risk are based, in addition, on the context of the decision. In Experiment 1 the set of options offered as certainty equivalents was shown to determine the value of simple gambles of the form "p chance of £x". Experiment 2 employed a novel procedure where the payment structure was such that it was optimal for participants to provide truthful certainty equivalents. Again, the context provided by the set of certainty equivalents influenced the choice of certainty equivalent.

Many existing theories of decision making under risk (e.g., Kahneman & Tversky, 1979; Quiggin, 1982; Tversky & Kahneman, 1992; von Neumann & Morgenstern, 1947) predict that participants use the absolute magnitudes of value and probability in making risky decisions, or that some monotonic transform of these attributes is used. For example, in expected utility theory (von Neumann & Morgenstern, 1947), the utility of an outcome is a negatively accelerated function of value, and outcomes which maximize the expected utility are preferred. The aim of the experiments described here was to investigate to what extent contextual factors also influence decision under risk.

Mellers, Ordóñez and Birnbaum (1992) measured the attractiveness ratings and buying prices of simple binary gambles presented in two different contexts. In one context, the distribution of expected values of accompanying gambles was positively skewed, and in the other context, the expected values were negatively skewed. Attractiveness ratings were influenced by context. However, for simple gambles of the form "p chance of £x" context had a minimal effect on buying price. With more complicated gambles of the form "p chance of £x otherwise £y", the effect was slightly larger. The effect of context on attractiveness and the lack of an effect of context on buying price is consistent with a similar demonstration by Janiszewski and Lichtenstein (1999), and consistent with a review of previous research by Poulton (1982).

However, context does affect choice of certainty equivalents (hereafter, CEs) in other conditions. (CEs are the amount of money that can be obtained for certain, participants feel is equivalent to a given gamble). Birnbaum (1992) demonstrated that skewing the distribution of CEs offered for simple gambles, whilst holding the range constant, influenced the selection of a CE. When the CE options were positively skewed (i.e., more small values) gambles were over-valued compared to the negatively skewed context, consistent with range-frequency theory (Parducci, 1965; 1974).

The aim of Experiment 1 was to demonstrate that the options offered as potential CEs influence estimates of a gamble's CE. Following a similar logic to a loudness judgment experiment by Garner (1954), participants were given a set of potential CEs for each gamble, and asked to choose the option closest to their estimate of the CE for each gamble. For each gamble, CE options were either all lower in value than the free choice CE (given by another group of participants) or all higher. If participants were not influenced by context, then their choices of CE should be highly skewed towards the mean free choice CE. If participants' responses are solely determined by context, then the distribution of responses across options should be the same for both the low and high value range of CEs. Experiment 2 introduces a new procedure to investigate these context effects in which it is optimal for participants to provide truthful CEs.

Experiment 1

The curve in Figure 1 represents a hypothetical normal distribution of CEs given under free choice conditions. If participants are not affected by the context provided by the range of CEs offered in the restricted choice conditions, it is possible to predict their distribution of responses. For an option at the lower end of the range, the probability of selecting that option is the integral of the free choice function between -• and a point half way between the lowest two options. Similarly for an option at the higher end of the range, the probability is the integral between a point half way between the highest two options and +• . For an option of intermediate value, the probability is the integral between the bound half way between the intermediate option and the next lowest option, and bound half way between that intermediate option and the next highest option. In other words, it is assumed

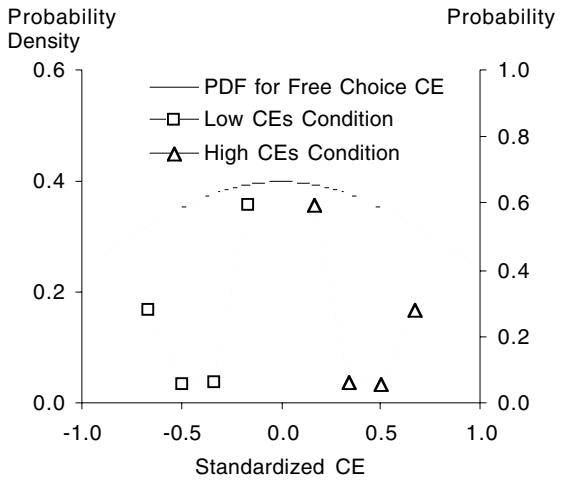

Figure 1: Predicted choices in Stage 2, under the assumption that context will not affect CE choice.

participants choose the option nearest to the CE they would have chosen under free choice conditions.

For the options used in Experiment 1 (see the Design for a description), the two lines in Figure 1 represent the expected distribution of responses. If participants are not influenced by the context provided by the four CE options then the key prediction is that participants in the high CEs condition should choose the lowest option more than half of the time, and participants in the low CEs condition should choose the highest option more than half of the time. This prediction holds for any symmetrical distribution of free choice CEs.

Method

Participants 30 psychology undergraduates from the University of Warwick participated for course credit. 14 took part in Stage 1 of the experiment. 16 took part in Stage 2.

Design Stage 1 was designed to measure participants' free choice CEs for a series of simple gambles. A set of 20 gambles was created by crossing the amounts £200, £400, £600, £800 and £1000 with the probabilities 0.2, 0.4, 0.6 and 0.8. In Stage 2 different participants were presented with the same gambles, and asked to select from a set of four CEs the CE that was closest to their judgment of the value of the gamble. For each gamble two sets of CEs were created. In the low CEs condition participants received options all lower than the mean free choice CE given in Stage 1. In the high CEs condition participants received CEs that were all higher. The CE sets were constructed as follows. The mean and standard deviation of the free choice CEs was calculated for each gamble. The two sets of equally spaced CEs (for the high value and low value conditions) were calculated so that their range was equal to approximately half the free choice standard deviation. One set of CEs was placed below the free choice value, and the other set above. This difference between the lowest CE in the high CEs condition (or the highest CE of the low CEs condition) and the mean free choice CEs was set to be roughly equal to the difference between CEs within a condition. Options were rounded to be familiar, easy to deal with values.

Procedure Participants were given written instructions. They were asked to imagine choosing between "£30 or a 50% chance of £100" to illustrate that gambles could have a value. They were told they would be asked to value a series of gambles, and that they should imagine they had the chance to play the gamble. For each gamble they were asked how much money for certain they thought it was fair for someone to give them for the other person to have a chance to take the gamble instead. They were also asked to consider the opposite situation, where they would be buying the gamble. It was explained that the purpose of the experiment was to investigate how much they thought the gambles were worth, and that there was no correct answer. For participants in Stage 2, it was explained that they should choose the CE option nearest the value they thought the gamble was worth.

Each gamble was presented on a separate page of a 20 page booklet. For participants in Stage 1 gambles were presented as follows:

For you, how much is the gamble
"80% chance of £600"
worth?

£____

Probabilities were always presented as percentages. For participants in Stage 2, a set of options was added. Options were always presented in numerical order, as with the following example of a low CE set:

How much is the gamble
"60% chance of £400"
worth?

Is it: £60 £80 £100 £120

Results

Participants took approximately 5 minutes to complete the task. Figure 2 plots the Stage 1 free choice CE against the gamble amount for the four gamble probabilities. As expected, the average CE increased with both probability of winning and gamble amount demonstrating that participants were sensitive to manipulations of both. The chosen CE was an approximately linear function of the independent effects of gamble amount and gamble probability. Participants were risk averse, with the mean CE being, on average,

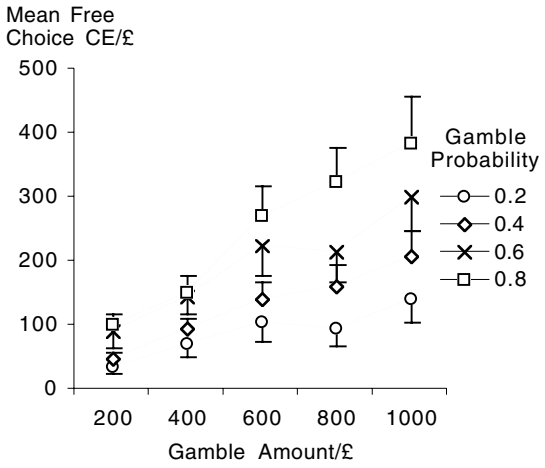

Figure 2: Mean free choice CE as a function of gamble amount for different gamble probabilities for Stage 1 of Experiment 1. (Error bars are standard error of the mean.)

61% of the expected value of the gamble (standard error 3%).

The results of Stage 2 are of most interest. Responses are labeled A through D, with A being the lowest CE, and D being the highest CE. The proportion of times each response type was chosen is plotted in Figure 3. There is no evidence of skewing – instead the distribution of options is approximately the same for the two conditions. The highest CE in the low CEs condition was chosen less than half the time $t(7)=4.21$, $p<0.05$. The same was true of the lowest CE in the high CE condition, $t(7)=5.26$, $p<0.05$.

Discussion

Participants were asked to value a simple gamble of the form "p chance of £x". The effects of p and x on the CE were linear and independent, consistent with Birnbaum's (1992) data. Mean value judgments were below the expected value (£px) of the gamble showing participants were risk averse. Different participants were given a restricted set of CEs for each gamble, either all lower than the mean free choice CE for every gamble or all higher. CE judgments were completely determined by the range of CEs offered, and were not skewed towards the mean free choice CE. Control conditions, not reported here, rule out task demand characteristics as a potential account of these findings, as participants were happy to give highly skewed responses in these conditions. Further, only one of the 16 participants from the second stage reported they were unhappy with the restricted range of CEs offered.

Experiment 2

Experiment 2 was designed to demonstrate the same effect of restricting the range of CEs in a task where it

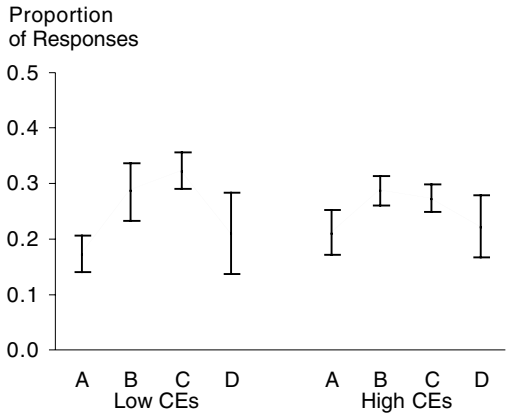

Figure 3: Proportion of responses to each CE for Stage 2 of Experiment 1. (Error bars are standard error of the mean.)

was optimal for participants to report CEs truthfully. This procedure is simpler than other methods used to elicit truthful CEs (e.g., the first price auction, or the Becker, DeGroot & Marschak, 1964, procedure). Specifically, participants divide a given amount into an amount for certain, and an amount to be won with a certain given chance. For example, they might split £1000 into a sure amount of £300 and a "60% chance of £700" gamble. Participants know that the experimenter will select either the gamble or the sure amount, taking the "better" of the two, leaving the participant with the other. Thus it is optimal for participants to split the given amount so that the resulting fixed amount has the same utility as the resulting gamble.

Method

Participants 17 participants took part in the Stage 1 of the experiment. 19 different participants took part in the Stage 2. All participants were paid £4 plus performance related winnings of up to £4.

Design In each trial in Stage 1 a participant divided a given amount of money, £x, into two smaller amounts, £y and £z, to make one fixed amount (£y) and a gamble. There is a given probability p of winning £z, otherwise nothing. Probability p is known to participants before splitting amount £x. Participants know that (if the trial is selected at random at the end of the experiment) the experimenter will take either the fixed amount or the gamble for themselves leaving the participant with the other. It is therefore optimal for the participant to split the amount £x into amounts £y and £z such that £y and a p chance of £z have equal utility for them, i.e., £y is the CE for the gamble "p chance of £z". Under the assumption that the experimenter has the same utility function as them, participants understand that the experimenter will choose the gamble with greater

utility, leaving them with less, if they do not split the amounts in this way.

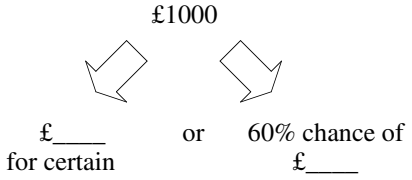
Stage 2 of the experiment differed by offering participants a choice from a set of four pre-split options, rather than giving them a completely free choice. That is, values for £y and £z were presented, and participants selected one pair which could be played at the end of the experiment. As in Stage 1, participants knew that the experimenter would choose the option from the chosen pair with the greatest utility, and therefore they should choose the pair of options closest in expected utility.

It was hypothesized that the pairs of values for y and z presented in Stage 2 would influence participants' choices, and that participants would therefore not just choose the optimal pair. To demonstrate this there was one between participants factor. The set of values for £y and £z were either selected such that £y was always greater than the free choice value of £y from Stage 1 (for equal £x) and £z smaller than the free choice value, or vice versa. The option sets were constructed as follows. The mean and standard deviation of the free choice amount was calculated for each gamble. The two sets of equally spaced options (for the high value and low value conditions) were calculated as described for Experiment 1. As in Experiment 1, if participants are not influenced by the set of choices, then the distribution of responses across the options should be skewed towards the free choice splitting.

Procedure For both stages the experiment began with instructions. It was explained to participants that they were playing a gambling game, and that they should try to win as much money as possible. They were told the purpose of the experiment was to investigate how much people thought gambles were worth. The task was described. It was emphasized that it was optimal for them to split the money so they thought the amount for certain was equal in worth to a chance on the gamble. They were told that if they allocated funds so either the certain amount was worth more than the gamble, or vice versa, then the experimenter would take the better one, leaving them with less than if they had allocated the money so the gamble was worth the certain amount. They were told that although they could not be certain what the experimenter would do, they should assume the experimenter would behave like them.

Participants were given five practice trials to complete. One of the trials was chosen at random, and it was explained that if the experimenter chose the fixed amount, then the gamble would be played, and they would get the winnings. They were also told that if instead the experimenter took the gamble they would get the fixed amount. Note that this discussion was hypothetical, and participants were not actually told what the experimenter's preference would be.

After the practice the experiment began. The participant completed a booklet of gambles. Gambles were presented in a random order to each participant. An example page from a free choice condition booklet is shown below.



In the restricted choice conditions, pre-split options were presented as in the example below.

			Tick
£322 for certain	or	60% chance of £678	
£334 for certain	or	60% chance of £666	
£346 for certain	or	60% chance of £654	
£358 for certain	or	60% chance of £642	

When the experiment was completed one trial was chosen at random, and played to determine each participant's bonus using an exchange rate.

Results

Participants took between half an hour and one hour to complete the booklet. One participant was eliminated from subsequent analysis for showing a completely different pattern of results to other participants, suggesting they had misunderstood the task. The participant had decreased the value of the fixed amount, £y, as the chance of the gamble amount, p, increased (i.e., they responded as if more likely gambles were worth less to them). 14 out of the remaining 512 trials (16 participants x 32 trials) with incorrect arithmetic were deleted, and treated as missing data.

Figure 4 plots the average fixed amount £y as a function of the gamble chance p for the different total amounts (£x). As the total amount £x increased, then participants' allocation of the fixed amount £y increased. As the probability p of winning the gamble increased participants' estimates of the value of the gamble, £y, also increased. Thus participants' responses seem lawful and sensible. These two effects are approximately independent. The dashed lines in Figure 4 represent risk neutral responding. Data points falling above the dashed line demonstrate risk averse behavior. On average, participants were risk averse for low gamble chances (p=0.2), risk neutral for intermediate gamble chances (p=0.6) and slightly risk prone for high gamble chances (p=0.8). However, standard deviations were approximately 15% of the mean fixed amount allocated and thus for larger gamble chances

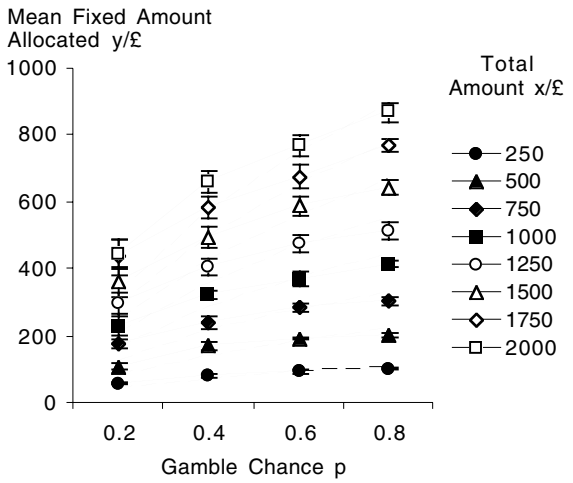


Figure 4: Mean fixed amount allocated in Stage 1 of Experiment 2 as a function of gamble chance for the different total amounts. (Error bars are standard error of the mean.)

approximately half of responses were risk prone, and half risk averse.

The choices made in Stage 2 are shown in Figure 5. Participants did prefer end options over central options in both conditions, consistent with the pattern of results expected if participants were to show no context effect. However, option D in the low y condition was chosen significantly less than half the time, $t(9)=3.47$, $p<0.05$. Similarly, option A in the high y condition was chosen significantly less than half the time, $t(8)=4.20$, $p<0.05$. This observation is consistent with participants showing some context effect. In other words, the proportion of times each option was selected differed significantly from the proportions expected under the assumption that context would not have an effect.

Discussion

The new procedure for eliciting CEs under free choice provides results consistent with Experiment 1. In Experiment 1 participants were, on average, risk averse. Under free choice conditions in Experiment 2 participants were only risk averse for low probability gambles, and were slightly risk prone for high probability gambles. This pattern is the opposite of Tversky and Kahneman's (1986, Problems 10 and 11). Risk averse responding for low probabilities, and risk prone responding for high probabilities is, however, consistent with over estimation of low probabilities and underestimation of high probabilities (e.g., Prelec, 1998; Tversky & Kahneman, 1992; Wu & Gonzalez, 1996). (Consider the case for $p=0.2$. If this probability is overestimated, say at 0.3, then the risk neutral strategy is to increase £y and decrease £z, as the gamble p chance of £z will be overvalued.)

The results of the restricted choice conditions in Experiment 2 replicate those shown in Experiment 1

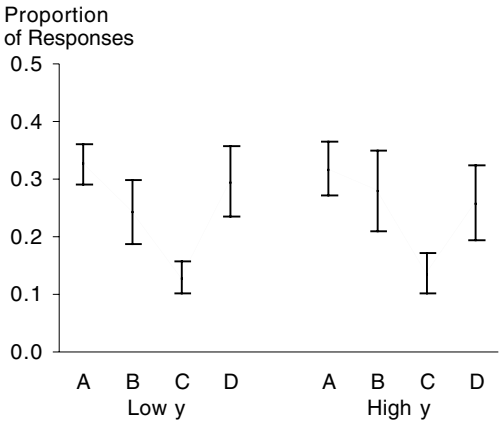

Figure 5: Proportion of each response choice for Stage 2 of Experiment 2. (Error bars are standard error of the mean.)

under a more rigorous procedure, despite participants taking at least six times longer to complete the task compared to Experiment 1. When participants were presented with a range of pre-split total amounts, so that the CE options were either always lower or always higher than the free choice value, their choice of CE was not skewed towards the mean free choice CE. The context provided by the pre-split options influenced their choice of CE.

General Discussion

In the experiments presented here, participants' choice of CE for simple gambles was affected by the range of option CEs offered to them, compared to CEs given by different participants under free choice conditions. For example, when the option CEs were all lower than the free choice CE, participants behaved as if their CE was lower.

Judged and Choice Certainty Equivalents

Careful discussion by Luce (2000) highlights the a difference between judged CEs, where participants provide a single judgement of the value of a gamble, and choice CEs, derived from a series of choices between gambles and fixed amounts. For example, for the kinds of gambles used here, with large amounts and moderate probabilities, judged CEs are overvalued compared to choice CEs (e.g., Bostic, Herrnstein & Luce, 1990). Luce (2000) advocates developing separate theories to for judged and choice certainty equivalents. Participants in these experiments were instructed to complete the restricted CE conditions by judging CEs. However, in Experiment 2, the design should certainly have encouraged imagining choices between gambles and fixed amounts. The degree to which this was the case may explain the 'u' shaped

pattern of results in Experiment 2, rather than the 'n' shaped pattern in Experiment 1.

Other Context Effects

Here the context provided by a set of certainty equivalent options has been found to influence the CE. In other experiments, the context provided by a set of gambles has been shown to influence preferences amongst those gambles. For example, Simonson and Tversky (1992) demonstrated that there was a tendency to prefer a given option when there are other options in the choice set that are unfavorable when compared to the given option. Specifically, in making risky choices between three three-outcome gambles, a gamble was preferred if it dominated another gamble in the choice set.

Implications

Existing models of decision making under risk typically assume that only the attributes of the gamble need be considered when reaching a CE decision. The context or anchoring effects demonstrated here show that the context also needs to be considered. The extent to which context can cause deviation from 'rational choice' has implications for other domains, such as economics and political science, where 'rational choice' models of the individual are applied (e.g., expected utility theory and game theory).

Relation to Perception

The demonstration of context effects in risky decision making suggests that the representation of the utility dimension is similar to that for perceptual psychological dimensions where context effects have also been demonstrated. For example, Garner (1954) showed that participants were completely unable to determine which of six tones was more or less than half as loud as a reference loudness. Instead, participants' judgments were entirely influenced by the range of the six tones. (Laming, 1997, provides an extensive discussion of other similar findings.) Further research is underway in this laboratory to investigate to what extent the context provided by simultaneously presented gambles (see also Mellers et al., 1992) and the context provided by recently considered gambles affects the utility of gambles. This research should help to establish whether utility really is like perceptual dimensions.

Abstract

Research on analogical mapping has not yet focused on the fate of information about the base and target domains that is not relevant to the correspondence. We suggest that there are two methods for dealing with irrelevant information in analogies. Nonalignable objects are ignored, while irrelevant attributes of alignable differences are packed away using a process that is a long term equivalent to the suppression process observed in the text comprehension literature. We report one study that supports this hypothesis by demonstrating that unpacking irrelevant information interferes with memory for domains involved in a comparison.

Introduction

Analogical reasoning allows people to compare across domains that might not seem similar on the surface (Gentner, 1983; Holyoak & Thagard, 1995; Keane, Ledgeway, & Duff, 1994). For example, the atom is like the solar system, because something (electrons and planets) revolves around something else (the nucleus and the sun) in each. An open question in analogy research is what happens to the knowledge that is not relevant to this similarity (e.g., electrons are very small and planets are very large)? Most research on comparisons and analogies has focused only on the relevant information. However, the fate of irrelevant information such as the size of the orbiting object in the above example can have important implications for models of analogy and comparisons in general.

In order to place this issue in context, we first discuss the structural alignment process. We then propose a mechanism for dealing with irrelevant information, called *packing*, and compare it to a similar mechanism in language comprehension. Finally, we report an experiment testing this mechanism.

Irrelevant information in analogy

The structural alignment process is used to compare two domains in an analogy. The process operates over structured representations in which the relations between objects are explicit. This leads to two types of information that can be used in the analogy: relational information and object information. Relational information is simply information about the relations between objects, while object information includes the relations the object participates in and the attributes of the object. In an analogy, the two domains are aligned so that their common relational structures are placed in correspondence, and this leads to relational information becoming focal (Markman & Gentner, 1997).

In structural alignment's original formulation, only relational information was used in the comparison of domains (Gentner, 1983, 1989). However, when the theory was extended to ordinary similarity comparisons (Gentner & Markman, 1997; Markman & Gentner, 1993; Medin, Goldstone, & Gentner, 1993), object attribute information became relevant. In a similarity comparison, if the object match is better than the relational match, then it will be preferred. There is also evidence that attribute information influences analogical comparisons. For example, analogs are easier to retrieve if they share attribute similarity to the target than when they share only relational similarity (Gentner, Rattermann, & Forbus, 1993). The fact that attribute information is available in analogical comparisons raises an important question: How does structural alignment deal with attribute information in analogies, where it is not relevant?

One way in that superfluous attribute information might adversely affect the comparison process is by taxing working memory. Recently the role of working memory in analogy has become a topic of study (Hummel & Holyoak, 1997; Waltz, et al., 2000). One finding from this work is that straining working memory hinders the discovery of common relational structures. This is because relational matches take up more working memory capacity than do surface (attribute) matches. Thus anything that decreases the working memory load (e.g., making attribute information less available) will facilitate relational comparisons.

Structural alignment handles some irrelevant information through the concept of alignability. Alignable objects, or objects that participate in the relational correspondence, are relevant to the comparison. In analogies, these objects are generally *alignable differences*, i.e., nonidentical objects that are

placed in correspondence by virtue of playing a common role in a matching relational structure. Alignable differences can be contrasted to *nonalignable differences*, which are objects that do not participate in the common relational structure. Alignable differences are more focal to comparisons than are nonalignable differences.

In this paper we are interested in a second type of irrelevant information that has not received much attention in the analogy literature. In particular, when an alignable difference is found, some of the attributes of the corresponding objects are likely to be irrelevant to the relational match. For example, in Figure 1, the pig in the top scene and the baby in the bottom scene are an alignable difference, because each is making a mess. Attribute information about the pig such as its snout and ears are not relevant to the relational match. Is information like this treated as focal to the comparison because it is part of an alignable difference, or is it treated like a nonalignable difference because it is irrelevant to the relational correspondence?

Packing and Suppression

The comparison process might deal with irrelevant attribute information by packing it away, or making it less available for processing. On this view, when a representation is packed during a comparison, the representations involved are changed so that only the information relevant to the match between domains is immediately available.

A similar mechanism—called *suppression*—has been suggested in the language comprehension literature. Suppression inhibits superfluous information about a word or concept during comprehension. For example, in the sentence "He won the match," borrowed from Gernsbacher & Robertson (1999), the inappropriate meaning of "match as a stick used to light a fire is inhibited. This mechanism is also useful for limiting the amount of information in working memory during processing. Nonetheless, there are key differences between the processes of analogical comparison and language comprehension that might limit the utility of a suppression mechanism in analogical reasoning. For one, language comprehension - and therefore suppression - occurs very rapidly, while analogies form over a longer period of time. In addition, suppression is short-lived, because the suppressed meaning of a word might be needed (and therefore accessed) in subsequent sentences. In contrast, packing involves representational change, and so we would expect longer-term effects than those observed with suppression.

If irrelevant information about a comparison is packed away, then attributes of alignable differences that are irrelevant to the relational match should be treated like nonalignable differences in comparisons. We tested this possibility by extending a previous study

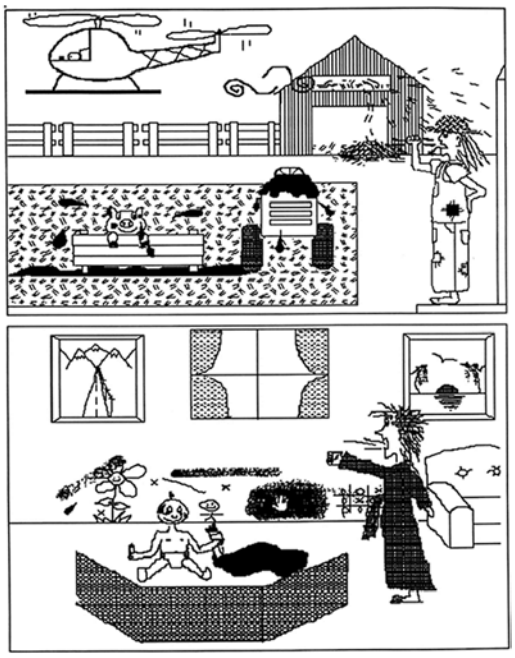

Figure 1: Example Scene Pair. In the top scene the pig is an alignable difference and the helicopter is a nonalignable difference.

by Markman & Gentner (1997). Their study showed that nonalignable differences make poor recall cues, while alignable differences make effective recall cues. In this experiment, subjects were shown pairs of scenes like the one in Fig. 1, and were asked to rate their similarity. As in Fig. 1, there was a *target scene* on top, which contained both alignable differences (e.g., the pig) and nonalignable differences (e.g., the helicopter) with the *comparison scene* on the bottom. After a filler task, subjects were given pictures of objects that were either alignable differences (the pig) or nonalignable differences (the helicopter), and they were asked to recall as much as they could about the scene in which the object had originally appeared. Subjects recalled more information when given the alignable cues than when given the nonalignable cues. This finding suggests that alignable differences are more focal than nonalignable differences.

What aspect of the alignable object is making it a good retrieval cue? The packing mechanism we propose suggests that the connection of the object to relational information is important for retrieval, and that the attributes of the object that are irrelevant to the relational match are packed away. If these attributes are made more salient, the alignable object may be treated more like the nonalignable object, and its efficacy as a recall cue will decrease. To test this idea we added an *unpacking task* in between the comparison and recall tasks of the Markman and Gentner (1997) experiment. In the unpacking task subjects were shown either the alignable or nonalignable difference from the

original scene, and were asked to describe what the object looked like. Listing properties of the objects should cause subjects to focus on the attribute information. If the comparison process made this information less available by packing it away, then when this object is later used as a retrieval cue, it should be ineffective. In particular, the encoding specificity principle suggests that the likelihood of retrieving an item in memory increases with the similarity between the context at retrieval and the context at encoding (Tulving & Thompson, 1973). Thus, if the unpacking task focuses subjects' attention on irrelevant information that was packed away during comparison, the alignable object should no longer be an effective recall cue. In addition, because nonalignable objects are not emphasized by the comparison process, unpacking them should not have any effect on their efficacy as recall cues.

In addition to the unpacking task, we added a packing task in between the comparison and recall tasks. This task was designed to reinstate the analogical mapping. First, during the initial comparison, people were asked to label each pair. This label generally referred to the relational match between the pictures. Later, subjects were asked to recall the titles. Recalling the titles should reinstate the relational mapping for the pair of scenes given that title, resulting in a pattern of recall similar to that observed by Markman and Gentner (1997), with alignable objects serving as effective cues and nonalignable differences as poor recall cues.

In pilot experiments conducted with the packing and unpacking tasks, the results fit with these predictions. When given the unpacking task, alignable cues were no longer effective recall cues. In contrast, when given the packing task, alignable objects retained their efficacy as recall cues. In the present experiment, each subject completed both the packing and unpacking tasks before recall. We predict that the tasks that subjects do last (before recall) should have the most influence on their ability to recall the original scenes. If subjects complete the unpacking task last, the unpacked alignable cues should be no better than the nonalignable cues because attention is focused on the irrelevant attributes. In contrast, if they complete the packing task last, and thus reinstate the relational mapping between scenes, the alignable cue should be a better recall cue than the nonalignable cue.

Method

Participants

Subjects were 172 undergraduates at the University of Texas, Austin, who participated for course credit. The data from 44 subjects was not used due to their failure to follow directions. Most of these either listed properties during the recall task or failed to complete one of the tasks. This left 128 subjects for analysis.

Procedure

The procedure is summarized in Figure 2. As this is a between subject design, each subject saw the tasks in the order specified by either the right or left column in this figure.

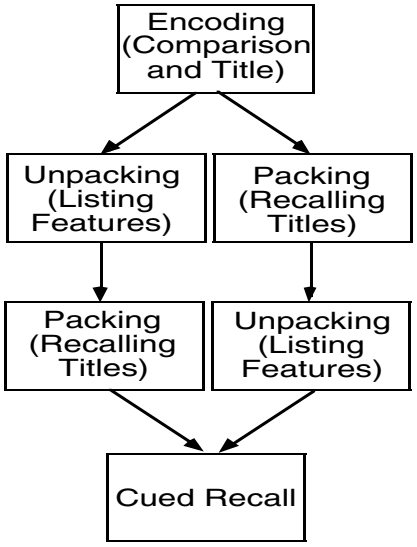

Figure 2: Design of the Experiment.

Subjects sat in cubicles and performed the experiment at their own pace. They were instructed to fill out a set of packets in order, from top to bottom, without looking back or ahead. The Comparison Task packet, which was always completed first, instructed subjects to look at each pair of scenes and rate their similarity on a nine-point scale. They were also instructed to write a descriptive title for the pair of scenes at the bottom of the page after rating their similarity. Participants took approximately 5-10 minutes to complete this task. Subjects then completed an unrelated filler task that took approximately 15-20 minutes.

After the filler task, subjects were given either the Packing Task packet or the Unpacking Task packet. In the Packing Task, subjects wrote down as many of the titles that they had given the scene pairs as they could remember. In the Unpacking Task, subjects wrote down as many properties of the objects, which had been either alignable or nonalignable objects in the comparison scenes, as possible on the lines provided. Each subject completed both the Packing and Unpacking Task. They then completed another unrelated filler task, which took approximately 15-20 minutes.

Finally, subjects were given the cued-Recall Task packet. They were told that they would see a series of objects that had appeared in the scenes they had seen earlier. They were instructed to write down as much as they could remember about the scenes in which the objects had originally appeared. These objects were

either the alignable or nonalignable objects from the comparisons scenes, as in the Unpacking Task.

Design

The study used a 2(Task Order: Packing Last vs. Unpacking Last) X 2(Unpacked Object: Alignable vs. Nonalignable) X 2(Recall Object: Alignable vs. Nonalignable) design. All ten items were run in all conditions. Task order was between subjects. A total of 8 subjects was required to get one observation for each item in each condition.

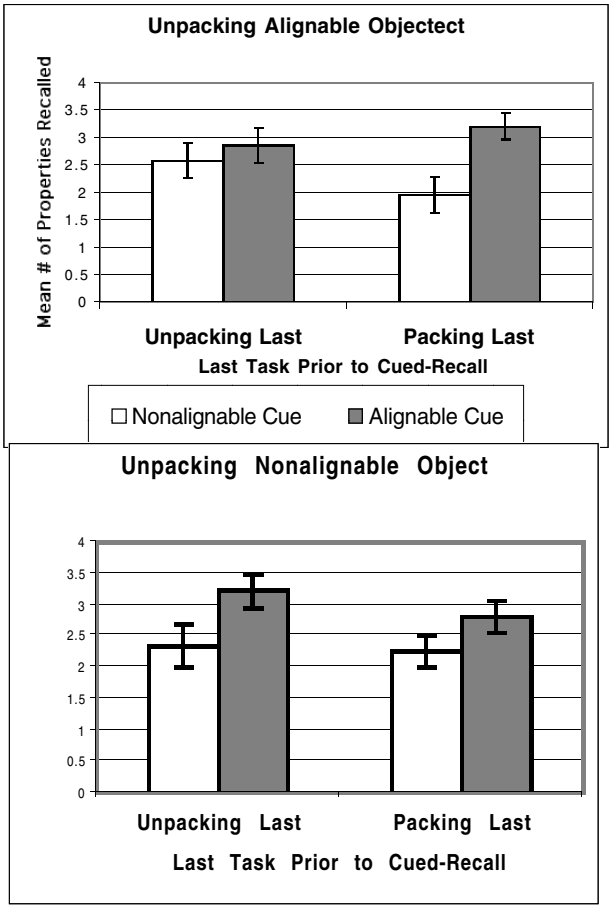

Figure 3a & 3b: Mean number of Properties Recalled.

Results

Figure 3a shows the pattern of recall for subjects who unpacked the alignable object during the Unpacking task. Figure 3b shows the recall data for subjects who unpacked the nonalignable object.. A repeated measures 2(Task Order) X 2(Unpacking) X 2(Recall) ANOVA was performed, by item, on the mean number of properties recalled. There was a main effect of recall, $F(19,1) = 6.33$, $p < .05$. This reflects the fact that alignable cues are generally better than nonalignable cues. There was also a significant Task Order by Recall interaction, $F(19,1) = 2.41$, $p < .05$. As predicted, there was a significant Task Order by Unpacking by Recall interaction, $F(19, 1) = 8.76$, $p < .05$.

The critical predictions for this study center on the conditions in which the alignable difference was unpacked. When the unpacking task was done last (i.e., most recently before recall), we expected this task to interfere with recall. In this case, the alignable difference should not be a good retrieval cue. In contrast, when the packing task was done last, subjects should be able to reinstate the analogical mapping. In this case, the alignable difference should be a much better retrieval cue than the nonalignable difference. Consistent with this prediction, when subjects completed the unpacking task last and unpacked alignable objects, the difference between alignable vs. nonalignable recall cues was not significant, $t(38) = .27$, $p > .10$. However, as predicted, when the packing task was completed last, the alignable cue was a better recall cue than the nonalignable cue, for subjects who unpacked the alignable object, $t(38) = 3.03$, $p < .05$. These data are shown in Figure 3a.

A different pattern of data was obtained when the nonalignable difference was unpacked. In this case, unpacking should not affect the efficacy of the alignable difference as a retrieval cue. Consistent with this prediction, subjects recalled more differences given the alignable difference cue than given the nonalignable difference cue regardless of whether the nonalignable difference was unpacked before or after the packing task was performed. These data are shown in Figure 3b.

Further tests were performed taking into account whether subjects remembered the title for the scene. This analysis is important for determining if it was the reinstatement of the relational mapping through recalling the title that resulted in the different patters of recall. For this analysis an additional factor, Title Recall, was added to the previous analysis. In the packing last condition, subjects who unpacked the alignable object and received the alignable recall cue recalled significantly more properties of the original scene when they recalled the title ($m = 3.97$) than when they did not ($m = 2.48$), $t(38) = 2.36$, $p < .05$. The same was true for subjects in the unpacking last condition. They recalled more when they remembered the title ($m = 3.47$) than when they did not ($m = 2.08$), $t(38) = 2.63$, $p < .05$. This finding suggests that successfully recalling the title of a pair, and thus reinstating the mapping, was beneficial for later recall.

We also looked at whether subjects recalled at least one thing about the original scene in the recall task. This tells us whether they were able to retrieve the original representation of the scene. The mean

proportions of subjects recalling at least one property of the scene are presented in Table 1. The proportions data shows the same pattern that the mean recall data showed. A 2(Task Order) X 2(Unpacking) by 2(Recall) ANOVA was performed on the proportions data, and showed the same results as the mean recall data. There was a main effect of recall, $F(19, 1) = 18.92$, $p < .05$, again showing that alignable cues are generally better than nonalignable cues at facilitating recall. Again, there was also an Order by Recall interaction, $F(19, 1) = 6.35$, $p < .05$. Most importantly, the Order by Unpacking by Recall interaction was significant, $F(19, 1) = 9.22$, $p < .05$. Thus the results exhibited the same pattern both for total amount of recall as well as proportion of subjects who recalled anything about a scene. This finding suggests that the packing task facilitates access to the original mapping rather than increasing the availability of additional properties of the scene.

Table 1: : Proportion of trials on which one or more properties were recalled

	Unpacking Alignable Object	
	Alignable Cue	Nonalignable Cue
Packing Last	0.70	0.39
Unpacking Last	0.58	0.51
	Unpacking Nonalignable Object	
	Alignable Cue	Nonalignable Cue
Packing Last	0.63	0.47
Unpacking Last	0.66	0.46

Discussion

This study provides evidence that information about alignable differences that is not relevant to the relational match is packed away during comparison. As expected, when people unpacked information about the alignable difference by listing properties of it, the efficacy of the alignable difference as a retrieval cue was reduced. Nonalignable differences, which are not focal in comparison, were not influenced significantly by the unpacking task. These data did not simply reflect a general interaction between the packing task and the retrieval task, because performing the packing task (in which subjects recalled titles they had given to the pair) restored the efficacy of the alignable difference as a recall cue.

It is straightforward to view the packing task as increasing the salience of properties of the alignable differences that had been packed away. It is less clear what is happening during the packing task. We suggest that recalling the title causes subjects to reinstate the relational mapping. One piece of evidence in favor of this interpretation is that recalling the title provides a significant boost in the level of recall. One aspect of the data that bears further scrutiny is the observation that successfully recalling the title of a pair increased the efficacy of the alignable cue regardless of whether the unpacking task was done before or after unpacking the alignable object.

This experiment raises several questions about the packing phenomenon that can be addressed in future research. First, how long lasting are the representational changes that occur when a representation is packed or unpacked? The results of this experiment demonstrate that the effects of packing or unpacking a representation last at least 10-15 minutes. This time course contrasts with the suppression mechanism (Gernsbacher & Robertson, 1999), which lasts a much shorter period of time. Future research could examine the effects of these tasks over longer delays.

A related question involves how packing or unpacking a representation affects future comparisons using that representation. One possibility is that the role of surface similarities, which have been shown to figure prominently in the early stages of comparisons (Goldstone & Medin, 1994; Ratcliff & McKoon, 1989) might be attenuated if packing makes these surface features less available than relational information.

This research is an initial step toward exploring the fate of irrelevant information in comparisons. The packing phenomenon is likely to be useful in guiding future research. It is consistent with the current interest in the role of working memory in analogical mapping, and may prove useful in answering questions about how relational information and working memory interact. In addition, it may provide valuable constraints for current models of analogy, which typically focus selectively on the relevant information in a comparison.

Acknowledgments

This research was supported by NSF grant SBR-9905013 given to the second author. The authors thank Eric Dietrich for discussions that laid the theoretical foundation for this work. They thank Sam Day, Dedre Gentner, Ryan Gossen, and Gregory Murphy for contributing to the ideas in this paper. Finally, the authors thank Kerry Collins for his performance all season (except in that last game).

Abstract

The fusiform face area (FFA) in the ventral temporal lobe has been shown through fMRI studies to selectively respond with high activation to face stimuli, and has been identified as a face specific processing area. Studies of brain-lesioned subjects with face recognition or object recognition deficits also have often been cited as evidence for face specific processing. Recent studies, however, have shown evidence that the FFA also responds with high activation to a wide variety of non-face objects if the level of discrimination and the level of expertise are controlled. Based on these recent results, we hypothesized that the features of faces that the FFA respond to can be useful for discriminating other classes of visually homogeneous stimuli with some tuning through experience. To test our hypothesis, we trained two groups of feed-forward neural networks on visual classification tasks. The first group was pretrained on basic level classification of four stimulus classes, including faces. The second group was pretrained on subordinate level classification on one of the stimulus classes and basic level classification on the other three. In two experiments that used different criteria to stop pretraining, we show that networks that fully acquire the skill of subordinate level classification consistently show an advantage in learning the new task.

Introduction

The functional role of the so-called fusiform face area (FFA) located in the ventral temporal lobe is controversial. The FFA has been shown in fMRI studies to respond with high activation to face stimuli but not to other visual object stimuli, and has thus been identified as a face specific processing area (Kanwisher, 2000). Studies of patients with face recognition or object recognition deficits also have often been cited as evidence for face specific processing. Recent studies by Gauthier and colleagues have questioned whether the FFA is really a face-specific area (Gauthier, Behrmann & Tarr, 1999a). They have proposed an alternative theory that the FFA engages in expert level classification of visually similar stimuli from a wide variety of categories not limited to faces.

The current study is an attempt to shed light on the debate through simulations of computational models. We constructed our hypothesis based on the recent view that the FFA is a domain-general processing area, specializing in visual expertise of fine level discrimination of homogeneous stimuli. Our experimental results show strong support for the hypothesis, thus providing further evidence for the plausibility of the domain-general view of the FFA.

In the following sections, we will describe the evidence for and against the FFA's face specificity, and our refinement of the domain-general hypothesis. The experimental methods are then described in detail followed by the results. We conclude by summarizing our findings and suggesting future research.

Evidence for the Face Specificity of the FFA

Studies of brain-lesioned subjects provide the strongest evidence for localized face specific processing. Patients with *associative prosopagnosia* reportedly have deficits in individual face identification, but are normal in face detection and object recognition (Farah, Levinson & Klein, 1995). On the other hand, patients with *visual object agnosia* are normal in identifying individual faces but have deficits in recognizing non-face objects (Moscovitch, Winocur & Behrmann, 1997). The two groups of patients serve as evidence for a double dissociation of visual processing of faces and other objects.

Through fMRI studies of normal brains, the FFA has been identified as the area being most selective to faces (Kanwisher, McDermott & Chun, 1997). Prosopagnosia patients usually have a lesion in an area encompassing the FFA (De Renzi et al., 1994), providing consistent evidence for the face specificity of the FFA.

Evidence against the Face Specificity of the FFA

Gauthier and colleagues argued that the FFA showed high activity in response to various classes of visual stimuli when the levels of discrimination and expertise were properly controlled (Gauthier et al., 1999a). One study showed significantly high activity of the FFA for car and bird experts when stimuli from their respective expert class were presented (Gauthier et al., 2000). Another study that utilized 3-D artificially rendered models called "Greebles" (Gauthier & Tarr, 1997), showed the FFA increasing its activation in response to the rendered models as the subjects were trained to classify them at a fine level (Gauthier et al., 1999b). For the latter study, the use of the Greebles allowed the authors to develop human subject experts of non-face objects while fully controlling the subjects' experience with the stimuli.

These results showing high activity of the FFA for non-face objects including completely novel objects,

serve as strong evidence against the face specific view of the FFA.

Our Approach with Computational Models

Why does the FFA engage in expert classification of non-face objects? We hypothesized that the features of faces that the FFA responds to can be useful for discriminating any class of visually homogeneous stimuli with some tuning through experience. If our hypothesis is correct, possession of expertise with faces should facilitate the expert level learning of other classes. In this paper, we consider individuating members of a homogeneous class (subordinate classification) to be an expert level task.

To test our hypothesis, we trained two groups of neural networks with hidden layers to perform a subordinate level Greeble classification task. Prior to training on the Greebles, we pretrained the networks on one of the following two tasks:

1. Basic level classification of faces and objects
2. Subordinate level classification of one of the classes and basic level classification of the rest

Developing the first visual expertise for non-face objects is one of the conditions that cannot be ethically achieved in human experiments. Our computational model attempts to overcome this limitation by pretraining neural networks on subordinate classification of non-face objects. If the advantage can be observed for all groups of networks with various pretraining tasks, we would conclude that the features that are discriminative of homogeneous visual stimuli *in general* are robust features that translate well to any other class of stimuli.

Experimental Methods

As described briefly in the previous section, we trained neural networks on subordinate level classification with various pretraining tasks. In this section, we will describe further details on the input database, the preprocessing procedure, network configurations and the simulation procedures.

Image Database

The images were 64x64 8-bit grayscale images consisting of five basic classes: human faces, books, cans, cups, and Greebles. Each class included 5 different images of 12 individuals, resulting in a total of 60 images for each class. Example images are shown in Figure 1 and 2. The non-Greeble images are described elsewhere (Dailey & Cottrell, 1999). For the Greebles, the 12 individuals were selected exclusively from one of the five families. Five images were obtained for each individual by performing random operations of shifting up to 1 pixel vertically and horizontally, and rotating up to 3 degrees clockwise or counterclockwise in the image plane. A region from the background of the common object images was randomly extracted and applied to the background of the Greeble images.

Figure 1: Example of face and common object images (Dailey & Cottrell, 1999)

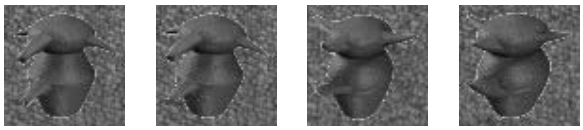

Figure 2: Example of Greeble images;The left two are images of the same Greeble

Preprocessing

To preprocess the images, we followed the procedures introduced by Dailey and Cottrell (1999), applying Gabor based wavelet filters and using principal component analysis (PCA) for dimensionality reduction.

2-D Gabor wavelet filters, which are relatively robust to variations in background, translation, distortion and size (Lades et al., 1993), have been used previously for face recognition tasks with neural networks. Each image was represented by the magnitude of the responses of 40 filters tuned to 8 orientations and 5 spatial frequencies, measured at 64 points subsampled in an 8x8 grid, resulting in a vector of 2560 elements (Buhman, Lange & von der Malsburg, 1990; Dailey & Cottrell, 1999).

PCA was done separately on each spatial frequency, extracting 8 components for each of the 5 scales to form 40-dimensional input vectors. Each element of the input vectors were normalized across all face/object images by z-scoring, i.e., a linear transformation to mean 0 and standard deviation 1. The Greeble patterns were not represented in the principal components to prevent any knowledge of the Greebles contaminating the model.

Network Configuration

Standard feed forward neural networks with a 40-unit hidden layer were used for all the experiments. The hidden layer units used the logistic sigmoid function while the output units were linear. The learning rate and momentum were .005 and .5, respectively. These parameters were tuned so that the networks reliably learned the most difficult task, which was the subordinate level classification on faces and Greebles with basic level classification on the common objects.

Training Set Variations

Each network was trained on a subset of the whole data set as follows. For the classes on which subordinate level

classification were performed, one image for each individual was randomly selected to test generalization. Another image was removed to be used as the holdout set (for early stopping) from the rest of the images, resulting in a reduced training set of 3 images per individual.

For the classes on which basic level classification were performed, images of one randomly selected individual were reserved for testing. Images of a different individual were used as the holdout set, resulting in a reduced training set of images of 10 individuals.

With the arrangements mentioned above, 3 images of 12 individuals were available for use as the training set for the subordinate level classification task and 5 images of 10 individuals were available for the basic level task. In order to control the number of images presented to the networks during the training, the training set was restricted to 3 images from 10 individuals for both levels of classification, for a total of 30 images for each class.

In the experiments reported below, we do not use the holdout and test sets, as we use RMSE thresholds and amount of training as conditions for stopping training phases. The holdout and test sets are used in preliminary experiments to find appropriate values of the RMSE thresholds.

Task Variations

Training of the neural networks was done in two phases. In the first phase, the pretraining phase, the networks were trained using only the face/common object data on one of the following two tasks:

1. Basic level classification on all 4 input categories
2. Subordinate level classification on 1 category and basic level on the rest.

The networks that were assigned the first task had 4 outputs, corresponding to book, can, cup, and face. We will refer to these networks as "Non-experts".

The networks that were assigned the second task had 13 outputs; 3 for the basic level categories and 10 for the individuals in the subordinate level. For example, if a network was assigned a subordinate level classification task for cans and basic level for the rest, the output units corresponded to book, cup, face, can 1, can 2, can 3, etc. We will refer to these networks as "Experts".

In the second phase, the pretrained networks were trained on a subordinate level classification task of individuating Greebles in addition to the pretrained task. Greebles were included in the input data set and 10 output units corresponding to each Greeble were added. Thus, the networks performed either a 14-way or a 23-way classification depending on their pretrained task.

We ran two sets of experiments using different criteria to determine when to stop pretraining:

Experiment 1 The networks were trained until the training set RMSE dropped below a fixed threshold.

Experiment 2 The networks were trained for a fixed number of epochs.

The first criterion controls the networks' familiarity with the input data with respect to their given tasks. This criterion is partly motivated by Gauthier et al.'s definition of experts that takes into account not only the classification accuracy but also the response time which reflects the subjects' degree of certainty. Response time is often modeled in neural networks by the RMSE on a pattern. The second criterion controls the number of opportunities the networks can learn from the input. Employing this criterion corresponds to the idea of controlling the subjects' experience with their tasks, which is often difficult to control in human subject experiments.

For the Greeble phase, the networks were trained to a fixed RMSE threshold for both experiments.

Provided that the networks adequately learned the pretraining task in the pretraining phase, any difference in the learning process of the new task (in the second phase) between the Non-experts and the Experts must be due to the differences in the pretraining task. For the first experiment, we set the pretraining RMSE threshold to 0.0806. This threshold value was determined through preliminary experiments by estimating the training set RMSE for the face expert task to be learned without overfitting. For the second experiment, the epoch limits ranged over $5 * 2^n$ with $n \in 0, 1, .., 10$ to fully analyze the effect of the pretraining task differences. We set the RMSE threshold for the second (Greeble) phase to 0.158. This was determined from similar preliminary experiments based on the estimated optimal RMSE on the most difficult task, subordinate level classification on faces and Greebles.

Evaluation

For the two experiments, we compared the number of epochs required to learn the new task for the Non-experts and the Experts. For experiment 1, we trained 20 networks with different initial random weights for all 5 pretraining tasks, for a total of 100 networks. For experiment 2, we trained 10 networks with different initial random weights for all 5 pretraining tasks for 5120 epochs. We stored the intermediate weights of each network at 10 different intervals ranging over 5 to 2560 epochs, training a total of 550 networks in the second phase.

Results

Experiment 1: Fixed RMSE Criterion

Pretraining

Figure 3 shows the number of training epochs for the two phases averaged across the 20 networks for each pretraining condition. The Non-experts required a much shorter training period than all the expert networks for the pretraining phase, reflecting the ease of basic level classification. For the second phase, the Non-experts were significantly slower than all the Experts in learning the new task ($p < 0.001$, pairwise comparison between Non-experts and the face, can, cup, book experts with $t(38) = 7.03, 5.74, 14.69, 10.76$, respectively). The difference between the can experts and the face experts was insignificant ($t(38) = 1.20, p > 0.2$), the face experts

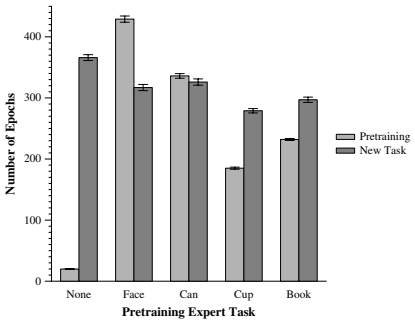

Figure 3: Number of epochs to reach the RMSE threshold. Error bars denote standard error.

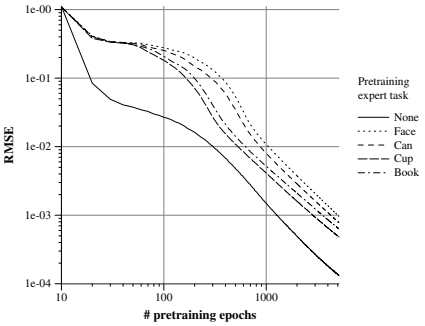

Figure 4: Learning curve for the pretraining phase

Table 1: Training set accuracy for just the Greebles. Figures in parentheses denote standard error.

Expert task	Greebles training set accuracy(%)
Non-expert	71.2 (2.00)
Face	93.5 (1.17)
Can	95.2 (1.04)
Cup	89.8 (2.00)
Book	88.8 (1.46)

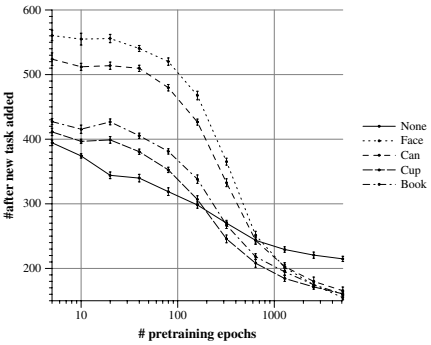

Figure 5: Number of epochs to learn the new task. Error bars denote standard error.

were slower than the book experts ($t(38) = 3.08, p < 0.005$), and the book experts were slower than the cup experts ($t(38) = 3.22, p < 0.005$).

Table 1 shows that despite the overall RMSE having been controlled, the Non-experts were still non-experts at Greebles after training on them. Further training on the Non-experts would have widened the gap between training times on the Greebles for Experts and Non-experts even more. On the other hand, for the Experts, there was a positive correlation between the training set accuracy and the number of training epochs, suggesting the differences in training epochs between the Experts would have narrowed if the training set accuracy on the newly added task had been controlled. Being an expert on some task prior to learning another expert task was clearly advantageous.

Experiment 2: Fixed Exposure Pretraining

Not surprisingly, the Non-experts maintained lower RMSE than all the Experts during the pretraining phase (Figure 4). Among the four groups of expert networks, the face experts had the most difficult pretraining task, followed by the can experts, book experts, and finally cup experts.

For the secondary task training, there was a crossover in effects at 1280 epochs: Fewer epochs meant the non-Experts had an advantage; more meant Experts had an advantage (Figure 5). If the networks were pretrained long enough, the improvement on the error for the pretrained portion of the task became negligible compared to the error due to the newly added task. In this case, we can safely argue that the epochs of training required in the second phase are fully determined by the learnability of the newly added task. If the pretraining stopped prematurely, however, the networks must improve their performance on the prior task as well as the newly added task to achieve the second phase RMSE threshold. All of the networks that were pretrained for at least 1280 epochs achieved a pretraining RMSE that was an order of magnitude lower than the second phase RMSE threshold. Therefore, the advantage that Experts with this amount of pretraining gained must be due solely to their performance in learning the new task.

Analysis: Network Plasticity We hypothesized that the advantage of learning a fine-level discrimination task would be due to greater plasticity in the hidden units. That is, we expected the activations of the hidden units to end up in the linear range of the squashing function in order to make the fine discriminations. This is also a good place to be for back propagation learning, as the higher the slope of the activation function, the faster learning occurs. We therefore analyzed how the features extracted at the hidden layer were tuned by measuring the plasticity (average slope) of the pretrained networks. Our findings surprised us.

We defined a network's plasticity as the value of the derivative of the activation function at the activation level averaged across all hidden layer units and all patterns in

a given set of input patterns:

$$P(S) = \frac{1}{N}\sum_{s\in S}\frac{1}{n}\sum_{i\in I} g'(x_{si})$$

where $g(x)$ is the activation function, S a set of patterns, N the number of patterns in S, I the set of hidden layer units, n the number of hidden layer units, and x_{si} the activation of unit i in response to pattern s. In the online backpropagation learning rule, $g'(x)$ scales the weight changes of the hidden layer units with respect to the errors computed for the output layer. The plasticity of neural networks is usually taken to be predictive of the ability to learn new tasks (Ellis & Lambon Ralph, 2000).

As the activation function, all the hidden layer units in our neural networks used the logistic sigmoid function:

$$g(x) = \frac{1}{1+\exp(-x)}$$

where x is the weighted sum of the inputs, or the inner product of the input vector $\vec{z}$ and the weight vector $\vec{w}$:

$$x \equiv \vec{z}\cdot\vec{w}.$$

The first derivative of $g(x)$ can be written as

$$g'(x) = \frac{\exp(-x)}{(1+\exp(-x))^2} = g(x)(1-g(x)).$$

For $x \in (\infty, -\infty)$, $g(x)$ ranges over $(0,1)$ and $g'(x)$ over $(0, 0.25]$. $g'(x)$ is a bell-shaped function with a global maximum at $g'(0) = 0.25$. By our definition of plasticity, the networks that produce intermediate responses at the hidden layer level would have higher plasticity than networks with bimodal responses. Networks with higher plasticity are generally more likely to learn new tasks faster since the hidden layer units would change their weights more rapidly in response to the errors propagated from the newly added output units.

Network plasticity can also be considered as a measurement of *mismatch* between the hidden layer weights and the input patterns. If the input patterns and the weights were orthogonal, x would be near 0, resulting in maximal plasticity. If, however, the weights tuned for some task matched the input patterns of a new stimulus class, $|x|$ would have a larger value resulting in lower plasticity. The issue is whether these features will be advantageous for learning the new stimulus class. When a network with a low plasticity (high match) measured on novel patterns learns faster on those patterns than a network with higher plasticity, this suggests that the highly matched features are efficacious for classifying the new stimuli.

Figure 6 shows the plasticity of the pretrained networks in response to the training set used for the pretraining and to the set of new patterns which would be added into the training set for the second phase. For both the pretrained patterns and the unseen patterns, Non-experts

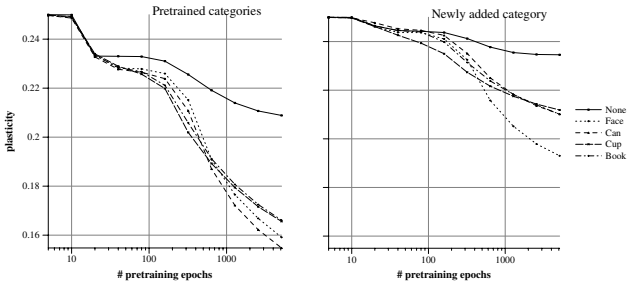

Figure 6: Plasticity of the pretrained networks

retained their plasticity better than all Experts. As we saw in the previous section, however, it was the Experts that eventually showed an advantage in learning the new task. All Experts learned the new task faster as they rapidly lost plasticity over pretraining time. Normally, we would expect the Experts to be generally poorer in learning new tasks due to their low plasticity. These results imply that the advantage the Experts gained in learning the Greebles task cannot be explained as part of a general capability of learning new tasks. Instead, it is more appropriate to interpret this to mean that the hidden unit features were well-matched to the new task.

The lower plasticity of the Experts for the pretrained data implies that the Experts had to finely tune their features to fit their respective expert category, while the Non-experts did not require fine tuning of the features to achieve the lower errors. The eventual advantage of the Experts can then be explained in terms of the features tuned for the expert tasks matching the Greebles data set as well. Given the strong trend regardless of the domain of expertise, we claim that the features useful for one subordinate classification task are general expert features that are good for discriminating individuals of other classes as well. Although other uncontrolled factors such as the length of the weight vectors can influence the plasticity of a network, they seem unlikely to explain our experimental results.

Experiment 2 Summary For longer pretraining epochs, the Non-experts took longer than any of the Experts to reach the final RMSE after the new task was added. While we would expect the Experts to have higher plasticity given their advantage in learning the new task, it was the Non-experts that retained higher plasticity. A comparison between Experts within each task also showed that the networks with longer pretraining and lower plasticity learned the new task faster. The results regarding network plasticity led us to interpret plasticity as a measurement of mismatch specific to a given set of patterns, rather than a predictor of the ability to learn arbitrary new tasks. Given these results, we claim that the underlying cause for the advantage gained by the Experts is the generality of the hidden layer features, fitting well with the subordinate classification task of other classes. This is remarkable in that *overtraining* on a prior task facilitates learning the new one.

Conclusion

Based on the recent studies that showed FFA's engagement in visual expertise of homogeneous stimuli is not limited to faces, we hypothesized that the features useful for discriminating individual faces are useful for the expert learning of other classes. Both of our experiments yielded results in favor of our hypothesis. Furthermore, while faces had a tendency to show the greatest advantage, the results were replicated with networks whose expertise was with other stimulus classes, including cups, cans and books.

The results of the two experiments showed that the possession of a fully developed expertise for faces or non-face objects is advantageous in learning the subordinate level classification of Greebles. Contrary to our expectation that expert networks would show greater plasticity, analyses of network plasticity for Experiment 2 showed that plasticity decreased for the expert networks over time, and it was lower than for non-Expert networks. Indeed, the *lower* the plasticity, the *less* time it took to learn the new task. By reinterpreting low plasticity to mean "high match," we take these results to mean that the features being learned not only match the Greeble stimuli well, but also are the *right* features for fine discrimination of Greebles. Since the choice of Greebles for the second experiment was arbitrary, this suggests that learning to discriminate one homogeneous visual class leads to faster learning in discriminating a new one. Therefore, we conclude that visual expertise is a general skill that translates well across a wide variety of object categories.

Future Work

Firm believers in the face specificity of the FFA might insist that it must be shown that individual neurons in the FFA can simultaneously code features for multiple classes of objects in order their theory to be rejected (Kanwisher, 2000). Even with the advances in brain imaging technology, monitoring each neuron in the FFA is infeasible. Simulations with computational models, however, allow us to monitor the behavior of every single unit in the network.

Naturally, then, one possible extension of the current research is to investigate in detail what the hidden layer units in the expert networks are encoding. Although our experimental results seem to suggest there are features that are useful for visual expertise of any object classes, it is unclear exactly what those features are. Visualization of these expert features would help understand how we develop visual expertise.

Abstract

The most popular theories of associative learning require some kind of external teaching signal, whether it be feedback on category membership or the presence of a US to determine whether a trial has been successful. However, under some circumstances (Bersted, Brown & Evans, 1969; Evans & Arnoult, 1967; Estes, 1994), it appears that such a signal is not required to produce accurate categorical decisions. The work presented here was motivated by Wills & McLaren (1998), which looked at Free Classification and demonstrated that human participants could accurately extract category structure with no feedback during the task. The current experiments compare performance on a generalisation task after training using one of a number of different conditions including Free Classification, allowing a comparison with participants who have had a teaching signal during training. The results seem to indicate that under some conditions, it is not feedback during training, rather the need for a decision to be made which is critical. The data also shows that there is no difference in accuracy between the ability of the groups to generalise, no matter what their initial training, rather the differences are manifested in the reactions times.

Introduction

There has been little work done on directly comparing performance on tasks where one group of participants receives feedback and another does not, as it seems intuitively obvious that if there is some external feedback, then this will aid rather than retard learning. The familiar notion that consistent feedback always produces the best performance (Homa & Cultice, 1984) can be challenged, however, with data showing that a teaching signal may not provide any advantage. Real world scenarios, where feedback may be absent, and theories of natural categorisation (Rosch & Mervis, 1975) seem to be in line with this idea. If we allow that reliable feedback is not always the key to success, then there must be other factors which participants are only able to take advantage of in some circumstances. Estes (1994) provides an experiment where two different types of feedback are compared. Observational training is the same as the Label condition described later in this report, where a label is provided with the stimulus and denotes which category it belongs to, with no decision being made by the participant.

This is compared to standard training, which has corrective feedback after a decision has been made about the category membership of a given stimulus by the participant. In Estes' study, the observational training was found to be more effective than the standard training on test, and it was deduced that the observational training was more consistent with the participants' perception of the categories. Both these types of training were included in the current experiment, as well as a free classification condition, and two other conditions designed to control for potential effects of response practice.

Experiment 1

Participants and Apparatus

The participants were 60 adults, aged between 18 and 35, who were paid for their participation. All were graduate or undergraduate students from the Cambridge area. Participants were tested individually in the same quiet experimental cubicle. The room contained an Acorn RISC PC600 microcomputer connected to a 14 inch colour monitor, model AKF60. Responses were made using a standard keyboard. Participants sat about one metre away from the screen which was approximately at eye level.

Stimuli

Each stimulus was a 16 × 16 array of black and white squares. These "chequerboards" measured 2.5 cm on a side and were presented on the centre left of the screen against a mid grey background. In some experimental conditions, a label for the chequerboard, either the letter 'A' or 'B' was presented in white on the centre right of the screen. The label was approximately the same size as the stimulus. For each participant, a new master pattern was created, and this was used as one of the prototypes during the experiment. The master pattern was a chequerboard of 128 white and 128 black squares randomly arranged, hereafter chequerboard A. A second prototype was created from the master pattern by selecting 120 of the squares (60 black and 60 white) and reversing the shade of those squares (black to white or vice versa), hereafter chequerboard B. The examples that were actually shown to the participants depended upon the phase of the experiment. During training the stimuli shown were created from the prototypes by subjecting each square to a small independent chance ($p = 0.05$) of reversing its colour. On test all stimuli were created from the master pattern and had a set number of squares reversed in colour, ranging from 0 to 120 in steps of 10, covering the artificial continuum between the prototypes. Each test stimulus reversed the colour of a different, randomly selected set of squares, depending on its position along the continuum between the prototypes. For example if a stimulus was in

position 4 out of 12, then 40 of the master pattern squares would be changed to be the same as those in the second prototype. Another stimulus at position 4 would have a different set of 40 squares reversed in colour so as to match those in the other prototype.

Design

The experiment incorporated one of five different training conditions, all followed by an identical test session.

Labelled

Participants were presented with the training chequerboards accompanied by a consistent label, either A or B during training. No response was required and the participants were asked to try to learn what features made a pattern either an A or a B.

Free Classification

Participants were presented with the training chequerboards, but without a label being present. They were asked to divide the stimuli that they were being shown into two groups, in any way which they saw fit, by pressing one of the appropriate keys. No feedback was given throughout.

Corrective Feedback

Participants were presented with the training chequerboards alone and had to learn which of the two keys to press when they saw a given chequerboard. Corrective feedback in the form of a beep from the computer indicated when the participant had pressed the wrong key. No label was presented.

Mental Decision

Participants were given similar instructions to the Free Classification group, except no response was required in this condition. All the participants had to do was decide to which one of the two groups the pattern belonged. No label was presented.

Matching to Label

Participants were given similar instructions to the Labelled condition, except that they were required to make a keypress once the chequerboard had disappeared. The key they pressed simply corresponded to the label that was presented with the stimulus. This same key assignment was carried over into the generalisation phase.

Procedure

Each participant was asked to read the general experimental description which was displayed on the computer screen. This included a brief description of the whole experiment, more detailed instructions about the training phase and an example stimulus, with a label if appropriate. Participants were told to try to learn as much as they could in the first part of the experiment, as they would need this information for the final part. Once the participant had read the instructions, the experimenter verified that they had understood them, and then left the room for the remainder of the experiment. Participants started the training phase by pressing the 'Y' key at the top of the keyboard, and then proceeded through the 60 training trials in a fashion determined by the experimental condition.

During training, the stimuli (and label if appropriate) were displayed for 5 seconds before disappearing from the screen. If a response was required, then participants were allowed to press an appropriate key, either the 'x' or the '>' key, once the stimulus had gone from the screen. If no response was required during training, then there was a two second inter-stimulus interval. Training consisted of 30 presentations of A and 30 of B in a random order. All participants were told that the chequerboards that they were to be shown could be divided into two groups, and that this was their task.

After the final training trial, the instructions concerning the test phase were displayed. The test phase was identical for all participants regardless of their training condition and consisted of 130 trials which displayed a chequerboard on its own. The instructions asked each participant to continue placing the stimuli into two groups in the same way as before, but were informed that there would now be no label, if there had been one before, and that a response was required for each chequerboard. In conditions where a label had been presented to the participants a key mapping was provided, for example, "Press 'x' if it's an A". If no label had been present during training, participants were simply asked to carry on placing the chequerboards into the most relevant group. The instructions for the Mental Decision group required them to make an arbitrary assignment of the groups they had formed during training to the keys to be used during the test phase. Once a response to a test stimulus had been made, it was immediately replaced by another stimulus. If any other key apart from the two that were designated was pressed, the computer beeped, and another response was required. Participants were asked to focus more on accuracy rather than speed in this part of the experiment, and there was no explicit time-out procedure, so participants cannot be considered to be under any time pressure.

The design of the test phase was such that participants were shown stimuli along the continuum from the master pattern (A) to the second prototype (B). Each test stimulus had a multiple of 10 squares changed from A, to make it more like B. As A and B differed by 120 squares, there are 13 steps along such a continuum and with each point being sampled 10 times, this gives 130 test trials. The 10 stimuli for any given point on the continuum were all different, and generated as described above.

At the end of the experiment the computer automatically recorded responses and reaction times from the training phase where possible, and from the test phase in a data file. Each participant was paid for their time and thanked for their participation.

Results

The two measures of performance recorded during the generalisation test phase were response and reaction time, and they are dealt with separately. The independent measure on the plots in this section is distance along the

Table 1: Factors in Experiment 1

	Information	No Information
Keypress	Match to Label	Free Classification
No Keypress	Label	Mental Decision

B-A continuum, with B at one end and A the other, and the intermediate values being examples of B with (10 × distance) squares changed to make the stimulus more like A. Data was analysed firstly by comparison of the groups using ANOVA. A factorial design was also used, as illustrated below (Table 1). The conditions included in the experiment have tried to control for possible effects of making a response interacting with the presence of accurate information about category membership.

Responses

A single mixed design analysis of variance (ANOVA), with one within-subject variable (continuum position, 13 levels) and one between subjects variable (training condition, 5 levels) was performed on the mean number of B responses at each point on the continuum for each participant. This failed to reveal any significant difference between the groups $F(4,55) = 2.25$, $p<0.1$ or any interaction between the groups and the position along the continuum $F(48,660) = 0.647$, $p>0.9$. There was a significant main effect of position along the B-A continuum $F(12,660) = 6.88$, $p<0.001$. No further analyses were carried out on the response data, as there was no clear difference between the groups at this stage. The mean responses for each group at each point along the continuum are plotted in Figure 1. A mixed design ANOVA, with one within subject variable (continuum position, 13 levels) and two between subject variables (the presence or absence of consistent information about category membership and the requirement to make a keypress) was performed. The analysis yielded a significant main effect of both the requirement to make a keypress, $F(1,44) = 4.76$, $p < 0.05$ and of continuum position, $F(12,528) = 99.45$, $p < 0.001$. No other effects approached significance in this analysis, $p > 0.15$. The mean responses for each level at each point along the continuum are plotted in Figure 2.

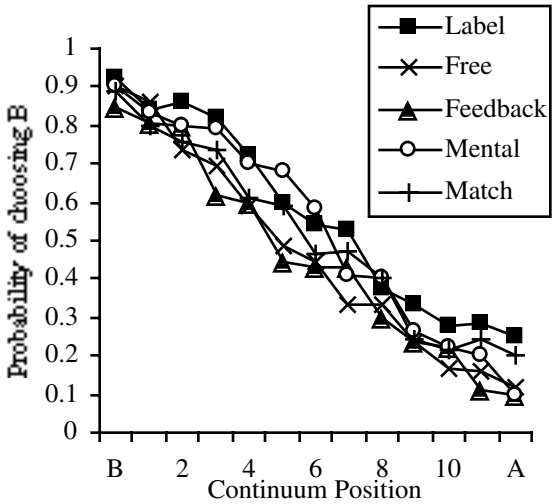

Figure 1: Response Data for All Groups in Experiment 1

Reaction Times

Participants were not considered to be under any time pressure, so the reaction times provide a secondary performance measure. The mean reaction times for each group are plotted against the distance from B along the B-A continuum in Figure 3. ANOVAs were performed on the mean reaction times for each participant. A single mixed design ANOVA, with one within subject variable (continuum position, 13 levels) and one between subjects variable (training, 5 levels) revealed a significant main effect of group, $F(4,55) = 5.00$, $p<0.01$, and of position along the continuum, $F(12,660) = 6.28$, $p<0.001$. There was no significant interaction between the two factors, $F(48,660) = 1.18$, $p > 0.15$.

A Tukey HSD test performed on the group factor revealed that each of the Free Classification, Mental Decision and Feedback conditions were significantly faster than the Label condition, all $p< 0.05$, with no other comparisons reaching significance. Pairwise analysis of the conditions reveals a significant quadratic interaction between the Label and Free Classification conditions, $F(1,22) = 5.84$, $p < 0.05$, and the Matching to Label and Free Classification conditions, $F(1,22) = 7.05$, $p < 0.05$, no other comparison of quadratic trends reached significance, $p > 0.1$.

A mixed design ANOVA, with one within subject variable (continuum position, 13 levels) and two between subject variables (the presence or absence of consistent information about category membership and the require-

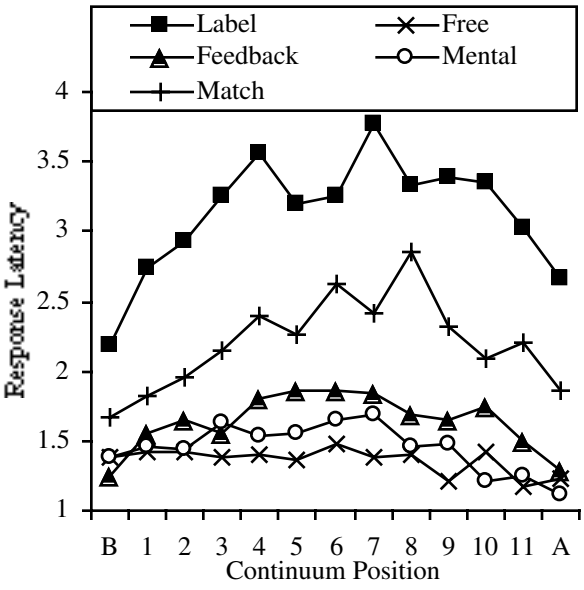

Figure 3: Reaction Times for All Groups in Experiment 1

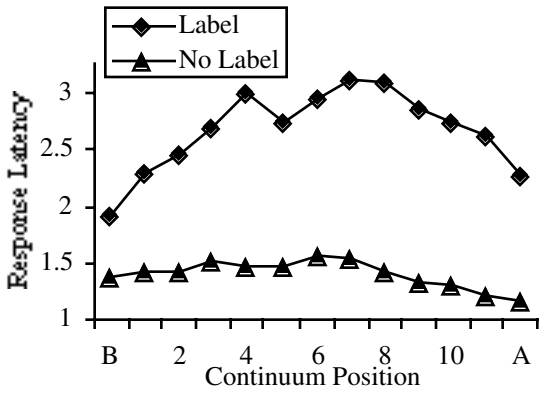

Figure 4: Effect of Label in Experiment 1

ment to make a keypress) was performed. This revealed a significant effect of information, $F(1,44) = 13.67$, $p = 0.001$, the expected main effect of continuum position, $F(12,528) = 4.83$, $p < 0.001$ and an interaction between these two factors $F(12,528) = 2.77$, $p < 0.05$. No other effects approached significance in this analysis, $p > 0.25$. The mean reaction times for each level at each point along the continuum are plotted in Figure 4.

Discussion

Experiment 1 provides evidence for a number of novel results with respect to the effect of feedback on categorisation. Whilst there is no significant observable effect of training condition on response performance, there is a significant effect on the reaction time data collected. Initially surprising is the fact that groups trained with a completely errorless teaching signal (Labelled and Match to Label) recorded the slowest reaction times. Two other groups received no feedback (Free Classification and Mental Decision), and both are found to be significantly faster than the Labelled condition. The response curves show that this speed advantage cannot be due to speed-accuracy trade off, and so there must be some other explanation for the deficit in performance observed in groups which intuitively should be the best at the task.

The main effect of labelling in the factorial analysis for the reaction time data confirms this finding, with the presence of a category label causing an increase in response time on generalisation. The effect of making a keypress can be seen in the response analysis, but can be regarded as relatively uninteresting as there is no sign of an interaction which might point to the task having been learnt better, causing one group to have a more step-like function.

The most obvious reason for the speed advantage seen for those groups who do not have a consistent piece of information relating to category membership is that they are required to make a decision about category membership during the training phase. This seemingly essential part of training is not present when a label is provided, as the stimulus and its category name are presented simultaneously. In the Feedback condition, even though there is consistent category information, a decision must be made before this feedback can be received and integrated. In the conditions where no feedback it present, a decision made internally about previous stimuli is the only information available when deciding to which group subsequent stimuli should be assigned. The similarity of the generalisation functions implies that all groups have learnt how to differentiate between the two categories to the same extent. However it may be that the application of this knowledge is mediated by a response mechanism which is yet to be set up by those groups which are not required to make a decision as to category membership during training. This leads to the difference seen between the relatively flat reaction time curves for the three conditions where decisions are required in training and the inverted U-shaped reaction time curves produced by those participants who are presented with the label during training. The inverted U-shaped curves are typical of those produced during generalisation along a continuum using these procedures (Jones, Wills & McLaren, 1998). The centre point of the continuum is no more like an A than a B, so any response made to these stimuli must be indeterminate, and hence produces a longer latency than those responses to items which are more like those in training.

Despite the potentially simple explanations for the differences observed between the groups, it is still an interesting result to have the Free Classification and Feedback conditions indistinguishable from one another even with the supposed added advantage of corrective feedback. This may be due to some motivational factor, as participants in the Free Classification group are never told that they are wrong, however with feedback, participants may be relatively sure that the stimulus that they are seeing is an A, but in fact turns out to be a B, which may disrupt their representation of the conditions for category membership. The feedback that they get may be consistent within the framework of the experiment, but may be inconsistent internally, and this may be part of the reason for the lack of benefit for the Feedback condition.

The reason the Label condition is so slow may be because it takes time to learn, and then to use, the response mapping. It cannot be entirely due to motor learning as although there is some advantage for the Matching to Label group over the Label group, there is still a difference between the Matching condition and the three where a decision was made during training. The results from the Mental Decision group also tend to discount this line of reasoning as they were not required to form a key mapping before the test phase but their responses are indistinguishable from the Feedback and Free Classification.

Experiment 2

Experiment 2 was designed in a factorial fashion to investigate the effect of both feedback and consistent label-

Table 2: Factorial Design of Experiment 2

	Feedback	No Feedback
Label	Match to Label (FB)	Match to Label (NFB)
No Label	Corrective Feedback	Free Classification

ling of the stimuli. In this respect it was similar to Experiment 1, but attempted to control for the formation of response mappings during training. Experiment 2 forced all participants to adopt a key mapping during training, so that any effect on test would be due to the actual training rather than differences in procedure. All participants were forced to make their responses to the stimuli within two seconds of the stimulus disappearing using the same keys as before.

Stimuli and Apparatus

These were identical to those in Experiment 1.

Participants and Design

Forty-eight Cambridge University students took part in the experiment. All were aged between 18 and 25. The experiment was designed to test the effect of two factors when learning an artificial categorisation problem. These were the presence and absence of feedback on the responses that were made during training, and the presence or absence of a consistent category label during training The design was similar to Experiment 1, with the test phase being identical, and is shown in Table 2.

Procedure

The procedure was similar to Experiment 1. The only differences were during training. All groups were presented with a stimulus and asked to respond within two seconds to that stimulus once it had disappeared. The training differed from Experiment 1 by presenting the label, if necessary, before the stimulus rather than concurrently. For those conditions without a label, a '#' symbol was presented before each stimulus, whether it was nominally an A or a B, in place of the label to equate the training time. The appropriate label or '#' was displayed for five seconds before the five second presentation of the stimulus. The instructions were identical to those from Experiment 1 apart from detailing the separate presentation of the label or '#' and the stimulus and informing the participants of their two second time limit.

Results

As with Experiment 1, there were two dependent variables, response selection and reaction time, and as a time limit had been imposed, the reaction times can be considered a more informative performance indicator. The data were analysed using an appropriate ANOVA. The performance of individual groups was analysed along with the effect of the factors built into the experiment.

Responses

A single mixed design analysis of variance (ANOVA), with one within-subject variable (continuum position, 13 levels) and one between subjects variable (training condition, 4 levels) was performed on the mean number of A responses at each point on the continuum for each participant. This failed to reveal any significant difference between the groups $F(3,44) = 0.76$, $p>0.5$ or any interaction between the groups and the position along the continuum

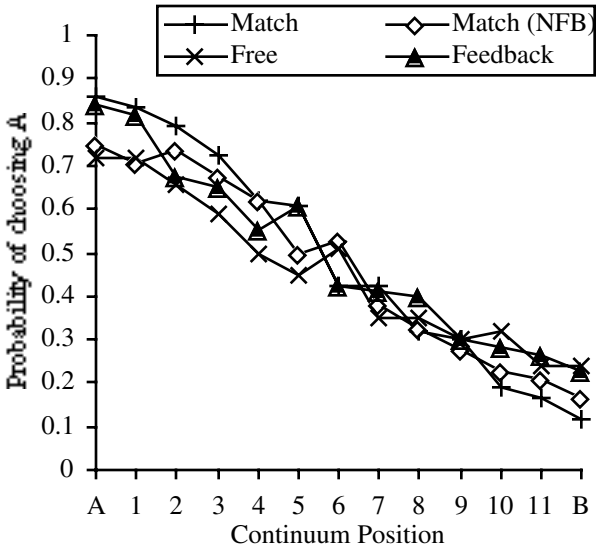

Figure 5: Response Data for All Groups in Experiment 2

$F(36,528) = 0.65$, $p>0.5$. There was a significant main effect of position along the A-B continuum $F(12,528) = 55.73$, $p<0.001$. No further analyses were carried out on the response data, as there was no clear difference between the groups at this stage. The mean responses for each group at each point along the continuum are plotted in Figure 5.

A mixed design ANOVA, with one within subject variable (continuum position, 13 levels) and two between subject variables (the presence or absence of consistent information about category membership presence of feedback) was performed. The analysis yielded only a significant main effect of continuum position, $F(12,528) = 55.73$, $p < 0.001$. No other effects approached significance in this analysis, $p > 0.15$.

Reaction Times

The mean reaction times for each group are plotted against the distance from A along the A-B continuum in Figure 6. ANOVAs were performed on the mean reaction times for each participant.

A single mixed design ANOVA, with one within subject variable (continuum position, 13 levels) and one between subjects variable (training, 4 levels) revealed a significant main effect of group, $F(3,44) = 3.38$, $p = 0.026$, and of position along the continuum, $F(12,528) = 5.64$, $p < 0.001$. There was no significant interaction between the two factors, $F(36,528) = .90$, $p > 0.6$. A Tukey HSD test performed on the group factor revealed that the Match to Label condition with feedback was found to be significantly slower than the Free Classification condition, $p < 0.05$. A mixed design ANOVA, with one within subject variable (continuum position, 13 levels) and two between subject variables (the presence or absence of category membership information and the presence of feedback) was performed. This revealed a significant effect of category information, $F(1,44) = 4.54$, $p = 0.039$, with the label conditions showing the longer mean

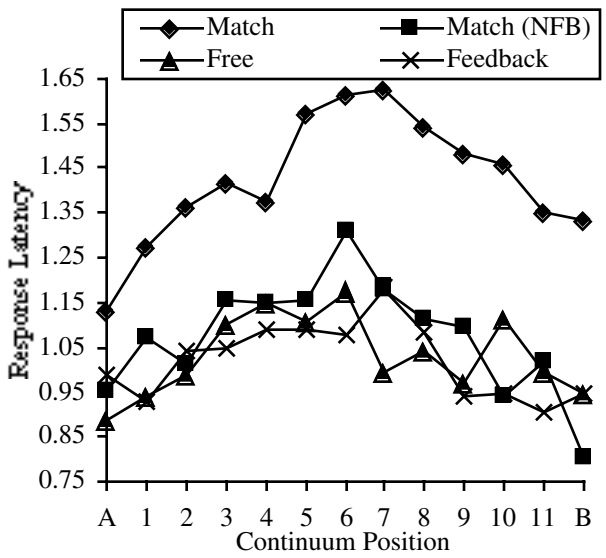

Figure 6: Reaction Time Data for All Groups in Experiment 2

reaction times, and the expected main effect of continuum position, $F(12,528) = 5.64$, $p < 0.001$. No other effects were significant in this analysis, $p > 0.09$.

General Discussion

The results from Experiment 2 are broadly in line with those obtained in Experiment 1. The inclusion of a consistent category label appears to have a detrimental effect when compared with the requirement to make an active decision about category membership. However, there appears to be a speed-accuracy trade off present in the results. Whilst the Match to Label with feedback (MFB) group are slowest, they also show the greatest difference between the ends of the generalisation gradients. Although this difference is not significant it would be difficult to conclude anything definite on the basis of this alone. However, taken with the results from Experiment 1, it seems clear that the fact that feedback is not present does not seem to have a detrimental effect on the performance shown by participants. Instead it seems that, in some cases, providing an entirely consistent label for the stimuli during training causes participants to perform worse. This is not what would be predicted from Homa & Cultice (1984), and is at odds with the results from Estes (1994) who showed that a condition analogous to the Label condition in Experiment 1 gave better performance on test than when participants were trained using a corrective feedback approach. It may be that the real advantage lies in being able to make active (i.e. self-generated) decisions during training rather than simply being exposed to the stimuli and the appropriate category information (Figure 4). Thus it may be the case that different processes are at work

Conclusion

It seems likely that the most successful approach to modelling such data will come form simple self-organising systems (Rumelhart & Zipser, 1986; Saksida, 1999) which are able to extract the necessary information from the stimuli encountered to form coherent categories through exposure to the stimuli alone. It may be the case that all that is needed is exposure to stimuli in order to extract information about them, and this raises the interesting question of what exactly feedback does if it does not always aid decision making.

Abstract

Previous experimental work has demonstrated that human participants can easily detect a small change in a visual stimulus if no mask intervenes between the original stimulus and the changed version and the inter-stimulus interval is small (Phillips, 1974). Rensink, O'Regan & Clark (1997) have shown that if a mask is used then detecting the change is extremely difficult, no matter how small the ISI is made. This work attempts to establish whether familiarity with a stimulus has any effect on a participants ability to detect a small change in it using Rensink's masking procedure with Phillips' stimuli (checkerboards). Participants were required to make judgements as to whether two stimuli, which alternated with one another in presentation, were the same or different. Some participants attempted the task using just one checkerboard pattern which became increasingly familiar across sessions, others were given new, randomly generated checkerboards for each trial. In both conditions, any change (which would occur on 50% of trials) would only affect one square of the pattern. The results show a clear advantage for the participants dealing with familiar stimuli in detecting any change, and go some way towards explaining why this is so.

Introduction

Phillips (1974) demonstrated how easy it was for participants to detect a change between two stimuli if they were presented one after the other without a gap in a single alternation. This is the Phillips Effect. He also investigated the consequences of inserting a grey mask and a blank screen between the two stimuli. The inclusion of an inter-stimulus interval adversely affected participants' performance, and the presence of a mask made performance even worse. Rensink et al. (1997) demonstrated that the brief inclusion of a grey mask between repeated presentations of two slightly different stimuli made any change extremely difficult to detect. This is the Rensink Effect. Their experiment used electronically altered images which allowed manipulation of the colour, position and presence of an object. Without the mask, spotting the difference becomes trivial, if the stimuli are positioned in the same place and then alternated. Current explanations of this phenomenon cite retinal transients (Klein, Kingstone & Pontefract, 1992) as the mechanism for detecting changes in this latter case, which would be unaffected by familiarity.

Some pilot work using a single participant indicated that the effect of familiarity with the stimuli was likely to be very significant. Hence introducing the notion of familiarity removes some of the difficulties intrinsic to the Rensink Effect and makes the task more similar in difficulty to the Phillips Effect. One drawback of this pilot experiment was that it contained familiar and random trials in each session so after a while the participant became able to tell which were the familiar trials, and this may have differentially affected the responses to each trial.

Nevertheless, the results of the pilot experiment (Figure 1) allowed the prediction that the Familiar condition would lead to better detection of changes than the Random condition. It was also predicted that there would be an improvement in performance as the amount of time spent on the task increased.

The main aim of this work was to take the Rensink Effect, and attempt to ameliorate it, by allowing participants to practice on the same stimulus all the time. This would require the use of a different type of stimulus, as the repeated use of a real life scene would be impossible to control properly, so checkerboards were used as the training stimuli. In this way, the participants were presented with essentially the same stimulus on every trial, but with the possibility of a change in one of the elements within the

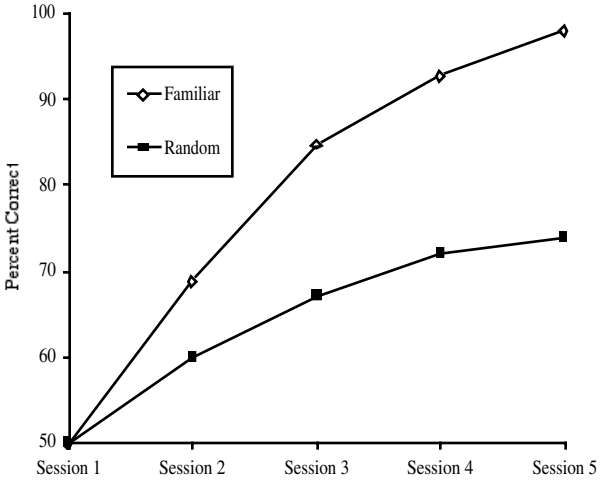

Figure 1: The Basic Familiarity Effect

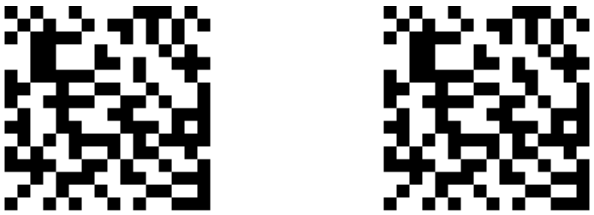

Figure 2: An example pair of chequerboard stimuli.

checkerboard. An example pair is shown in Figure 2) with the difference being rather difficult to spot.

Once a reliable difference had been found between the Familiar and Random groups, subsequent testing concentrated on the mechanism being used by participants to detect the changes.

Experiment

The experiment was conducted with two groups, each with different sets of stimuli. The Random group was a control group, and received different, randomly generated checkerboards for each trial during the experiment. In the Familiar group, each participant was trained on a single checkerboard unique to that participant. The primary aim of the experiment was to determine whether familiarity with the stimulus affected the participants' performance.

Initially two participants were run in each condition followed by a preliminary analysis. It was found that a large difference between the groups had already been established, and the final four participants were all run in the familiar condition. This allowed manipulations in the familiar condition, namely test blocks which departed from the standard task. The test blocks used manipulations intended to disrupt the performance of the participants in the Familiar group in the hope that this would suggest a possible mechanism for the way the changes were being detected. Clearly an effect of familiarity or session needed to be established first, as there is no directly relevant and properly controlled research in this area.

Stimuli and Apparatus

All the stimuli were randomly generated, two centimetre square checkerboards, with sixteen elements on a side giving a total of 256. Each base pattern stimulus had equal numbers of black and white squares, before any change was introduced. An example pair for the change condition is shown above (Figure 2), with the difference between the two checkerboards in the top right centre of the stimulus. Checkerboards were chosen as they are easy to manipulate for this type of experiment. Many different individual changes could be made whilst keeping the majority of the stimulus the same. In addition, the participants were unlikely to be familiar with the stimuli prior to the experiment

Those participants assigned to the random condition were given a newly generated checkerboard on each trial, whereas those in the familiar condition were always presented with the same pattern, albeit with a change on half the trials.

The experiment was run in a quiet room on an Apple Macintosh LCIII computer using a colour monitor. Participants responded to the stimuli by pressing one of two keys, either [x] or [.] on a QWERTY keyboard. Between blocks, participants were required to fill in a sheet to record their errors and reaction times before pressing the space bar to continue to the next block. The responses for each block were logged in separate data files.

Participants and Design

In total eight Cambridge undergraduates took part in the study. Four were allocated to the initial phase to determine the possible existence of a familiar/novel distinction. Two participants were allocated to the novel condition and two to the familiar condition. The remaining four participants were all allocated to the familiar condition.

The experiment consisted of a training phase for all participants and a test phase for those participants in the familiar group. The first four sessions were used for training for both groups, with the fifth session containing some test blocks for participants in the Familiar condition. All sessions for the random group were identical, as the tests given to the familiar group would have made no difference to a participant receiving a new checkerboard on every trial. Each one hour session consisted of ten blocks of stimuli, each containing 24 trials giving 240 trials in a session. Each block contained twelve trials where a change was present and twelve where there was no change between the two checkerboards. These trials were presented in a random order.

Participants were asked to try to detect a change between the two checkerboards, and respond appropriately as to whether or not they thought that a difference was present. For each trial, two checkerboards were alternated with one another, separated by a randomly generated mask. These checkerboards were either the same, or differed by one element within the pattern, i.e. one element that was black in one checkerboard was white in the other. The trials were such that each checkerboard was displayed for 500 milliseconds and the mask for 100 milliseconds. Over one trial, each checkerboard could be presented ten times, giving nineteen changes in a trial if the checkerboards were different. After the final alternation, the trial ended and if no decision had been made by the participant, then they were timed out.

During the fifth session, the participants in the familiar group were given test blocks in between familiar blocks, in an attempt to determine how they might be detecting the changes. These test blocks were ones containing random trials, such as those given to the participants assigned to the random group, and another type of block, labeled "C". In these blocks, there was always a fixed, random one square difference from the original base pattern, on both checkerboards, whether the trial was one of change or no change. This fixed change was different on each trial within the block. On change trials, there was also an additional change made to one of the checkerboards. This manipulation ensured that some difference from the base pattern was no longer a cue for change, although there was still a single change present between the two checkerboards

on change trials. The idea behind this manipulation was to contrast any changes in performance on "C" trials with that obtained on Random trials. In the former case, the perturbation of the familiar pattern is minimal, in the latter case it is, in some sense maximal. The sequence of blocks was: Familiar, "C", Familiar, Random, Familiar, "C", Familiar, Random, Familiar, "C". This gave three Familiar (as the first block is removed from any analysis), three "C" and two Random blocks to be used in the analysis for each participant from a session of ten blocks. The Familiar blocks were inserted between the test blocks to allow the participants an opportunity to re-establish baseline performance before the next test block was administered.

Procedure

The participants were seated in front of the computer approximately 50 centimetres from the screen and asked to make themselves comfortable. They were then read the instructions concerning their task, and were then asked if they had any questions about the instructions they had just been given. The participants were asked to respond to a "change" trial with their left index finger, by pressing the [x] key, and to a "no change" trial by pressing the [.] key with their right index finger. The participant was then asked to press the space bar to begin, and follow the on screen instructions that occurred throughout the experiment. The experimenter waited in the room until the first few trials had been completed, to ensure that the participant fully understood what it was that they were meant to be doing before leaving the room. Each block was started by pressing the space bar. The trials consisted of the alternation of two checkerboards, with a random black and white dot pattern mask being presented between presentations of the checkerboards. These checkerboards were either the same or differed by one element. The checkerboards subtended a visual angle of approximately two degrees and were presented in the centre of the screen. The participants were given feedback on each trial, with the words "correct" or "error" being displayed on the screen. If an error was made, the computer also beeped. After each block of twenty-four trials, participants were required to record their errors and reaction times on a sheet provided for them in the room. This was primarily to get the participants to take a break between blocks. It also gave a readily available source of data that could be tallied with the analysis on the computer. At the end of the session of ten blocks, the participants were given a short questionnaire to determine how motivated they were feeling during the session and what, if any strategy they were using.

After the questionnaire had been completed the participants were thanked for their time and the next session was arranged. After the fifth session, a more thorough questionnaire was administered, and the participants were paid and thanked for their participation.

Results

The basic familiarity effect is shown below in Figure 3. The Familiar and Random groups are denoted by F and R respectively. The graph shows that both groups improved at the task at roughly the same rate, but that performance in the Familiar group is better than that in the random group on all sessions by a roughly constant amount.

The initial analysis focused on finding significant effects of both group and session. Three dependent variables have been determined for each session: overall accuracy; percentage of changes detected; percentage of correct no change trials. Each of the three variables used may indicate something different about the way that the participants may be performing their task.

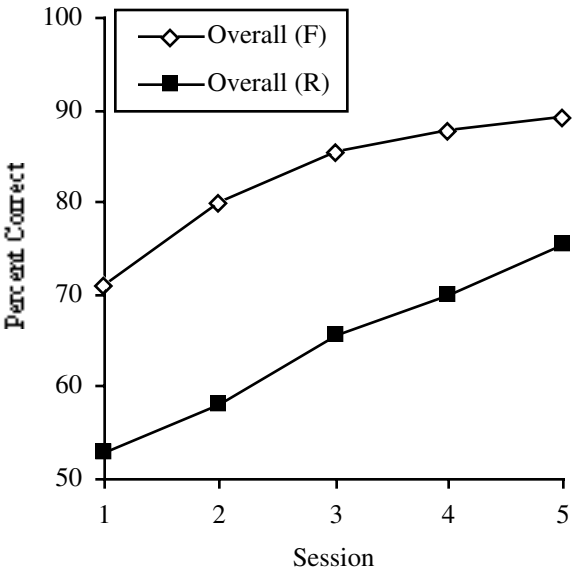

Figure 3: Between Groups Familiarity Effect.

Table 1: Within Session Comparisons between Random and Familiar Groups

(All probabilities are one-tailed)

	Overall Percentage Correct	Percentage of No Change Trials Correct	Percentage of Changes Detected
Session 1	U=0, p=0.022	U=0, p=0.023	U=0.5, p=0.032
Session 2	U=0, p=0.022	U=0, p=0.020	U=1, p=0.046
Session 3	U=0, p=0.022	U=0, p=0.022	U=0, p=0.022
Session 4	U=0, p=0.022	U=0, p=0.020	U=0, p=0.023
Session 5	U=0.5, p=0.033	U=0, p=0.017	U=1, p=0.048

Table 2: Between Session Comparisons Collapsed across Groups

(All probabilities are one-tailed)

Change between Sessions	Overall Percentage Correct	Percentage of No Change Trials Correct	Percentage of Changes Detected
1 and 2	T=1, p=0.009	T=5, p=0.034	T=2, p=0.013
2 and 3	T=0, p=0.009	T=2, p=0.036	T=0, p=0.014
3 and 4	T=2.5, p=0.024	T=6.5, p=0.100	T=6, p=0.046
4 and 5	T=6, p=0.173	T=0, p=0.008	T=8, p=0.156

Only non-parametric tests were used to analyse the data, as there were both small and unequal numbers in the groups. A significance level (α) of $p<0.05$ was used for all analyses. In each session, the score from the first block was not included in any subsequent analysis. This was to allow the participants an opportunity to practice the task before the session proper began. Means for each variable for a given session were used for all analyses. In the session 5 analyses, the different block types were separated and then the average for each variable was used.

Differences between Groups

This analysis compares the performance of the two groups on all three variables. For session five, only the familiar blocks are used for the analysis. The Mann-Whitney U-Test is used to compare the two unrelated samples.

The effect of group is so large that the difference between the Familiar and Random groups is significant for all variables in all sessions. In each case the percentage is higher for the Familiar group. A summary of the statistical results obtained from the analyses for comparisons between the Familiar and Random groups for each session is given in Table 1. Probabilities reported are one-tailed following the results of the pilot work discussed in the introduction.

Differences by Session

The test used in these analyses was the Wilcoxon Matched Pairs Test, as the values being compared were from the same participant, tracking their improvement as the sessions progressed (Table 2).

The effect of session is also a major factor in the performance of all the participants. Early in training there is the greatest effect of session, where participants rapidly become more familiar with their task and are able to improve easily. In later sessions, ceiling performance is being approached, so the difference between subsequent sessions will not be as great and the effect will be reduced.

Results from Session 5

The differences between the variables for the different blocks were compared. The comparisons of greatest interest were between the familiar and "C" test blocks and the performance of the participants in the familiar group on the random blocks compared with the performance of the participants trained solely on random stimuli. The predictions made for the effect of the test are that the participants' performance will be worse on the test blocks than on the familiar blocks presented during the session. This prediction was made as the familiar stimulus which the participants have been trained was to be distorted, to a greater (Random blocks) or lesser ("C" blocks) extent in session 5. It was deemed extremely unlikely that these manipulations would improve performance, hence one-tailed probabilities were used.

Figure 4 shows the data obtained in session 5. The Familiar, "C" and Random entries in the histogram are the averages for each block type collapsed across all the participants in the Familiar group. The control group has been included so that their performance can be compared with that of the Familiar Group on the Random blocks.

When comparing the familiar with the random blocks, all three variables produced significant results. The familiar blocks produced higher scores in the overall percentage correct (T=0, p=0.014) and the percentage of change (T=0, p=0.014) and no change trials correct (T=0, p=0.015). The Random group have been trained on the general task of detecting one square changes within a randomly generated checkerboard. The Familiar group

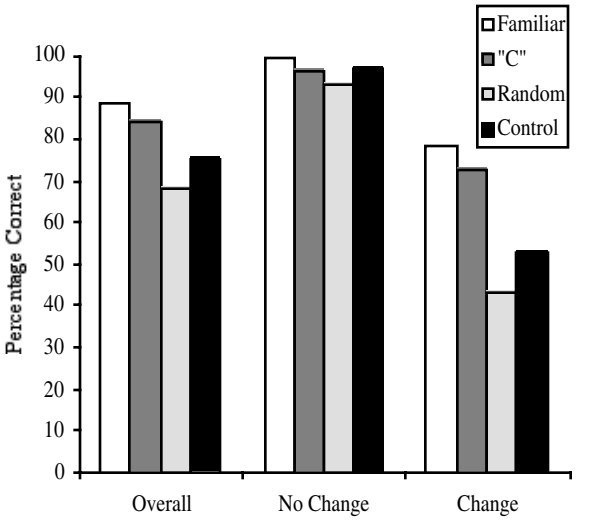

Figure 4: Comparisons between different blocks during Session 5.

have been trained on a task which can be considered as much more specialised. Using the task on which the Random group have been trained allows the comparison between the their performance and the performance attained by the Familiar participants to see if there is any overall advantage of training on a unique stimulus. No significant differences were found for any of the three variables when comparing the performance of the participants in the random group with the scores obtained by the participants in the familiar group on their test blocks with randomly generated stimuli. If anything, the familiar group participants were worse on these trials (Figure 4).

Comparing the results from the familiar and "C" trials, the only significant difference was found between the scores for the percentage of no change trials correct ($T=1$, $p=0.039$) with performance on the familiar trials being better. The other variables were found not to have any significant difference between them. Figure 5 shows the elevated false alarm rate for the "C" condition when compared with the Random and Familiar trials in session 5 and also the control group. The difference between the "C" condition and other blocks is significant in both cases ($T=0$, $p<0.05$). For this analysis, only trials where a response was made are included, thus removing any occasions on which a decision was not made in time.

Figure 5 illustrates the differences in false alarm rates for the four different cases from session 5. These rates for the Familiar participants, using their familiar stimulus, and the control group are on zero, as they registered no false alarms.

Discussion

The effects of session and group have been found to be significant. Although this is not in itself surprising, these two effects had to be established before any further investigations could be carried out. The main effect of group was surprising in its magnitude, with the effect being carried through the sessions. If the participants were allowed to reach asymptotic performance, the prediction from the pilot study is that this significant difference would be maintained. However, this prediction cannot be confirmed as the Random group were not trained for long enough to allow their performance to plateau.

Although the effect of group may have been expected with it being easier to detect changes in a stimulus that is familiar, it could have been the case that there was no difference. If the participants were simply detecting the change between the two checkerboards, then there might have been no difference in the scores. It could have been the case that the unchanging part of the pattern was irrelevant as it was the change between the checkerboards which was being probed. However, the demonstration of a difference between the groups implies that there must be another process at work, apart from the mechanism being used to detect the changes themselves. This position is supported by the finding of no significant difference between the two groups of participants when tested on the random stimuli in session five. Whatever the mechanism

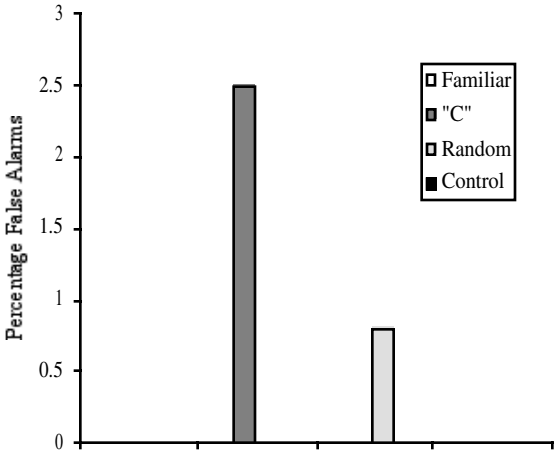

Figure 5: Comparisons of False Alarm rates during Session 5.

favouring the Familiar group, it is specific to the familiar stimuli and not some global strategic advantage developed during training.

The questionnaires administered after the sessions give an insight into how the participants were trying to detect the changes. Every participant reported using a scanning strategy, starting in a particular place for each trial, and then working around the checkerboard, attempting to spot the change. Participants in the random group employed this method throughout their sessions, with no modifications. Participants allocated to the familiar group also used such a strategy, but they reported some modification in later sessions. The scanning became faster, whilst still improving in accuracy between the sessions, there was also a chance to learn about the pattern. They were able to divide the stimulus into sub-patterns and detect changes in these, rather than searching for a single change. This certainly seems to make the detection of differences easier, as performance for the Familiar group was significantly higher for all variables during all five sessions.

The test session produced a significant difference between the percentage of no change trials detected for the "C" blocks and the familiar. In the "C" blocks, there was always a random one-square difference in the checkerboard pairs from the original, familiar stimulus. This additional fixed difference made sure that novelty from the familiar was no longer a necessary signal that there was a difference between the two checkerboards. Many of the participants reported that they had noticed the additional fixed change, and were consciously trying to avoid mistaking it for the actual change between the checkerboards. This result implies that novelty, in addition to a strategic search is central to the task being performed by the participants in the Familiar group. If it were solely a search strategy, then there should be minimal disruption of performance on test blocks which involve a minimal change in the familiar stimulus. The

analysis of the false alarms (Figure 5) supports this position, as there was a greater disruption to the participants on the "C" trials than on the Random trials, where the stimulus was completely different from the one that they were familiar with, and despite the fact that overall performance was significantly lower on the Random trials.

Conclusion

There is good evidence that stimulus familiarity makes it easier to detect a change in that stimulus when compared with participants trained on random stimuli. This is in addition to the necessary attentional requirements reported in Rensink et al. (1997). The ability to detect the change improves with increasing familiarity with the stimulus. However, this ability is limited to that particular stimulus, or ones very close to it, and there is no advantage for other random stimuli of the same type as shown by the test blocks given in session 5.

The mechanism for the detection of the change may be based, at least in part, on novelty. The use of a distracting fixed change induces more false alarms on no change trials than would otherwise be expected. This result indicates that the strategy of scanning the image for change cannot completely account for the enhanced ability to detect the changes. The method for detecting the changes in a given stimulus may involve a combination of better stimulus scanning and the use of novelty to discriminate between familiar stimuli. It is likely that both mechanisms are important in the detection of change. The degree to which each is employed will doubtless depend on both the type and familiarity of the stimulus.

Abstract

This paper explores a mechanism underlying cue-readiness in insight problem-solving. Cue-readiness is concerned with situations where previously neglected information suddenly and unexpectedly becomes illuminative. From the view point of dynamic constraint relaxation theory (Suzuki & Hiraki, 1997), this can be explained by constraint relaxation caused by noticing failures. The theory predicts that constraint violations increase during the problem-solving process, and that a specific combination of constraint violations takes place which leads people to an insight. In this paper, we examined the time-course differences of frequencies of constraint violations, and of sensitivity to the crucial information using a rating task. Although Experiment 1 did not provide supporting evidence, in Experiment 2 we found increased frequency of constraint violations during problem-solving, and that subjects who experienced more failure were more sensitive to crucial information. These results are discussed in terms of other theories of insight.

Insight, one of the most outstanding cognitive activities, is more and more a topic within the scope of rigorous scientific investigation. For the past decade, various approaches have been taken to explore the nature and processes of insight (see, for example, Sternberg & Davidson, 1995).

However, there still remains a mystery. People sometimes find a crucial cue in a relative early stage of problem-solving, but they cannot make use of it. This cue, however, suddenly and unexpectedly becomes illuminative at a certain point, leading problem-solvers to an insight. To put it another way, the same cue has different meanings during the problem-solving process. This can be called "cue-readiness" because it appears analogous to developmental readiness in that the effectiveness of instructional intervention depends on the child's developmental stage.

A good example of the cue-readiness is found in Kaplan and Simon (1990). They used the mutilated checkerboard (MC) puzzle as a material. To solve this puzzle, it is crucial to realize the parity of differently colored squares. In order to control the ease of noticing parity, some subjects in their experiment were given a special board where a word, Bread or Butter, was printed on each square (bread and butter connote parity), instead of colors black or pink. As they predicted, subjects noticed parity more easily and solved the puzzle more quickly. However, they reported one puzzling result. The times from their first mention of parity to the final solution were longer for these subjects than those who were given a standard checkerboard or blank one. While subjects with a Bread–Butter board took 653 s on average to solve the puzzle from their first mention of parity, those with a standard checkerboard took only 110 s.

The problem immediately poses the questions of why people can make use of the crucial cue that they could not do so initially, and what distinguishes the internal states in these two situations.

This problem cannot easily be explained by current theories. Theories based on spread of activation presuppose that the inappropriate problem representations prevent problem-solvers from retrieving an important cue. If this explanation is correct, people could solve the puzzle immediately after noticing the important cue, because the representation of the cue should be activated and the activation spreads over to related information. In the MC puzzle case, subjects could obtain an insight immediately after they mentioned parity.

The idea of the prepared-mind proposed by Seifert et al. (1995) appears to be relevant to the cue-readiness problem. According to them, when people find a standard approach inappropriate, they generate failure indices that mark initial problem solving attempts as unsuccessful. These failure indices are presumed to have the special status in long-term memory, in the sense that they are activated for a longer period than other types of memory traces. In the incubation phase where people stop their initial attempts and are engaged in other activities, a relevant cue is sometimes provided externally, which reminds them of their initial failure and leads them to an AHA experience. We agree that failure and externally provided information play important roles. However, this idea cannot be applied directly to the cue-readiness problem, because their idea deals with a situation where people do not encounter or find crucial information in the initial phase but are given that information externally in the incubation phase. The cue-readiness problem is, however, concerned with a situation where people find crucial information in the initial stage.

In order to deal with the cue-readiness problem, we have developed a dynamic constraint relaxation theory of insight (Suzuki & Hiraki, 1997; Hiraki & Suzuki, 1998).

In the next section, we briefly illustrate the theory.

Dynamic Constraint Relaxation

The dynamic constraint relaxation theory consists of three kinds of constraints (object-level, relational, and goal), and a relaxation mechanism. The main idea is that impasses are formed by these constraints and that qualitative changes are caused probabilistically by the failure-driven incremental relaxation of these constraints.

Constraints

Since it is unlikely that we are equipped with a special cognitive engine for insight problem-solving, it would be desirable that theories of insight do not involve insight-specific mechanisms. One of the most important findings in problem-solving research is that people construct a problem representation consisting of objects, relations, and a goal of the given problem. Reflecting on these findings, we postulate three constraints with objects, relations, and goal. Although the notion of constraints in insight literatures is not new (Isaak & Just, 1995; Knoblich et al., 1999; ; Ohlsson, 1992), our treatment is different from theirs and very similar to analogy (Holyoak & Thagard, 1995).

Object-level constraint There are numerous ways of encoding objects. However, we have a natural tendency to encode them at a basic level (Rosch, 1978). This tendency sometimes becomes an obstacle for insight. For example, in the "Candle" problem, it is well known that people do not notice a pasteboard box of tacks as a holder of the candle. This is because the basic level of a box is "box," not a "solid body" (more abstract) or a "pasteboard box" (more concrete).

We call this tendency the object-level constraint, because it constrains, among possible alternatives, the selection of a specific encoding of a single object. Note here that the constraint is a soft one. It is not that this constraint precludes any other encodings.

Relational constraint Relations define the ways in which objects relate to one another, and each object is assigned a specific role within the relation. Usually, one can relate something to others in various ways. The box in the candle problem, for example, can interact with others in ways of containing, standing on, being thrown to, other objects. However, people usually select the "contain" relation as its default relation.

We call this tendency the relational constraint, because it leads people to select specific relations among numerous alternatives. This constraint is, like object-level constraint, a soft one.

Goal constraint The representation of a goal involves the desired state and evaluation function. This constraint evaluates a match between present and desired states, and gives feedback to the other constraints. Thus, the goal greatly constrains how objects and relations are represented. Although a relation of a candle to other objects is, by default, to light something, a relation such as to glue something by its wax is likely to be selected by the goal constraint.

It is important to note that these constraints interact each other. For example, one reason why the "tacking" relation is selected for the tack is that the basic level encoding of the tack enhances this selection. Another reason is that the goal constraint prevents them from being thrown.

In ordinary problem-solving, these constraints play important roles by eliminating an infinite number of useless representations. However, as noted above, they operate in a harmonious way to form an impasse in insight problem-solving.

Relaxation mechanism

It is important to note that each constraint is not constant during problem-solving, but that its strength changes dynamically. In the course of problem–solving, the mismatch computed by the goal constraint decreases the strengths of initially dominant constraints, which leads to an increase in the probability of constraint-violations. When specific constraint violations occur simultaneously at object-level and relational level, people reach an insight.

In this constraint relaxation process, failure or mismatch detected by the goal constraint plays a key role. A current computational model uses a sort of Q learning algorithm to relax the constraints (Hiraki & Suzuki, 1998). The basic idea is that the strength of the constraint responsible for the failure is reduced to some degree and that the amount of the reduction is distributed to other less dominant constraints by the softmax algorithm (Bridle, 1989).

The dynamic constraint relaxation theory owes much to the multiconstraint theory of analogy (Holyoak & Thagard, 1995). Types of constraints are similar between the two. This is partly because both theories are based on the general characteristics of human problem-solving. However, a crucial difference is that multiconstraint satisfaction often leads to a fruitful analogy, whereas constraint violation leads to an insight in insight problem-solving. Another important difference is that whereas constraint relaxation is purely internal in ARCS and ACME, our theory presumes dynamic interaction with the external environment via feedback.

Previous Studies

We used the T puzzle, similar to the tangram, as material. The goal of this puzzle is to construct the shape of a "T" using four pieces depicted in the left side of Figure 1. At first glance, it appears quite easy to solve, since there are only four pieces and one can easily identify possible positions that some of them should be placed. However, a pilot study, in addition to our own experiences, showed that it is awfully difficult. It usually takes more than half

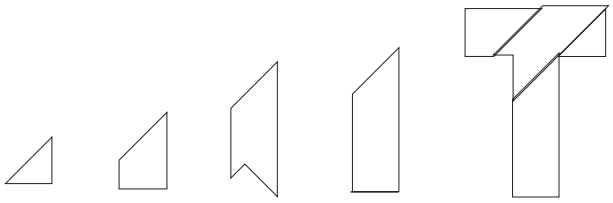

Figure 1: The T puzzle: Construct a shape of "T," using four pieces on the left side.

an hour to solve it spontaneously. Furthermore, more than a few give up trying to solve it.

The difficulties can be explained by the constraints described in the previous section. The object-level constraint in this puzzle is concerned with the preference for how a single piece should be placed, because pieces are objects in the problem representation. People have a strong tendency to place the pentagon piece either horizontally or vertically (Suzuki & Hiraki, 1997). A previous study revealed that subjects placed this piece horizontally or vertically in about 70% of their trials.

The relational constraint in this puzzle is concerned with how one piece is physically connected to one another. The puzzle of this type has an infinite number of relations, because one can produce different patterns by sliding a side of a piece touching another. But, again, people have a strong tendency to connect pieces so as to form a "good" shape with fewer angles. If this constraint actually operates with the goal constraint that evaluates the difference between the current shape and the image of T, it is predicted that people spend most of their time filling the notch of the pentagon. The prediction was confirmed by a previous study which showed more than 70% of the subjects' trials involved notch filling.

Experiment 1

Since our theory predicts that the frequency of constraint violation increases during problem-solving by noticing failure, we analyzed the time-course of constraint violation in Experiment 1. Another dependent variable was subjects' rating score. We used a rating task where subjects evaluated the closeness of various types of combinations of two pieces to the goal. The rating materials were a set of combinations of the pentagon and one of the other pieces, produced by systematically violating the constraints. To control the degrees of relaxation, we divided subjects into two groups, 2-min and 7-min conditions. Subjects were required to solve the puzzle for two or seven minutes, then proceeded to the rating task.

Since subjects in the 7-min condition have failed more often than those in 2-min condition, the theory predicts that the degree of relaxation is higher in the former than in the latter (this is an empirical issue to be examined later). If so, their ratings should be different. According to the theory, the 7-min subjects are more sensitive to crucial information in the rating stimuli than the 2-min subjects. Hence, we expect a statistical interaction between the types of stimuli and before-rating times (2- and 7-min).

Method

Subjects Participants were 33 undergraduate students without any prior experience to solve the T puzzle. They were randomly assigned to 2-min or 7-min condition. We omitted subjects who solved the puzzle before the rating task. Resulting 26 subjects (12 in the 2-min and 14 in the 7-min conditions) were analyzed.

Rating Materials The rating materials consisted of 12 combinations of the pentagon and one of the other pieces (big, small trapezoids, or triangle). These combinations formed four types: O–R– where neither constraints were violated, O–R+ where not object-level, but relational constraint was violated, O+R– where the violating pattern was reversed, and O+R+ where both constraints were relaxed. Since each type had three members depending on which piece was used (big, small trapezoids, or triangle), the total number of rating stimuli was 12.

Procedure The subjects were given the four pieces of the T puzzle and a sheet of paper printed with a 25% reduced-size image of a constructed T. Subjects were asked to construct the shape of "T" using the pieces, with the information about the time allowed to spend before the rating task (2 or 7 minutes).

In the rating task, they were told to rate how close a presented stimulus was to the shape of T with respect to the goal of constructing T, and to click "10" if the stimulus was very close, "0" if it was far from the goal, and other numbers for the intermediary degrees of closeness. Stimulus was presented in a semi-random order that stimuli belonging to the same type were not presented successively. Stimulus presentation time was two seconds, and time for the rating was five seconds.

After completing the rating task, the subjects were asked to resume solving the puzzle. If subjects could not solve the puzzle within 10 minutes from the beginning, the experimenter gave subjects the first hint not to fill the notch of the pentagon (the hint for the violation of the relational constraint). When subjects could not solve the puzzle within five minutes after the first hint, the experimenter gave the second hint not to place the pentagon horizontally or vertically. The entire problem-solving processes were video–taped for the later analysis.

Results and Discussion

To analyze the problem-solving performance, we used a segment as a unit of analysis, in addition to the solution time. A segment is operationally defined as a series of actions that was initiated by physically joining two pieces and terminated by their separation. A segment roughly corresponds to a trial that begins with trying an approach and ends up with noticing failure. It is worth noting that

the notion of segment is not a subjective one, because the definition is based only on physical connections and separations of pieces.

Constraint violation To analyze the time-course of constraint violation, we divided problem-solving processes into four phases, based on the segments (segments after the hints were not included). We counted a segment as a violation of object-level constraint, if the segment did not include the horizontal or vertical placement of the pentagon. We counted a segment as a violation of the relational constraint, if the segment did not have actions to fill the notch of the pentagon by other pieces. Since we found no difference between the two conditions, we merged data obtained from 2- and 7-min conditions. Table 1 shows the proportions of constraint violations in each phase. We conducted one-way ANOVAs for the violation of each constraint separately. We could not find significant time-course difference in the number of segments where the constraints were violated.

Table 1: The percentages of constraint violation in each phase.

	1/4	2/4	3/4	4/4
object-level constraint (%)	24	21	25	25
relational constraint (%)	36	38	38	46

Presenting various types of stimulus did not have a strong effect on the problem-solving performance. The proportions of subjects who solved the puzzle within three minutes after the rating task were 25% in the 2-min condition, and 28.6% in the 7-min condition. These results suggest that majority of the subjects were unable to utilize the useful information presented in the rating task. Additionally, the solution times were not different between the two conditions ($U_{2-min}(12,14) = 66, ns.$).

Rating Before analyzing the rating task data, it is necessary to examine the assumption about constraint-relaxation. Our theory predicts that the more often subjects fail, the more relaxed their constraints are. Hence, we must first examine whether the subjects in the 7-min condition actually failed more often before the rating task than those in the 2-min condition. As we expected, the average number of the segments before the rating task in the 7-min condition was 45.6, while that in the 2-min condition was 17.4 ($t(24) = 7.79, p < 001$).

Table 2 shows the rating score for each type of stimulus. Although the ratings for R–O–, R–O+, R+O– were not different between the two groups, it appears that the 7-min subjects rated the R+O+ type stimuli closer to the goal than the 2-min subjects did. Thus, we conducted a three-way ANOVA to examine the interaction between the types of the stimulus and the conditions. However, the interaction did not reach the significant level ($F(3,72) < 1, ns.$), although there was a main effect of the stimulus types ($F(3,72) = 10.93, p < 005$). Pair-wise comparisons revealed that for both conditions, the R+O+ type was rated closer to the goal than the other types.

Table 2: Mean rating score.

	R–O–	R–O+	R+O–	R+O+
2-min	2.73	2.96	3.90	4.29
7-min	2.83	3.04	3.94	5.35

Experiment 2

The results of Experiment 1 did not support the hypotheses. We found no time-course difference in the frequencies of constraint violations. Furthermore, there was no statistical interaction between the rating scores and the problem-solving time before the rating task. Do these results dismiss the dynamic constraint relaxation theory?

There is, however, the possibility that even for the 7-min subjects, the constraints were less relaxed than expected. According to our theory, one reason is concerned with the goal constraint. As described earlier, the goal constraint plays crucial roles by evaluating the match between the goal and the present state and by giving feedback to the constraints for their relaxation. Actually, previous research revealed that the goal constraint greatly facilitated problem-solving performance (Suzuki et al., 1999). In that experiment, some subjects were given a template sheet printed with an image of a constructed "T," and asked to cover the image by placing the four pieces. Providing the template sheet is expected to facilitate the evaluation of the (mis)match between a current state and the goal. As expected, these subjects solved the puzzle significantly faster than those without the template sheet.

In Experiment 1, subjects were given a sheet of paper printed with an image of "T," but the size was reduced to 25%. In addition, the subjects were not allowed to put the pieces on the sheet. This procedure may cause the goal constraint to operate less effectively. Experiment 2 explores this possibility, by providing the template sheet and instructing subjects to cover the sheet by the pieces.

Method

Subjects Subjects were 20 undergraduate students who had no experience with the "T" puzzle. None of them participated in the previous experiment. These subjects were randomly assigned to either the 1-min or 5-min condition. We omitted three subjects in the 1-min condition and one subject in the 5-min condition who solved the puzzle before the rating task.

Materials The rating materials were 12 combinations of the pentagon and one of the other pieces used in Experiment 1.

Procedure The procedure was basically the same as that of Experiment 1, but there were two modifications.

The first one was to provide subjects with a template sheet printed with an image of "T" and to ask them to cover the image by placing the four pieces. The second one was that the time to solve the puzzle before rating was changed from two and seven to one and five minutes. This was because in a previous study, half of the subjects with the template sheet solved the puzzle within seven minutes.

Results and Discussion

Constraint violation To examine the time course of constraint-violation, we divided the entire problem-solving processes into four phases and counted the number of violations in each quarter, as for Experiment 1. We omitted segments after the hints and merged data obtained from 1- and 5-min conditions. Although the increase of the violation of the relational constraint was not statistically significant ($F(3,48) = 1.07, ns.$), the number of violations of object-level constraints increased dramatically ($F(3,48) = 7.89, p <. 001$). Pair-wise comparisons revealed that the violations of object-level constraints in the final quarter was higher than the others.

The lack of an increase in the number of the relational constraint violations might be due to the fact that the template sheet relaxed the relational constraint from earlier stages. It should be noted that, although the number of constraint violation increased during problem-solving, the constraint violations were observed even in the first quarter. It means that the cue-readiness problem is involved, even when the template sheet was available.

Table 3: The percentages of segments violating the object-level and relational constraints.

	1/4	2/4	3/4	4/4
Object-level constraint (%)	6	19	13	46
Relational constraint (%)	40	41	47	47

Rating As in the previous experiment, we first examined the assumption that 5-min subjects failed more often than 1-min subjects. The average numbers of segments was 50.7 in the 5-min condition and 7.6 in the 1-min condition ($t(11) = 10.15, p <. 001$).

The ratings of each condition were summarized in Table 4. Unlike Experiment 1, we obtained different patterns of ratings. A three-way ANOVA (object-level $\times$ relational constraint $\times$ before-rating time (1- or 5-min)) revealed a significant main effect of the relational constraint($F(1,14) = 41.12, p <. 001$) and interaction between the relational constraint and the time before the rating ($F(1,14) = 10.06, p <. 01$). Although subjects in both conditions gave high rating scores for stimuli that violated the relational constraint, the 5-min subjects gave the highest score for stimuli violating both constraints, whereas the 1-min subjects did so for the stimuli violating only the relational constraint.

Table 4: Mean rating score.

	R–O–	R–O+	R+O–	R+O+
1-min	2.54	2.42	4.38	2.88
5-min	2.58	3	4.04	5.46

General Discussion

In this paper, We propose the dynamic constraint relaxation theory to investigate mechanisms underlying the cue-readiness in insight problem-solving. Our theory assumes that initial impasses are caused by the object-level and relational constraints and that these constraints are gradually relaxed by failures detected by the goal constraint. If our theory is correct, two predictions can be made. First, constraint violations increase during problem-solving processes, because constraints are more relaxed by facing more failures. Second, for the same reason, sudden noticing of crucial information is more likely observed in problem-solvers with more failures than those with fewer. If so, the ratings for constraint-violating stimuli should be different between them.

In order to examine these predictions, we conducted two experiments, using the T puzzle. Subjects' tasks were to solve the puzzle and to rate the closeness of various types of stimulus to the shape of "T." However, we could not obtain any supporting results in Experiment 1. The frequencies of constraint violations did not increase during problem-solving, and the ratings were not statistically different between the 2- and 7-min conditions. However, we found confirming evidence in Experiment 2 where the goal constraint operated more effectively by the template sheet. Violation of the object-level constraint increased when problem-solving proceeded. Furthermore, the ratings of subjects with more failures were different from those with fewer failures in a predicted way.

These results suggest that cue-readiness is caused by constraint relaxation. Due to noticing failure, the probabilities of constraint violations increases during the problem-solving processes, which makes problem-solvers ready to utilize crucial information. Another implication for the problem is that constraint violation at a single level may not be sufficient for insight and it should be coupled with violation at another level.

It is interesting to contrast our theory with a similar view proposed by Knoblich et al. (1999). They have proposed that constraint relaxation and chunk decomposition play key roles in insight problem-solving. Using matchstick arithmetic problems, they found empirical evidence supporting their theory.

Although both theories admit the key roles of constraint relaxation, there are a number of differences between the two. First, constraints used by Knoblich and their colleagues are task-specific. For example, they listed constraints concerning values, operators, and tautology. These constraints are specific to matchstick arithmetic problems, which makes it difficult for their theory

to apply to a large number of insight problems that have no numerical values, mathematical operators, or equal sign.

Second, their theory is not dynamic in the sense that they do not assume any interactions with external environment. In their experiment, subjects were required to *mentally* transform various equations to desired states, which prohibits feedback from the external environment. As Seifert et al. (1995) properly claimed, we obtain information important for modifying our internal states as well as achieving the goal. Therefore, their theory of insight cannot explain findings in the present study, such as the time-course differences of the frequencies of constraint-violation and in the rating patterns observed in Experiment 2.

Third, related to the second, their theory cannot deal with the issue of what relaxes the constraints. They predicted the ease of relaxation based on the notion of the scope of constraints. However, what triggers constraint relaxation remains unanswered. In addition, the scope of the constraint cannot give a principled explanation for the relaxation patterns of the constraints. According to their theory, the relational constraint in our study has wider scope than the object-level one, because the former binds more than one element whereas the latter binds a single element. Thus, their theory predicts that the object-level constraint is more easily relaxed than the relational one. However, we obtained the opposite patterns of relaxation in Experiment 2.

To summarize, we agree that constraints forms an impasse and that insight is achieved by constraint relaxation, but oppose their notion of purely "cognitive" insight as well as task-specificity of constraints.

Extending the Past-tense Debate: a Model of the German Plural

Niels A. Taatgen (niels@ai.rug.nl)
Artificial Intelligence, University of Groningen
Grote Kruisstraat 2/1, 9712 TS Groningen, the Netherlands

Abstract

One of the phenomena that has been studied extensively in cognitive science is learning the English past tense. Many models have been made of the characteristic U-shape in performance on irregular verbs during development. An important test case for such models is whether they can be extended to other examples of inflection. A case that is often quoted as particularly tough is the German plural. In the present study, an ACT-R model of the past tense is applied to the German plural. The model not only successfully learns the default rule, but also exhibits some other characteristics of the German plural.

Introduction

Learning the English past tense has been one of the central topics of debate in cognitive science since McClelland and Rumelhart published their original neural network model in 1986. The phenomenon is very simple. English verbs can be broken down into two categories: regular and irregular verbs. The past tense of a regular verb can be obtained by simply adding *-ed* to the stem. Irregular verbs on the other hand are unsystematic: each verb has a unique inflection. When children have to learn the inflection of the past tense, they go through three stages. In the first stage their use of the past tense is infrequent, but when they use the past tense they do so correctly. In the second stage they use the past tense more often, but they start overregularizing the irregular verbs. So instead of saying *broke*, they now say **breaked*. On the other hand, inflection of regular verbs increases dramatically, indicating that the child has somehow learned the general regular pattern. In the third stage, they inflect irregular verbs correctly again. This pattern of learning is often referred to as U-shaped learning.

Although learning the past tense seems to be a rather simple problem, it nevertheless encompasses a number of issues in language acquisition and learning in general. Apparently the past tense has two aspects: on the one hand there is a general rule, and on the other hand there is set of exceptions. Children are able to learn both aspects, and the phenomenon of U-shaped learning seems to implicate that children learn the general rule in stage 2. The important point McClelland and Rumelhart make is that this does not necessarily imply that this knowledge is actually represented as a rule in the cognitive system: their neural network model has no separate store for rules, but it nevertheless exhibits rule-like behavior in the form of U-shaped learning. Ever since their original model, the neural network approach has been challenged (e.g., Pinker & Prince, 1988), improved (e.g., Plunkett & Marchman, 1991), challenged again (e.g., Marcus, 1995) and improved again (e.g., Plunkett & Juola, 1999). I would like to highlight two unresolved issues in this debate, because they will be addressed here. The first issue is feedback. A well-known fact in language acquisition is that children do not rely on feedback on their own production of language (at least with respect to syntax), simply because they do not receive any (Pinker, 1984). Although this problem is addressed by some modelers (e.g., Plunkett & Juola, 1999), its resolution is not entirely satisfactory: the assumption is that learning takes place while children perceive past tenses, and not while they actually produce past tenses. This idea is at odds with the picture of skill acquisition in general, where practice is considered as a main means of learning. A second issue is the frequency of the regular cases. In English, most verbs are regular. This fact is essential for neural network models, as they need to be presented with regular cases at least 50% of the time (Marcus, 1995). This is already slightly problematic in English, as the token-frequency of regular verbs, how often a verb is actually used in language, is only around 30% (irregular verbs are just used much more often than regulars). Connectionist modelers have therefore introduced the input/uptake distinction: not every word that is perceived is presented to the network. This assumption becomes especially problematic if regular forms are much more rare. An example of inflection where the regular form is very rare is the German plural.

The German Plural

German has five different suffixes to mark plurality of a noun: zero (no suffix), *-(e)n*, *-e*, *-er* and *-s*. Moreover, the stem-vowel sometimes receives an Umlaut (¨), something we will ignore for the present. The plural is almost always indicated by suffixation: there are only a few exceptions, mainly words derived from Latin (e.g., *Thema-Themen*). Careful analysis of these suffixes has revealed that the *-s* suffix is actually the default rule (Marcus, Brinkmann, Clahsen, Wiese & Pinker, 1995). Interestingly enough, this suffix is also the least frequent of all five, both in *type-frequency* (how many words are there) and *token-frequency* (how often are they used). Marcus et al. estimate the type frequency of nouns ending in *-s* at 4%, and the token frequency at only 2%. It appears however that at least some of the other suf-

fixes are somehow tied up by additional constraints: for example, zero and *-er* are never used for feminine words, *-e* cannot be used if the stem already ends with and *e*, etc.

The combination of a default rule that is based on very low frequencies and the fact that there is no feedback on production makes it very hard to understand how the default rule can be learned at all. If there is no feedback, the cognitive system has to construct its own language based on perceived inputs from the environment. But why would the cognitive system always elect to use *-s* as a default rule, while there are other options as well?

A possible source of information on this topic is to look at children, and examine the type of errors they make. Marcus et al. (1995) quote a number of studies that indicate children overregularize using the *-s* suffix (in 10-15% of the opportunities), although it is not the most common overregularization (*-(e)n* is the most common overregularization). This pattern is similar to the English past tense, which has been studied much more extensively, except that in English the default rule is also the dominant source of overregularization.

Regular versus irregular inflection is often characterized by competition between a rule and exceptions. It appears that in the case of the German plural there is also competition among rules, a competition the *-s* rule eventually wins.

To summarize, the German plural is in some sense similar to the English past tense, but more complicated. There is competition among candidate rules, while the English past tense has only one apparent candidate rule, and the eventual rule is based on nouns that have a low frequency, as opposed to the high frequency of regular English verbs. The German plural is therefore an interesting test case for existing models of the past tense in English: can these models successfully account for the German plural as well? Taatgen and Anderson (submitted) developed a model for the English past tense, the present study will show it is extendable to the German plural as well, without many modifications.

Towards a General Model of Regular and Irregular Inflection

The Taatgen and Anderson (submitted) model of learning the past tense is based on the ACT-R architecture (Anderson & Lebiere, 1998). It is a so-called dual-representation model, so it separately represents examples and rules, corresponding to ACT-R's declarative chunks and procedural rules. Although two representations make the model weaker than neural network models that use only one type of representation, it does not need a number of assumptions neural network models need. The ACT-R model does not need a specific input regimen, in which the vocabulary is gradually increased. Neural network models typically start training with a small set of words, in the order of 10 to 20. This number is increased during training. A problem with this approach is that the way in which the input-set is increased can be manipulated to get the desired outcome. The ACT-R model on the other hand can be trained on the full vocabulary right from the start, and with the exact token frequencies as in normal language.

A second advantage of the ACT-R model is that it can learn without feedback on its own performance. The model assumes examples of past tenses are perceived and stored in declarative memory, and that no feedback is given on production. The only feedback the model uses when it produces language is its internal feedback: the effort production took. It will prefer strategies that take the least effort, as opposed to strategies that produce the right answer (as it has no way of knowing what the right answer is). Neural networks have to make additional assumptions to account for the lack of feedback. As a neural net needs to know the correct answer to adjust its weights, it has to learn during the perception of language instead of during production. It is assumed that once an inflected form is analyzed, it is "recreated" by a hypothesis generator. To quote Plunkett and Juola (1999):

> The child is continually taking in word tokens and comparing the words actually heard (e.g., "went") to the tokens that the child's hypothesis generator would have expected to produce as inflected forms of a given stem; when they differ, this provides evidence to the child that the hypotheses are wrong and should be modified. (p. 466)

Although this view on language acquisition is not necessarily false, there is no clear evidence for it, and must be considered as an extra assumption. To summarize, although neural network models need only one form of representation, and are stronger theories in that respect, they are weaker with respect to the shape of the input and the organization of feedback.

One of the main claims of cognitive modeling is that models can be generalized to other tasks and contexts. A model of the past tense should be a stepping stone towards a more general model of regular and irregular inflection in different languages. The first step is discussed in this paper: the German plural. Before I will discuss the model, I will briefly explain a few relevant ACT-R aspects.

Rules and Examples in ACT-R

According to the ACT-R theory and architecture (Anderson & Lebiere, 1998) human memory consists of two long-term stores: a declarative memory and a procedural memory. As ACT-R is a hybrid architecture, representations in both memory systems have symbolic and subsymbolic aspects.

Declarative memory is used to store facts, goals and perceptual information. For the purposes of the model, it will store the words in the vocabulary, and examples of how an inflected form, in this case the plural form, is constructed. The declarative memory may store the fact (called a *chunk*) that "Jahr" (year) is a noun, and that "Jahre" is the plural of "Jahr". Declarative memory may contain false facts along-

side true facts, so it may have a chunk "Jahr"-"Jahren" as well as the correct chunk. Each chunk has an activation value, that represents the log odds that the chunk will be needed in the current context. So ACT-R doesn't really care about truth although true facts are probably more often needed than false facts.

For the purpose of the current model, the main determiner of the activation value is repetition. If a certain chunk is retrieved often from memory, or is perceived often, its activation value will be high. The main effect of activation for the present model is that chunks whose activation is too low cannot be retrieved from memory. Also, if two or more chunks are candidates for retrieval at the same time, the chunk with the highest activation is chosen (more precisely: has the highest probability of being chosen as noise is added to the process).

Chunks cannot act by themselves, they need production rules from procedural memory for their application. In order to use a chunk, a production rule has to be invoked that retrieves it from declarative memory and does something with it. Since ACT-R is a goal-driven theory, chunks are always retrieved to achieve some sort of goal. In the context of inflection of words the goal is simple: given the stem of a word, produce the proper inflection. One strategy to produce a certain inflection is to just retrieve it from declarative memory, using a production rule like:

```
IF    the goal is to produce a certain
      inflection of a word
      AND there is a chunk that specifies this
      inflection for that word
THEN  the set the answer of the goal
      to that inflected form
```

If the goal is to produce the plural of a certain word, this production rule will attempt to retrieve a chunk from declarative memory that specifies what the plural is of that word. Of course this production rule will only be successful if such a chunk is present and its activation is high enough.

The behavior of production rules is also governed by subsymbolic parameters. Each production rule has some real-parameters associated with it that estimate its expected outcome. This expected outcome is calculated from estimates of the cost (in time) and probability of reaching the goal if that production rule is chosen. The unit of cost in ACT-R is time. ACT-R's learning mechanisms constantly update these estimates based on experience. If multiple production rules are applicable for a certain goal, the production rule is selected with the highest expected outcome. This is again a noisy process, so the rule with the highest expected gain only has the highest probability of being selected first. If a rule is selected and subsequently fails, the next best rule is tried. For example, if the example rule above fails to retrieve a chunk that specifies the inflected form, the next best rule will be tried.

New rules are learned through a process of specialization and compilation. In the present model, this process will specialize the general strategy of analogy into specific rules for inflection[1]. I will discuss the details of this process later in the paper.

The Model of the German Plural

Prior knowledge in the model

The model starts out with a set of general problem-solving strategies that are often used in ACT-R models:

1. **Retrieval**. A general strategy for problem solving is to search declarative memory for a case that is identical to the case at hand. If an identical case can be found, it immediately produces the answer, else one of the other strategies is tried.
2. **Analogy**. Another general strategy is to look for a case that is similar to the current problem. After a suitable example has been found, a mapping has to be found between the problem and the answer in the example. This mapping is then applied to the case at hand. In the present model, an arbitrary case of a plural noun is retrieved from declarative memory, after which very simple pattern-matching productions identify the mapping and apply it to the current noun.
3. **Do nothing**. A third strategy is to just do nothing. This strategy is not as stupid as it sounds, as some problems may not be worthwhile solving as long as no additional knowledge is available. The result of doing nothing is that the singular form will be used instead of the plural.

Input

The CELEX database was used to select the 538 most frequent German nouns. After removing the nouns that have no plural, 472 nouns were left. The frequencies of the plural forms are in Table 1. Note that the frequencies for the *-s* suffix are even lower than the Marcus et al. estimates, probably because only high frequency words were selected.

Table 1: Frequencies of suffixation in the CELEX sample

Suffix	Type frequency	Token frequency
-(e)n	48%	50%
-e	34%	35%
zero	11%	8%
-er	5%	7%
-s	1.3%	1%
other	1%	0.4%

To simulate a child's perception and production of plurals, the following input regimen for the model is used: every 2000 seconds, one word is randomly drawn from the set of

1. The process of proceduralization used in this model is not part of ACT-R 4.0, the current version of ACT-R, but is part of a proposal for the next version of the architecture

472 words, based on the token frequency of the word. The model has to produce the plural of this word, simulation production by child. As token frequencies are used, high-frequency words are drawn more often, in the same proportion as they occur in the corpus. Also, every 2000 seconds two random plurals, drawn in the same manner, are added to declarative memory, reflecting perception from the outside world.

Learning

During the simulation, several learning processes influence the behavior of the model, from symbolic to subsymbolic and from declarative to procedural. Table 2 summarizes the different learning mechanisms.

Table 2: Learning mechanisms and their effects

Type of learning	**Effect on the model**
Declarative Symbolic	Examples of plurals are added to memory. Examples are perceived in the environment, and produced by the model itself.
Declarative Subsymbolic	Examples that occur often or are retrieved often are more readily available in memory, as they receive a higher activation. Low-activation examples cannot be retrieved.
Procedural Symbolic	Rules are learned to add specific suffixes to the stem in order to create a plural.
Procedural Subsymbolic	The expected gain of each strategy is estimated based on experience: the rule that takes the least effort to produce a plural is favored.

A first aspect of learning is that new production rules are learned that add the different suffixes to the stems. These rules are learned by specializing analogy. Analogy can be characterized by two steps: retrieving an example from declarative memory and applying this example to the new case. Proceduralization eliminates the retrieval of the example, and substitutes variables in the rules with a certain example. It then combines the two steps in a single step. The result is a rule that approximately acts like analogy, but always with the same example. In the case of inflection, the suffix of the retrieved example determines what the new rule will do: if the example has an *-e* suffix, the new rule will always add the *-e* suffix to produce a plural.

A second procedural aspect of learning is that rules compete. The three strategies mentioned before, together with the rules that proceduralization produces, all compete in producing an inflection. Although they do not receive feedback whether what they produce is correct, they do receive feedback on how much effort it took to produce an inflection. This effort can be influenced by many factors. For example, if the retrieval rule fails to find an example, another strategy has to be tried afterwards, increasing the average effort of retrieval. If a rule produces a suffix that is long to pronounce, using that strategy takes more effort than a short suffix. With respect to this pronunciation effort, the model assumes that using a suffix implies some extra effort. It shares this assumption with the past tense model. Moreover, it assumes the *-s* suffix takes slightly less effort than the other suffixes, because *-s* suffix is just an additional phoneme, while the other suffixes are extra syllables. This is an important assumption, because it will be the main reason why the *s*-suffixation rule will eventually dominate other suffixation rules.

Learning in declarative memory also plays a key role in this model. On the symbolic level, examples of past tenses are constantly added to memory, by perceiving them in the outside world, but also by producing them. The fact that an example is in declarative memory does not guarantee that it can be retrieved. This is where the subsymbolic level is important: activation decays with time, making the example irretrievable. Another aspect of activation is to decide in the case of multiple choices: if two chunks match, the chunk with the highest activation is chosen.

It is important to note than whether or not a produced plural is correct has no impact on the learning. Correctness only plays a role in the examples that the model perceives in the world, but even there an occasional error will not disrupt performance.

Results of the Model

The model was run for 80000 trials, or slightly over 60 simulated months. Figure 1 shows the expected gains of the different rules. Remember that the rule with the highest expected gain is generally tried first, and if it fails the next best rule is tried (although noise may change the order from time to time). Right from the start, retrieval is the dominant strategy. Its expected gain improves quickly as more and more examples are learned. Retrieval is not always successful, so the order of the remainder of the rules is especially important. The rules for the zero, *-e*, *-(e)n* and *-er* suffixes are learned very early in the simulation, and appear to be reasonably productive, as they pass both the do-nothing and the analogy strategy around month 5. Only after 10 months in the simulation the *-s* rule is learned, due to the fact that its occurrences and therefore the opportunities for generalization are rare. Once the *-s* rule is learned, however, it quickly dominates the earlier suffixation rules due to its pronunciation advantage.

The expected gains of the rules have a direct impact on the performance of the model, depicted in Figure 2. As the expected gain of the retrieval-rule increases, the proportion of correct responses also increases (Figure 2a). When after

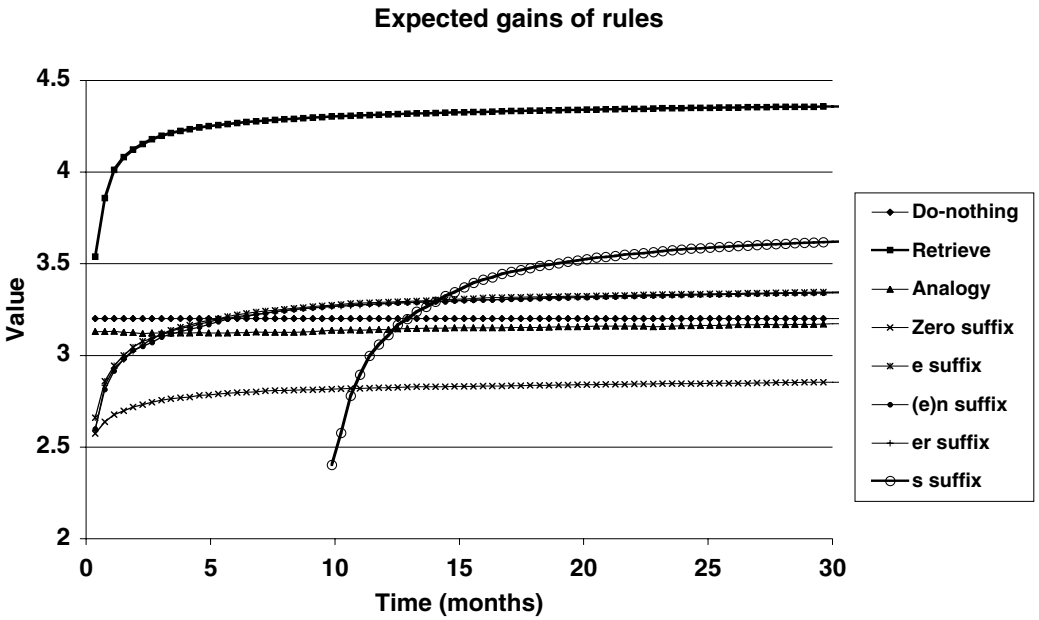

Figure 1: Expected Gains of the different strategies during the first 30 months of the simulation

10 months the *-s* rule is learned, the model starts making errors by adding it to other stems.

Figure 2b shows all the errors that the model makes: at the start of the simulation, errors are dominated by the "do-nothing" rule (producing just stem, so a zero-suffix), as very few plurals are yet known. Soon afterwards, the rules for *-(e)n*, *-e* and *-er* are learned, so they dominate the errors. After month 10, the rule for *-s* dominates the errors, although other errors are still made due to noise, and retrieval of past errors. If we extrapolate the results presented here towards adulthood, the dominant strategy will be to retrieve the plural form from memory. If that process fails, the rules that add the *-s* suffix will be used: exactly what one would expect from a default rule.

Discussion

The present model shows that the original Taatgen and Anderson (submitted) model of the English past tense can be extended to the German plural without modifications. The model is able to learn the default rule despite the low incidence of examples, which is an important problem for other models. But how well does the model fit the data? Unfortunately, the data on the German plural is not as extensive as data on the English past tense.

The basic facts from Marcus et al. (1995) are that German children overregularize by using the *-s* suffix, but also by using other suffixes like *-(e)n*. Also, German children make much more errors in the plural (Marcus et al. quote percentages between 11% and 25% for just the *-s* overregularization) than English children with the past tense (usually less than 10%). Both these facts are supported by the model. The fact that retrieval is the dominant strategy implies that rules play only a minor role in inflection, and that this role is most important during the learning phase, when not all inflected forms are memorized yet. In English, the regular rule for the past tense leads to reasonable performance, as the majority of the verbs is regular. In German, however, the regular rules will generally not produce correct behavior, so it is no surprise children make many errors.

The present model operates on a rather global level, largely ignoring some issues concerning phonetics and gender. Obviously, the *-e* suffix cannot be used when the stem already ends with an *-e*. This would make the *-e* rule less attractive, as it will sometimes fail. Gender may also place additional constraints on certain rules. Furthermore, due to phonological constraints, it is sometimes necessary to add the Umlaut to the vowel in the stem with certain suffixes. The *-s* suffix is free of all these constraints, and can in principle be applied in all cases. Together with the fact that it is also the shortest suffix, this makes the rule the most attractive one, despite its low incidence.

Despite the fact that it largely ignores some of the low-level details, this model demonstrates how generalization in language acquisition can be explained in the absence of feedback. Although it does not solve the learnability problem in language, it nevertheless points at a different source of feedback that may play a role in different areas of language acquisition as well: internal feedback that is not based on the correctness of the produced utterance, but based on the amount of effort it took to produce the utterance.

Acknowledgments

I would like to thank Jack Hoeksema for help in consulting the CELEX database.

The modality effect in multimedia instructions

Abstract

The influence of presentation format on the effectiveness of multimedia instructions was investigated. According to Cognitive Load Theory (Sweller, Van Merriënboer & Paas, 1998) and Mayer's theory of multimedia learning (Moreno & Mayer, 1999), replacing visual text with audio will decrease working memory load and improve learning (modality effect). This hypothesis was tested in two experiments in which students studied multimedia instructions on an instructional design model. The students reported the mental effort spent on the instructions, and made a retention and a transfer test after the instructions. The results show that replacing text with audio is only effective when multimedia instructions are system-paced.

Introduction

Guidelines for the design of multimedia instructions are often based on intuition and practical experience rather than on the results of experimental research (Park & Hannafin, 1994). However, two recent lines of research that have yielded some interesting results are the work by John Sweller and his colleagues on Cognitive Load Theory (Sweller, 1988; Sweller, van Merriënboer & Paas, 1998), and the experiments carried out by Richard Mayer and his colleagues on multimedia learning (for an overview, see Moreno & Mayer, 1999). Both researchers claim that multimedia instructions consisting of verbal and pictorial information, like for example a picture of a machine and a text about its functioning, place a high demand on working memory resources, because the learner has to switch between text and picture in order to integrate them mentally. An interesting finding in their research is that this memory load can be reduced by presenting the verbal information auditorily instead of visually. They call this phenomenon the *modality effect* or *modality principle*. The explanation they give is based on the working memory model of Baddeley (1992). In his model, working memory has two modality-specific slave systems: one for processing visual and spatial information and one for acoustic information. When information is presented in two sensory modalities (visual and auditory) rather than one, both slave systems are addressed and total working memory capacity is increased. So relative to the available resources, the memory load of the multimedia instructions is reduced, leaving more space for the actual learning process.

Sweller and Mayer have demonstrated the superiority of audio over written or on-screen text in a number of experiments. For example, Jeung, Chandler and Sweller (1997) and Mousavi, Low and Sweller (1995) showed that students receiving multimedia instructions with audio spent less time on subsequent problem solving compared to students receiving visual-only instructions. Furthermore, students in experiments by Kalyuga, Chandler and Sweller (1999) and Tindall-Ford, Chandler and Sweller (1997) reported less mental effort during instruction and attained higher test scores, while in the studies by Mayer and Moreno (1998; 1999) students had higher scores on retention, transfer and matching tests. In one experiment, Moreno and Mayer (1999) even used instructions in which the animation and the accompanying text were presented sequentially instead of simultaneously. Despite the temporal detachment of text and picture, bimodal instructions still proved to be superior to visual-only instructions. This shows that the modality effect seems to be at least for some part the result of an increase in available memory resources.

Based on these results, Sweller and Mayer strongly advocate the use of audio in multimedia instructions. However, one limitation of the above-mentioned studies is that they all deal with short multimedia instructions on well-defined technical subjects like geometry (Mousavi et al., 1995; Jeung et al., 1997), scientific explanations of how lightning develops (Mayer & Moreno, 1998; Moreno & Mayer, 1999) and electrical engineering (Kalyuga et al., 1999; Tindall-Ford et al., 1997). This raises the question how powerful the modality effect actually is. Can it also be demonstrated with multimedia instructions that are outside the technical domain and are of greater length? This question is dealt with in the first experiment of this study.

The second issue that can be raised given the evidence so far, is that the results can be explained in more than one way. For example, Jeung et al. (1997), Mousavi et al. (1995) and Tindall-Ford et al. (1997) used visual-only instructions in which the complete explanatory text was printed next to the diagram and

compared it to instructions in which the students only saw the picture and could listen to the explanation. That means that they not only replaced visual text with audio, but also reduced the visual search necessary to link the right parts of the text with the right parts of the diagram. So in their experiments, the difference in effectiveness between bimodal and visual-only instructions could also be attributed to the difference in visual complexity.

On the other hand, Mayer and Moreno (1998; 1999) and Kalyuga et al. (1999) cut their explanatory texts in smaller pieces and still found a modality effect. However, in their experiments the instructions were presented as system-paced animations. The time a student could study a picture and its accompanying texts was determined by the speed of the narration in the bimodal condition. The learners in the bimodal condition could use this limited period of time effectively because they could look at the picture and listen to the text at the same time. The learners in the visual-only condition on the other hand had to spend part of their time in a process of skipping back and forth between text and picture in order to integrate them mentally. We question if the modality effect will still appear if you give the students in the visual condition more time to relate the text to the picture. This issue is dealt with in the second experiment.

Experiment 1

The aim of our first experiment was to see if we could replicate the modality effect using longer multimedia instructions in a non-technical subject domain. For this purpose we developed web-based instructions on an instructional design model. The material mainly consisted of diagrams with explanatory texts. Jeung et al. (1997) showed that replacing visual text with audio does not always improve the effectiveness of multimedia instructions, especially when using pictures with a high visual complexity. They argued that the visual search needed to find the part of the picture the text is referring to increases the memory load. After adding visual cues to the pictures in the form of electronic flashing they regained the modality effect. In our experiment we used colour coding as a means of preventing unnecessary visual search.

The hypothesis that follows from Cognitive Load Theory and Mayer's work on multimedia learning is that presenting the texts accompanying the diagrams as audio will decrease the working memory load of the instructions. Therefore we divided the students in two groups, one receiving bimodal instructions (the audio group) and one receiving visual-only instructions (the visual group), and measured the mental effort spent on the instructions. Paas and Van Merriënboer (1994) argue that mental effort is just one dimension of cognitive load that is not only influenced by task-characteristics but also by subject characteristics like prior knowledge and subject-task interactions like motivation. We tried to exclude any of these effects by randomization of our subjects over the groups, so that differences in mental effort scores could be attributed to the differences in presentation format.

It is also possible that the freed working memory resources are used for the learning process itself and no differences in mental effort are reported. Therefore we also looked at the extent in which students could recall elements of the design model in a retention test, and at the extent in which they could apply the model in a new situation with a transfer test, to see if there was any difference in performance. Finally, we also measured the mental effort spent on both tests.

Method

Participants The participants were 41 students from a Teacher Training College for Primary Education in Heerlen, the Netherlands (20 second-years and 21 third-years; age between 18 and 24; 11 males and 30 females). They had applied on a voluntary base and were paid forty guilders for their participation. During their studies, the students hadn't had any lessons on instructional design models. Twenty participants were randomly assigned to the visual group and 21 to the audio group.

Materials We developed web-based multimedia instructions on the Four Component Instructional Design (4C/ID)-model of Van Merriënboer (1997). This model describes a design strategy for the training of complex cognitive skills. The instructions focused on the question how to develop a blueprint for a training program based on the skills-hierarchy of a complex skill. The instructional website started with a short textual introduction to the model. Subsequently, the design strategy of the 4C/ID-model was demonstrated in a series of eleven diagrams representing skill hierarchies and sequences of learning tasks. These diagrams formed two worked-out examples and a general explanation of the strategy. The first example consisted of six diagrams that showed the different stages in developing a blueprint for the training of the complex skill *doing experimental research* (see Figure 1a and 1b for screen examples). The second worked-out example consisted of three diagrams showing the same process for the complex skill *designing a house*, and finally the general strategy of the 4C/ID-model was explained in the last two diagrams.

All eleven diagrams were accompanied by a textual explanation on how the model was applied in the specific situation. These explanatory texts were cut up into smaller pieces of only one or two sentences long, in such a way that each piece of text referred to a specific part of the diagram. Moreover, these parts were

coloured bright red in the diagram to prevent any unnecessary visual search. So while studying a diagram, only the accompanying text and the colour coding changed, not the diagram itself.

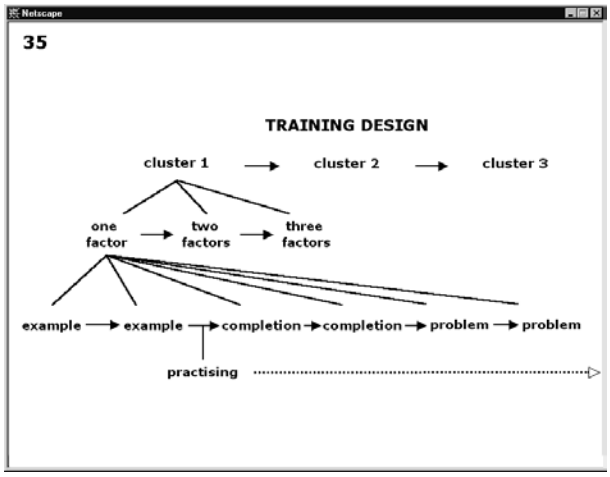

Figure 1a: Screen example of the audio version of the multimedia instructions.

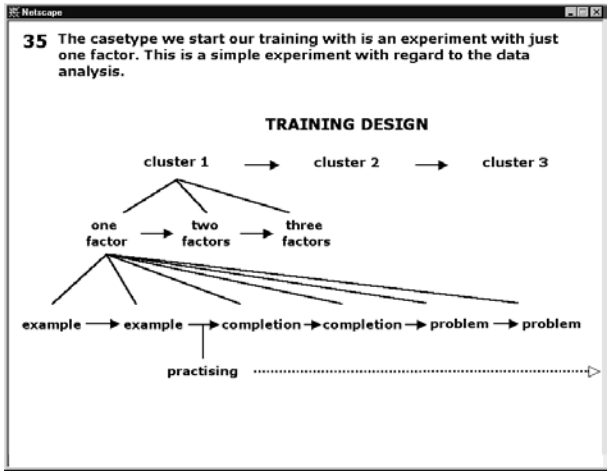

Figure 1b: Screen example of the visual text version of the multimedia instructions.

Two versions of the instructional website were created that differed in the way the texts accompanying the diagrams were presented. In the audio version (Figure 1a), students could listen to the pieces of explanatory text that accompanied a diagram through a headphone. Three seconds after the audio had finished playing, the colour coding in the diagram changed and the next piece of audio started. In the visual text version (Figure 1b) the pieces of explanatory text were depicted right above the diagrams. After the same period of time as in the audio condition, the colour coding in the diagram changed and a new piece of text appeared above the diagram. The time it took to study all eleven diagrams was about 30 minutes

After each diagram, a separate page followed with a nine-point rating scale on which the students could rate the mental effort they had spent on the instructions. This scale was developed by Paas and others (Paas & van Merriënboer, 1994; Paas, van Merriënboer & Adam, 1994). When a student clicked on one of the nine options, the program automatically continued with the next diagram. The average score on the eleven rating scales was taken as a measure of mental effort during instructions.

The retention test consisted of two paper-and-pencil tests, one of 30 and one of 20 multiple-choice items. The 30-item test contained only verbal statements, while the 20-item test combined verbal statements with small parts of diagrams. All items were statements about the 4C/ID-model like “A macro-sequence in the 4C/ID-model is a series of subskills in a cluster”, or “According to the 4C/ID-model, the same subskills can be trained in more than one learning task”, and the students could choose between *correct*, *incorrect* or *I don't know*. Each right answer yielded one point. The retention score was calculated by taking the sum of the scores on all fifty items (Cronbach's alpha = .74). A nine-point rating scale similar to the ones used in the instructions followed both multiple-choice tests. The average score on both scales was taken as a measure of the mental effort spent on the retention test.

The transfer test was also a paper-and pencil test that contained a short description of the skills an expert researcher applies when he or she is doing a literature search. The assignment was to design a blueprint for the training of this complex skill according to the 4C/ID-model on a blank answering form. After this test again a nine-point rating scale had to be completed as a measure of the mental effort spent on the transfer test. To be able to score the results of the transfer test a scoring form was developed consisting of twenty-eight *yes*/*no*-questions that checked to what extent and how accurately the strategy prescribed by the model had been applied in the transfer task. Every *yes* scored one point, and the sum score ranged from zero (no steps from the model taken) to 28 (all steps taken accurately). After the experiment, two independent raters scored the transfer tests using the form, showing an inter-rater agreement of .95. The average rating score was taken as the transfer score.

Procedure The experiment was carried out in eight sessions of about two hours, and in each session between one and seven students were tested simultaneously. These sessions took place in a multimedia lab that had seven computers connected to the Intranet of the Open University. Three computers had headphones attached to them. When the students entered the room they were randomly assigned to one of

the computers. Each computer showed a browser-window (without any of the menu options visible) set on a webpage displaying some general information about the experiment. When the students had finished reading, the experimenter told all the students to log in onto the actual instructions by typing in a password. All students started at the same time and studied the instructions all by themselves. The server on which the instructional website ran kept record of the mental effort scores of each participant.

After the instruction phase the three paper-and-pencil tests were administered. For each multiple-choice test the students got ten minutes, and for the transfer test they got thirty minutes.

Results

The variables under analysis were mental effort spent on the instructions, on the retention test and on the transfer test, and retention and transfer score. All scores were analysed with one-tailed t-tests. For all statistical tests, a significance level of .05 was applied. Table 1 shows the average scores on the dependent measures for the experimental groups.

Table 1: group means on dependent measures (standard deviations in brackets)

	audio	visual text
mental effort instructions	4.3 (0.8)	4.9 (0.9)
mental effort retention test	6.2 (0.8)	6.4 (1.2)
mental effort transfer test	6.4 (1.4)	7.1 (1.1)
retention score (0-50)	31.4 (6.1)	29.8 (5.4)
transfer score (0-28)	9.6 (6.2)	10.3 (5.4)

The reported mental effort during instructions showed a significant effect for the modality of text ($t(39) = -2.19$, $p < .05$). Students in the audio group had spent less effort than their colleagues in the visual group. The mental effort spent on the retention test showed no differences between the groups ($t(39) = -0.53$, $p > .10$). However, the mental effort scores in the transfer test did show a significant difference between the groups ($t(39) = 3.42$, $p < .05$), with the students in the audio group spending again less effort than their colleagues in the visual groups.

Although the audio group did a little better than the visual group on the retention test, this effect was not significant ($t(39) = 0.88$, $p > .10$). Also no significant difference was found between the groups on the transfer test ($t(39) = -0.40$, $p > .10$).

Discussion

The results of the first experiment show that the modality effect can be replicated with longer multimedia instructions on a non-technical subject like instructional design. Students in the audio group report lower mental effort scores during the instructions as a result of decreased memory load. This is confirmed by the fact that in both the retention and transfer test the students in the audio group score just as good as the students in the visual group. Moreover, getting the same result in the transfer test has cost them less mental effort. The modality effect is not as strong as in the experiments by Kalyuga et al. (1999) and Tindall-Ford et al. (1997), who found both lower mental effort and better test scores. However, the fact that students in the audio condition reach the same test results with less mental effort still points at the superiority of audio over visual text in multimedia instructions.

Experiment 2

In our second experiment we wanted to investigate the question if the modality effect can still be found if the students in the visual group get more time to relate the verbal information to the diagram. Therefore we not only varied the modality of the text, but also the pacing of the instructions. The system-paced groups were identical to the two groups in the first experiment, while students in the user-paced groups could set the pace of the instructions for themselves. This way we compared four groups: audio-user, audio-system, visual-user, and visual-system.

Method

Participants The participants were 81 second-year students from the Department of Education of the University of Gent in Belgium (age between 18 and 30 years; 8 males and 73 females). The experiment was part of a regular course on instructional design, but at the time of the experiment the students had not received any lessons on instructional design models yet. Eighteen participants were randomly assigned to the audio-user group, another 18 to the audio-system group, 24 to the visual-user group, and 21 to the visual-system group.

Materials The multimedia instructions were the same as in the first experiment, only two extra user-paced versions were created. In the audio-user version (Figure 2a), the students were able to replay the sentences they had just heard by clicking on a small *play*-button, while in the visual-user version (Figure 2b) students could reread the text as many times as they wanted to. To continue with the next piece of text students in both groups had to click on a forward arrow.

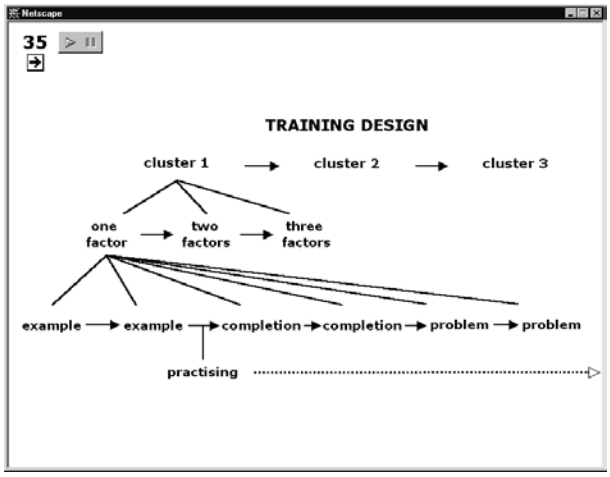

Figure 2a: Screen example of the audio-user version of the multimedia instructions.

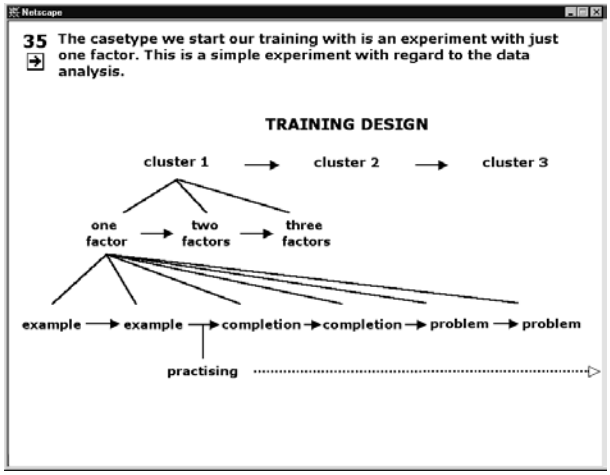

Figure 2b: Screen example of the visual-user version of the multimedia instructions.

The measurements were the same as in the first experiment, only this time all tests were presented on the computer. Moreover, the retention test consisted of 40 items taken from the retention test of the first experiment. The sum of the 40 items formed the total retention score (Cronbach's alpha = .68). After the experiment, two independent raters scored the transfer tests, showing an inter-rater agreement of .92.

Procedure The experiment was carried out in four sessions of about two-and-a-half hour, and in each session between fifteen and twenty-four students were tested simultaneously. These sessions took place in a classroom that had twenty-four multimedia computers connected to the Internet through the university network, with six computers for each experimental group. The procedure was almost identical to the first experiment. Only this time, students could immediately continue with the tests whenever they had finished studying the instructions. The server on which the instructional website ran kept record of the time spent on the learning task (in minutes), of the mental effort scores and of the retention score of each participant.

Results

The variables under analysis were training time, mental effort spent on the instructions, on the retention test and on the transfer test, and retention and transfer score. Except for training time, all scores were analysed with two-factor analyses of variance (ANOVAs), with modality (audio vs. visual text) and pacing of the instructions (system pacing vs. user pacing) as the between-subjects factors. For all statistical tests, a significance level of .05 was applied. Table 2 shows the average scores on the dependent measures for all four groups.

Table 2: group means on dependent measures (standard deviations in brackets)

	audio-user	audio-system	visual-user	visual-system
time on instructions	33.7 (3.3)		37.8 (5.5)	
mental effort instructions	4.3 (1.0)	4.1 (0.7)	4.0 (1.0)	4.2 (1.0)
mental effort retention test	6.5 (1.3)	6.7 (1.0)	6.5 (1.3)	6.7 (1.0)
mental effort transfer test	7.3 (1.1)	7.3 (1.5)	7.5 (1.1)	7.1 (1.5)
retention score (0-40)	26.5 (4.8)	28.9 (3.7)	28.6 (3.6)	25.3 (5.6)
transfer score (0-28)	17.8 (4.4)	17.7 (4.1)	16.8 (4.8)	14.1 (5.6)

With regard to the time spent on the instructions, only the two user-groups were compared, because in the system groups time was equal for all students (about 30 minutes). It showed that the students in the visual-user group had spent significantly more time on the instructions than the students in the audio-user group ($t(40) = -2.7$, $p < .01$, two-tailed).

There were no significant differences between the groups on mental effort during instructions. The same goes for the mental effort spent on the retention test, and for the mental effort spent on the transfer test.

The results on the retention test showed a significant interaction effect ($F(1,77) = 7.99$, $MSE = 20.16$, $p < .01$). In the two system groups, the audio group did better than visual text, while in the user groups this effect was reversed, with visual text outperforming the audio group. The scores on the transfer task showed a significant main effect for the modality of the text

($F(1,77) = 4.67$, $MSE = 23.07$, $p < .05$), with the students in the audio groups scoring higher than the students in the visual groups ($M = 17.8$, vs. $M = 15.5$, respectively). Inspection of the separate group means shows that especially the students in the visual-system group did worse that their colleagues in the audio groups. However, this interaction was statistically not significant.

Discussion

The results show that in the system-paced groups, a modality effect is found in terms of improved learning outcomes, but not in mental effort. This is a little different from the results in the first experiment in which the audio group spent less mental effort but did not have better test scores. This reversal might be accounted for by the fact that the second experiment was part of a regular course, and that the students in the audio condition were more prepared to invest the freed memory resources in the learning process itself, resulting in higher test scores with equal mental effort.

However, in the two groups in which the students set the pace of the instructions, no modality effect is found at all. Not only do the students in the visual-user group perform almost equally well on the transfer test, on the retention test they even outperform the students in the audio-user group. The visual-user group has taken more time to study the instructions, which confirms our idea that the modality effect in the system-paced condition is at least partly the result of a lack of time to relate the text to the diagrams in the visual-system group.

General Discussion

The results of both experiments show that replacing on-screen text with audio will only increase the effectiveness of multimedia instructions if the student has no control over the pacing of the instruction and the pace is set by the time of the narration. In that case we find either lower mental effort or better test results, even with a subject matter from a non-technical domain like instructional design. However, with more time (or the possibility to let the student determine the pace) visual-only instructions can be just as effective as bimodal instructions.

From a theoretical point of view, the results seem to indicate that the modality effect as demonstrated in earlier experiments can be accounted for in other terms than an increase in memory resources. One possible explanation is the lack of time to relate verbal to pictorial information in visual-only conditions. One of the things we will do in our future research is get a closer look at what actually happens when students are studying multimedia instructions by measuring eye-movements and look for different patterns in visual search.

Abstract

This paper focuses on the optimum use of representational space by words in speech and in the mental lexicon. In order to do this we draw the concept of entropy from information theory and use it to plot the information contour of words. We compare different representations of Spanish speech: a citation vs. a fast-speech transcription of a speech corpus and a dictionary lexicon vs. a speech lexicon. We also compare the information profiles yielded by the speech corpus vs. that of the speech lexicon in order to contrast the representation of words over two representational spaces: time and storage space in the brain. Finally we discuss the implications for the mental lexicon and interpret the analyses we present as evidence for a version of Butterworth's (1983) Full Listing Hypothesis.

Introduction

In this paper we focus on the optimum use of representational space by words over time (the sequence of sounds in speech) and over space (the storage site of the mental lexicon in the brain). We draw the concept of entropy from information theory and propose that it can be used to study the information structure of the set of words uttered in speech and of those stored in the mental lexicon in the face of the constraints of communication and of storage, respectively, in a potentially noisy medium.

We have two representational spaces for words: time and storage space. Further, we will consider the phonology and morphology of word systems. Our data sets are phonetic representations of words, and recent research demonstrates that information on the probabilistic distribution of phonemes in words is used in language processing (see Frisch, Large & Pisoni, 2000 for review). Morphology is involved in this research because we will be comparing groups of words with different inflectional and derivational features. We will initially assume the Full Listing Hypothesis (Butterworth, 1983): every word-form, including inflected and derived forms, is explicitly listed in the mental lexicon.

Shillcock, Hicks, Cairns, Chater and Levy (1995) suggest the general principle of the presentation of information in the brain that information should be spread as evenly as possible over time or over the representational space. Therefore, if the entropy of the mental lexicon is to be maximized so that the storage over a limited space is most efficient, then all the phonemes will tend to occur as evenly as possible in each segment position of the word. The phonology of each individual word, because it will have an effect on the entropy of the system, affects whether it is likely to become part of the mental lexicon.

Shillcock et al. stated that "the optimum contour across the phonological information in a spoken word is flat; fast-speech processes cause the information contour to become more level". We generalize this notion and propose the Levelling Effect of Realistic Representations (LERR): *processes that make the representation of words more accurate will flatten the information profiles*.

In order to test this, we will use Spanish word systems to calculate the slope and overall level of entropy of a citation (idealized pronunciation of the word in isolation) transcription and of a fast-speech (more realistic) transcription and of a dictionary lexicon and the speech lexicon. Our prediction is that the second system in each comparison should yield flatter information contours. We also compare a representation of words over time and another one over storage space - a speech corpus and the speech lexicon.

Entropy

We will use the concept of entropy in the context of information theory (Shannon, 1948), also employed in speech recognition studies (e.g. Yannakoudakis & Hutton, 1992). Entropy H is defined for a finite scheme

(i.e., a set of events such that one and only one must occur in each instance, together with the probability of them occurring) as a reasonable measure of the uncertainty or the information that each instance carries. E.g. the finite scheme formed by the possible outcomes when throwing a dice has maximum entropy: each side of the dice has 1/6 probability of occurring and it is very difficult to predict what the outcome will be. A loaded dice, on the other hand, has an unequal probability distribution, and the outcome is less uncertain. In this research, the possible events are the phonemes and allophones, and for each word only one of them can occur at each segment position.

For probabilities (p_1, p_2, p_3...p_n):

$H = - \Sigma (p_i \cdot \log p_i)$

The relative entropy H_{rel} is the measured entropy divided by the maximum entropy H_{max}, which is the entropy when the probabilities of each event occurring are equal and the uncertainty is maximized. Using H_{rel} allows us to compare entropies from systems with a different number of events (in this case, a system with 30 phonemes with another one with 50).

$H_{max} = \log n$

$H_{rel} = H / H_{max}$

Redundancy R is a measure of the constraints on the choices. When redundancy is high, the system is highly organized, and more predictable, i.e. some choices are more likely than others, as in the case of the loaded dice.

$R = 1 - H_{rel}$

In order to obtain the information profiles of words (see Figure 1), the entropy was calculated separately for each segment position in a set of left-justified words of equal length, i.e., for the first phoneme in the words, the second phoneme etc.

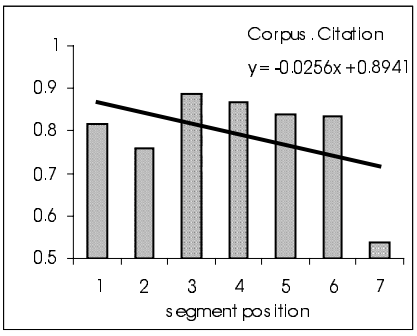

Figure 1: Information profile of 7-segment words from the citation transcription of the speech corpus.

The information profile of the word was measured as the linear trendline of these individual segment entropies. The slope (m) (multiplied by (-1)) of these trendlines and the mean relative entropy for each word length are shown in the figures below. E.g. In Figure 1, (-m)=0.0256. The flatness of the slope refers literally to how horizontal the trendline is.

Transcriptions

We have restricted ourselves to phonemic representations of word and will not report data concerning the distributions of phonemic features. We have used citation transcription rules (the idealised pronunciation of the isolated word) and fast-speech rules (an attempt to represent normal speech more realistically). Both citation and fast-speech rules were applied uniformly to the whole data sets. For the citation transcription we used 29 phonemes including 5 stressed vowels; for the fast-speech transcription we used 50 phonemes and allophones:

Citation transcription: Vowels: /a/, /e/, /i/, /o/, /u/, /á/, /é/, /í/, /ó/, /ú/. Consonants: /p/, /b/, /t/, /d/, /k/, /g/, /m/, /n/, /ɲ/, /ɾ/, /r/, /f/, /θ/, /s/, /ʝ/, /χ/, /l/, /ʎ/, /tʃ/.

Fast-speech transcription: The above plus semivowel /i̯/, /u̯/, voiced approximants /β̞/, /ð̞/, /ɣ̞/, voiceless approximants /β̞̥/, /ð̞̥/, /ɣ̞̥/, labiodental /m/, dental /n/ and /l/, palatalised /n/ and /l/, velarized /n/, /z/, dental voiced /s/, dental /s̪/, fricative /ɾ̞/, voiced /θ/ and a silenced consonant /Ø/. The transcription was made following the rules for consonant interactions, such as feature assimilation, set out by Rios Mestre (1999, chapter 5). Diphthongs were treated as two separate segments, as is usual in Spanish. Rules to mark stressed vowels were applied to all but monosyllabic words without an orthographic accent. For the corpus, the whole text was used, including repetitions and false starts of words. After deleting all the tags, the corpus was divided into chunks separated by pauses (change of speaker, comma, full stop, or pause marked in the transcription). The resulting text was transcribed automatically word by word (orthographic forms being replaced by phonetic forms) and then word boundary effects were introduced within the chunks, following the same rules as for the intra-word transcription.

Data

We used these three sets of data:

The speech corpus: a 707,000 word Spanish speech corpus, including repetitions and unfinished words. This corpus was developed by Marcos Marín of the Universidad Autonoma de Madrid in 1992 and contains transcribed speech from a wide range of registers and fields, from everyday conversation to academic talks and political speeches.

The dictionary lexicon: a 28,000 word Spanish word lexicon (the Spanish headword list of the Harrap Compact Spanish Dictionary, excluding abbreviations). This list does not include inflections, but approximately 40% of the words are derived words (we take the infinitive of verbs and the simple form of the noun as

the basic forms). This word system could represent a mental lexicon where that only word stems are listed and where inflected words are assembled during speech production.

The speech lexicon: the 42,000 word types found in the corpus. Some 80% of these types were derived and inflected words. We take this word system to be the most realistic representation of the mental lexicon, assuming Butterworth (1983)'s Full Listing Hypothesis, where all the wordforms are individually represented in the mental lexicon.

The dictionary lexicon and the speech lexicon share only ~30% of the words. The remaining ~70% of the words in the dictionary lexicon are mostly low frequency words which do not appear in our sample of speech. The new ~70% in the speech lexicon are verbal inflections (~35%), plurals and feminine inflections (~25%), some derived words absent from the dictionary lexicon (~4%), unfinished or mispronounced words (~4%) and proper nouns (~2%).

From these data, we used 4, 5, 6 and 7-segment transcriptions. Words were separated by length in order to see a clearer picture of the information profiles, especially as far as the word-ending contribution is concerned. Considering that the information profiles of Spanish words follows the same pattern as those of English words as seen in Shillcock et al. (1995), we can extend research in English to Spanish words. In English, word recognition typically occurs before the end of the word is uttered (Marslen-Wilson & Tyler, 1980), and information about word-length is typically available once the nucleus is being processed (Grosjean, 1985). It is, therefore, legitimate to assume that recognition processes are restricting their activities to the subset of words in the lexicon that match the word being uttered both in terms of initial segments and approximate overall length. The particular word lengths were chosen because the structure of shorter words is simpler, and the effects are less likely to be obscured by greater variation in the internal structure of each word-length group. These word lengths are equidistant from the modes of the word-length distribution of the three data sets (lexicon: mode = 8, speech lexicon: mode = 7 and speech corpus: modes = 2, 4 – the mode of the normal distribution is 4, but the proportion of 2-segment words is even higher, accounting for 32% of all tokens). The sum of these four word lengths accounts for 41% of the dictionary lexicon, 45% of the speech lexicon and 37% of the speech corpus.

The effect of the transcription

Shillcock et al. (1995) showed that fast-speech processes cause the information contour to become more level for English, German, Welsh, Irish and Portuguese. Here we compare the slope of the information profiles of 4-7 segment words from the corpus transcribed with citation rules and with fast-speech rules.

As predicted by the LERR principle, Figure 2 confirms that this is also the case for Spanish. The information profile is consistently flatter for the more realistic fast-speech transcriptions in all word lengths. Note that in the figure, a higher value of (–m) indicates a steeper profile.

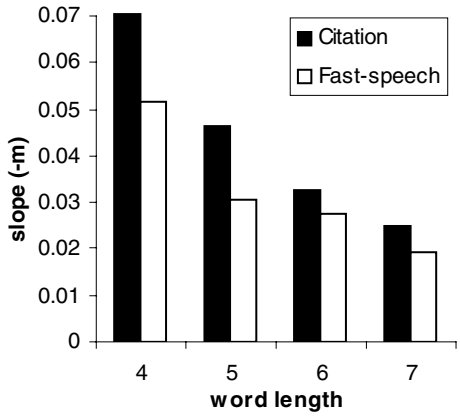

Figure 2: Slopes of the information profiles of the citation and the fast-speech transcriptions applied to the corpus, over the four word lengths.

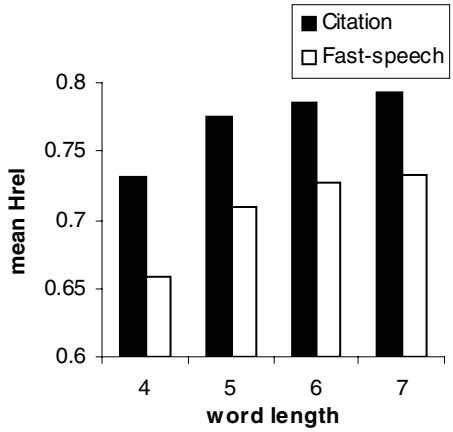

Figure 3: Mean relative entropy of the citation and fast-speech transcriptions over the four word lengths.

Figure 3 shows how the overall entropy is lower for the fast-speech transcription: when we introduce the allophones and the assimilation rules, the system becomes more redundant and thus, more predictable.

The Speech Lexicon

Some current models of lexical access propose two parallel word recognition routes, a whole-word route and a morpheme-based one (e.g. Wurm (1997) for English; Colé, Segui & Taft (1997) for French; Laine, Vainio & Hyona (1999) for Finnish). Following this hypothesis, the full forms of words need to be stored in the mental lexicon (cf. Butterworth, 1983). It is relevant, then, to study the behaviour of the set of all word types, including derived and inflected words, that appear in speech: the speech lexicon.

We have seen that fast-speech transcriptions yield flatter information contours than citation transcriptions, so we will use the fast-speech transcriptions of the speech lexicon, the lexicon and the corpus.

Comparing the slopes of the information profiles of the speech lexicon on the one hand and the dictionary lexicon and the corpus on the other hand will help characterize the active mental lexicon.

Speech lexicon vs. dictionary lexicon

The speech lexicon contains inflected and derived forms, and does not contain the more obscure words that can be found in the dictionary. The LERR principle that data that are closer to real speech should produce flatter information contours is confirmed in Figure 4, where we see that the values of the slope of the information profile of the speech lexicon are lower than those of the dictionary lexicon.

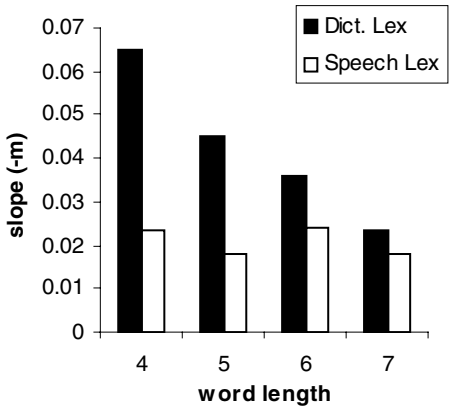

Figure 4: Slopes of the information profiles of the dictionary lexicon and the speech lexicon over the four word lengths.

Figure 5 shows that the overall entropy level is higher for the speech lexicon. This means that the speech lexicon is less redundant than the dictionary lexicon. The representational space is now a limited amount of memory storage space in the brain, and for maximal efficiency redundancy has to be reduced as much as possible. The results from both the slopes and the entropy levels support the Full Listing Hypothesis that all wordforms, particularly inflected forms, are listed in the mental lexicon – the system that includes all wordforms (the speech lexicon) could be stored more efficiently over a limited representational space.

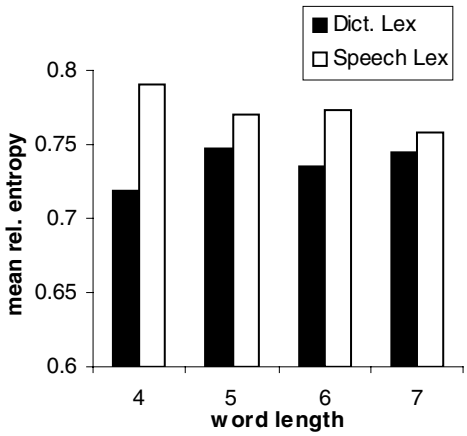

Figure 5: Mean relative entropy of the dictionary lexicon and the speech lexicon over the four word lengths.

Speech lexicon vs. corpus

The fact that entropy and redundancy statistics obtained from a lexicon are different from those obtained from a corpus has been noted by Yannakoudakis and Angelidakis (1988). Here we are comparing the word tokens with the word types in a speech corpus. Figures 6 and 7 show that the speech lexicon has consistently flatter slopes and higher entropy levels than the corpus.

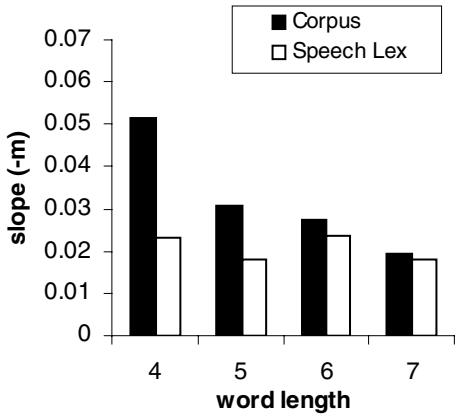

Figure 6: Slopes of the information profiles of the corpus and the speech lexicon across the four word lengths.

We are comparing two representational spaces: words in the brain are constrained by a limited space and words uttered over time are constrained by the efficiency of communication. We saw in the last section that the flat slopes and high entropy levels of the speech lexicon information profiles are best suited to enhance storage efficiency. Slopes in the corpus are relatively flat, but still steeper than those of the speech lexicon. This may reflect the fact that there are other factors affecting the information contour of words in speech, such the need to encode cues to lexical segmentation (signals that indicate where words begin and end). These other factors may be interacting with the optimization of communication.

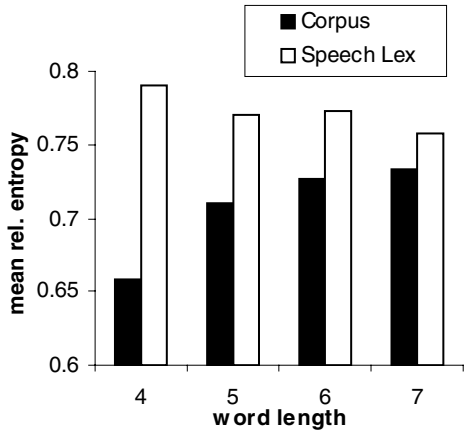

Figure 7: Mean relative entropy of the corpus and the speech lexicon across the four word lengths.

The corpus presents lower entropy levels than the speech lexicon. Speech over time is not constrained by space limitations, but rather by the need to communicate efficiently. The higher redundancy means that this system reduces the uncertainty and is indeed better for communication.

Discussion

The present study points in the direction of the LERR principle that the more realistic data - the fast-speech transcription and the speech lexicon - produce flatter information profiles.

The flatter profile of the fast-speech transcription can be partly explained in terms of the Markedness Ordering Principle (Shillcock et al., 1995) that when consonant interactions introduce phonological ambiguity, the ambiguity introduced is always in the direction of a less frequent phoneme. As for the comparison between lexicons, let us remember that the 70% of words in the speech lexicon that do not appear in the dictionary lexicon are mostly inflected words, and the 70% of words in the dictionary lexicon not present in the speech lexicon are mainly low-frequency words. The flatter profile of the speech lexicon is due to the fact that the inflected words (which are derived from one third of the dictionary lexicon words) yield a flatter profile than the low-frequency dominated group. This suggests that inflected words are included in the mental lexicon, and so it supports the Full Listing Hypothesis.

Additionally, the overall level of entropy and redundancy gives us an insight into the degree of complexity of a system. Highly organized systems will show low entropy and high redundancy. Fast-speech rules make the system more redundant than the citation rules. This higher predictability helps to deal with the loss of information produced by noise and thus enhance communication. The speech lexicon is less redundant than the dictionary lexicon. Here again, the higher entropy must be attributable to the fact that the phonemes in inflected forms are more evenly distributed over the phonological space than the more obscure words present in the dictionary lexicon.

The comparison between the corpus and the speech lexicon shows the features of the representation that has evolved to enhance communication and storage, respectively. Both systems are “realistic”, and indeed both show relatively flat information contours, but more so the speech lexicon, suggesting that communication has other constraints that interact with this measure, such as word-boundary recognition. This is true particularly for shorter words. The fact that the corpus is markedly more redundant than the speech lexicon is only to be expected, since it reflects the added complexity of different word-frequencies.

In conclusion, we have shown that it is possible to use psychological theories of the mental lexicon and spoken word recognition to make testable predictions concerning distributional information in large samples of language, and, conversely, that data from information distribution may potentially falsify particular aspects of those psychological theories. Our current conclusions from the analyses of Spanish favour versions of Butterworth's original Full Listing Hypothesis, in which all the wordforms encountered in speech are individually stored.

The Rational Basis of Representativeness

Joshua B. Tenenbaum & Thomas L. Griffiths
Department of Psychology
Stanford University
Stanford, CA 94305-2130 USA
jbt,gruffydd @psych.stanford.edu

Abstract

Representativeness is a central explanatory construct in cognitive science but suffers from the lack of a principled theoretical account. Here we present a formal definition of one sense of representativeness – what it means to be a good example of a process or category in the context of Bayesian inference. This analysis clarifies the relation between representativeness as an intuitive statistical heuristic and normative principles of inductive inference. It also leads to strong quantitative predictions about people's judgments, which compare favorably to alternative accounts based on likelihood or similarity when evaluated on data from two experiments.

Why do people think that Linda, the politically active, single, outspoken, and very bright 31-year-old, is more likely to be a feminist bankteller than to be a bankteller, even though this is logically impossible? Why do we think that the sequence is more likely than the sequence to be produced by flipping a fair coin, even though both are equally likely? The standard answer in cognitive psychology (Kahneman & Tversky, 1972) is that our brains are designed to judge "representativeness", not probability: Linda is more representative of feminist banktellers than of banktellers, and is more representative of flipping a fair coin than is , despite anything that probability theory tells us.

Not only errors in probabilistic reasoning, but numerous other phenomena of categorization, comparison, and inference have been attributed to the influence of representativeness (or prototypicality or "goodness of example"; Mervis & Rosch, 1981; Osherson, Smith, Wilkie, Lopez, & Shafir, 1990; Rips, 1975). However, a principled account of representativeness has not been easy to come by. Its leading proponents (Kahneman & Tversky, 1996; Mervis & Rosch, 1981) have asserted that representativeness should be defined only operationally in terms of people's judgments; an a priori, analytic definition need not be given. Critics have countered that this concept is too vague to serve as an explanation of intuitive probability judgment (Gigerenzer, 1996).

This paper presents a framework for constructing rational models of representativeness, based on a Bayesian analysis of what makes an observation a good example of a category or process. The goal is to identify precisely one sense of representativeness and show that it has a rational basis in normative principles of inductive reasoning. We will first point out some shortcomings of previous accounts based on likelihood or similarity, and show how a Bayesian approach can overcome those problems. We will then compare the quantitative predictions of Bayesian, likelihood, and similarity models on two sets of representativeness judgments.

Previous approaches

Likelihood. In trying to relate intuitions about representativeness to rational statistical inferences, a natural starting point is the concept of likelihood. Let d denote some observed data, such as a sequence of coin tosses, and h denote some hypothesis about the source of d, such as flipping a fair coin. The probability of observing d given that h is true, $P(d\ h)$, is called a likelihood. Let $R(d,h)$ denote representativeness – how representative the observation d is of the generative process in h.

Gigerenzer & Hoffrage (1995) have proposed that representativeness, to the extent that it can be defined rigorously, is equivalent to likelihood: $R(d,h) = P(d\ h)$. This proposal is appealing in that, other factors aside, the more frequently h leads to observing d, the more representative d should be of h. It is also consistent with some classic errors in probability judgment, such as the conjunction fallacy: a person is almost certainly more likely to match Linda's description given that she is a bankteller and a feminist than given only that she is a bankteller.

While likelihood and representativeness seem related, however, they are not equivalent. Two observations with equal likelihood may differ in representativeness. Knowing that and are equally likely to be produced by a fair coin does not change our judgment that the latter is the more representative outcome. Tversky & Kahneman (1983) provide several examples of cases in which a more representative outcome is actually less likely. Any sequence of fair coin flips, such as , is less likely than one of its subseqences, such as or , but may easily be more representative. More colorfully, "being divorced four times" is more representative of Hollywood actresses than is "voting democratic", but the former is certainly less likely.

Figure 1 illustrates a simple version of the dissociation between representativeness and likelihood. Each panel shows a sample of three points from a Gaussian distribution. With independent sampling, the total likelihood of a sample equals the product of the likelihoods for

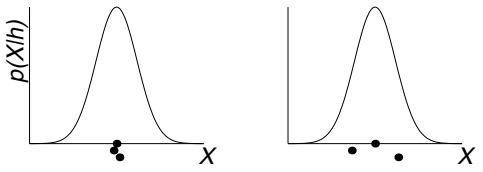

Figure 1: Given a normal distribution, the left sample has greater likelihood but the right is more representative.

each item in the sample. Thus the left sample has much greater likelihood, because each point is much closer to the peak of the distribution than in the right sample. Yet the more spread-out sample on the right seems more representative. We tested this intuition in a survey of 138 Stanford undergraduates. They were first shown a normally distributed set of thirty "widgets" produced by a factory. The widgets were simple drawings resembling nuts or bolts, varying only in their sizes. They were then shown three different samples, each with three widgets, and asked to rate on a scale of 1-10 how representative each sample was of the widgets produced by this factory. Each sample contained a point at the mean of the original distribution, and points at $z = \ 2.85$ ("broad sample"), $z = \ 1$ ("intermediate sample"), or $z = \ 0.05$ ("narrow sample"). The intermediate sample, with a standard deviation similar to the population, received a significantly higher rating than did the much more likely narrow sample (7.1 vs. 5.2, $p < .05$). The broad sample, with lowest likelihood of all, also received a lower rating (6.9) than the intermediate sample, but not by a significant margin.

We also tested whether intermediate-range samples are more representative for natural categories, using as stimuli black-and-white pictures of birds. In a design parallel to the widget study, 135 different Stanford undergraduates saw three samples of birds, each containing three members, and rated how representative they were of birds in general. The samples consisted of either three robins ("narrow"); a robin, an eagle, and a seagull ("intermediate"); or a robin, an ostrich, and a penguin ("broad"). Although the robins were individually rated as more representative than the other birds (by a separate group of 100 subjects), the set of three robins was considered the least representative of the three samples. As with the widgets, the intermediate sample was rated more representative (6.3) than either the narrow (5.1) or broad (5.3) samples ($p < .05$ for both differences).

For natural categories as well as for the artificial widgets, a set of representative examples turns out not to be the most representative set of examples. Sample likelihood, because it is merely the product of each example's individual likelihood, cannot capture this phenomenon. At best, then, likelihood may be only one factor contributing to the computation of representativeness.

Similarity. Most attempts to explicate the mechanisms of representativeness, including that of Kahneman & Tversky (1972), rely not on likelihood but on some sense of similarity. That is, an observation d is representative of a category or process h to the extent that it is similar to the set of observations h typically generates.

Similarity seems to avoid some of the problems that likelihood encounters. may be more representative of a fair coin than because it is more similar on average to other coin flip sequences, based on such features as the number of heads or the number of alternations. Likewise, someone who has been divorced four times may be more similar to the prototypical Hollywood actress than someone who votes democratic, if marital status is weighted more heavily than political affiliation in computing similarity to Hollywood actresses.

However, the explanatory power of a similarity-based account hinges on being able to specify what makes two stimuli more or less similar, what the relevant features are and how are they weighted. Similarity unconstrained is liable to lead to circular explanations: having had multiple divorces is more representative of Hollywood actresses because marital status is more highly weighted in computing similarity to Hollywood actresses, but why is marital status so highly weighted, if not because having multiple divorces is so typical of Hollywood actresses?

Equating representativeness with similarity also runs into a problem when evaluating the representativeness of a set of objects, as in Figure 1. Similarity is usually defined as a relation between pairs of stimuli, but here we require a judgment of similarity between two sets of stimuli, the sample and the population. It is not immediately obvious how best to extend similarity from a pairwise to a setwise measure. The individual elements of the left sample are certainly more similar to the average member of the population than are the elements of the right sample. The left sample also comes closer to minimizing the average distance between elements of the population and elements of the sample. If similarity between sets is defined according to one of these measures, it will fail to match up with representativeness.

Finally, and most problematic for our purposes here, a definition in terms of similarity fails to elucidate the rational basis of representativeness, and thus brings us no closer to explaining when and why representativeness leads to reasonable statistical inferences. Hence we seem to be left with two less-than-perfect options for defining representativeness: the simple, rational, but clearly insufficient concept of likelihood, or the more flexible but notoriously slippery concept of similarity.

A Bayesian analysis

In this section we present a Bayesian analysis of representativeness that addresses some of the shortcomings of the likelihood and similarity proposals. As with likelihood, Bayesian representativeness takes the form of a simple probabilistic quantity, which in fact includes likelihood as one component. But like the similarity approach, it can account for dissociations of representativeness and likelihood, when a less probable feature of the stimuli is also more diagnostic of the process or category in question. Moreover, it applies just as well to evaluat-

ing the representativenes of a set of examples (e.g. Figure 1) as it does to individual examples.

Our notion of a "good example" is defined in the context of a Bayesian inductive inference task. As above, let d denote some observed data, and let $H = h_1, \ldots h_n$ denote a set of n hypotheses (assumed to be mutually exclusive and exhaustive) that might explain the observed data. For each h_i, we require both the likelihood $P(d\ h_i)$ and a prior probability, $P(h_i)$, which expresses the degree of belief in h_i before d is observed. Let $\bar{h}_i = h_j \quad H : j = i$ denote the negation of hypothesis h_i, the assertion that some hypothesis other than h_i is the true source of d. Then we define our measure of representativeness $R(d, h_i)$ to be the logarithm of the likelihood ratio

$$L(d\ h_i) = \frac{P(d\ h_i)}{P(d\ \bar{h}_i)}. \tag{1}$$

This definition is motivated by Bayes' rule, which prescribes a degree of belief in hypothesis h_i after observing d given by the posterior probability

$$P(h_i\ d) = \frac{P(d\ h_i)P(h_i)}{P(d)}. \tag{2}$$

Defining the posterior odds $O(h_i\ d) = P(h_i\ d)\ \ P(\bar{h}_i\ d) = P(h_i\ d)\ \ (1 - P(h_i\ d))$, and the prior odds $O(h_i) = P(h_i)\ \ (1 - P(h_i))$, we can write Bayes' rule in the form:

$$\log O(h_i\ d) = \log L(d\ h_i) \quad \log O(h_i). \tag{3}$$

Equation 3 shows why the log likelihood ratio, $\log L(d\ h_i)$, provides a natural measure of how good an example d is of h_i: it indicates the extent to which observing d increases or decreases the posterior odds of h_i relative to the prior odds. Researchers in statistics (Good, 1950), artificial intelligence (Pearl, 1988), and philosophy of science (Fitelson, 2000) have previously considered $\log L(d\ h_i)$ as the best measure for the weight of evidence that d provides for h_i, because it captures the unique contribution that d makes to our belief in h_i independently of all other knowledge that we have (reflected in $P(h_i)$).

To compute $R(d, h_i)$ in the presence of more than one alternative hypothesis, we express it in the form

$$R(d, h_i) = \log \frac{P(d\ h_i)}{\sum_{h_j\ H} P(d\ h_j)P(h_j\ \bar{h}_i)}. \tag{4}$$

$P(h_j\ \bar{h}_i)$ is the prior probability of h_j given that h_i is not the true explanation of d: 0 when $i = j$ and $P(h_j)\ \ (1 - P(h_i))$ otherwise. Equation 4 shows that d is representative of h_i to the extent that its likelihood under h_i exceeds its average likelihood under alternative hypotheses.

To illustrate the analysis concretely, consider the simple case of two coinflip sequences, and . Unlike the likelihood model, we cannot compute how representative an observation is of a hypothesis without specifying the alternative hypotheses that an observer might consider. In the interests of simplicity, we consider just three relevant hypotheses about the origins of and : a fair coin (h_F), a two-headed coin (h_T), and a weighted coin (h_W) that comes up heads with probability 3/5. The likelihoods of the two sequences under these hypotheses are, for the fair coin, $P(\quad h_F) = P(\quad h_F) = (1\ \ 2)^5 = 0.03125$; for the two-headed coin, $P(\quad h_T) = 1$ while $P(\quad h_T) = 0$; and for the weighted coin, $P(\quad h_W) = (3\ \ 5)^5 = 0.0778$ while $P(\quad h_W) = (3\ \ 5)^3(2\ \ 5)^2 = 0.0346$. For concreteness, we choose specific prior probabilities for these hypotheses: $P(h_F) = 0.9$, $P(h_T) = 0.05$, and $P(h_W) = 0.05$. Substituting these numbers into Equation 4, we have $R(\quad , h_F) = \log \frac{0.03125}{1\times 0.05\ \ 0.1\ \ 0.0778\times 0.05\ \ 0.1} = -2.85$, while $R(\quad , h_F) = \log \frac{0.03125}{0\times 0.05\ \ 0.1\ \ 0.0346\times 0.05\ \ 0.1} = 0.59$. This result, that is more representative of a fair coin than , accords with intuition and holds regardless of the prior probabilities we assign to the three alternative hypotheses. In a later section, we go beyond a qualitative reconstruction of intuitions to test a quantitative model of representativeness judgments for sequences of coin flips.

The Bayesian approach also accounts for cases where a sample with lower likelihood appears more representative. For instance, $P(\quad h_F)$ is strictly lower than either $P(\quad h_F)$ or $P(\quad h_F)$, but is no less representative than . The Bayesian account also offers an intuitively compelling definition of representativeness for a set of examples, such as the widgets in Figure 1. We demonstrate by computing the representativeness for a sample X from a Gaussian population h_1. Let $x_1, \ldots, x_N$ be the N examples in X, m be the mean of X, and $S = \sum_i (x_i - m)^2$ the sum-of-squares. Let h_1 have mean μ and variance σ^2. We take the hypothesis space H to include all possible Gaussian distributions in one dimension – each a conceivable alternate explanation for the sample X. Because H is an uncountably infinite set, the sum in the denominator of Equation 4 becomes an integral. Assuming an uninformative Jeffreys prior on μ, σ (Equation 3 of Minka, 1998), our expression for Bayesian representativeness in Equation 4 then reduces to

$$R(X, h_1) = N \log S - \frac{1}{\sigma^2}\left[N(m - \mu)^2 \quad S\right], \tag{5}$$

plus a term that depends only on N and σ^2.

Equation 5 is maximized when $m = \mu$ and $S\ N = \sigma^2$, that is, when the mean and variance of the sample X match the mean and variance of the population h_1. This result is intuitive, and it accounts for why people preferred intermediate samples of widgets or birds over broad or narrow samples in the surveys described above: the $N \log S$ term penalizes narrower samples and the $-S\ \sigma^2$ penalizes broader samples. Yet this result is also not particularly surprising. More interestingly, Equation 5 gives a general metric for scoring the representativeness of any sample from a Gaussian distribution, which we will test quantitatively against people's judgments in the following section.

Quantitative modeling

In this section, we present quantitative models of representative judgments for two kinds of stimuli: sequences of coin flips and sets of animals. For each data set, we compare the predictions of Bayesian, likelihood-based, and similarity-based models.

Coin flips

Methods. 278 Stanford undergraduates rated the representativeness of four different coin flip sequences for each of four hypothetical generative processes, under the cover story of helping a casino debug a new line of gambling machines. The sequences were $d_1 =$, $d_2 =$, $d_3 =$, and $d_4 =$. The generative processes were h_1 = "A fair coin", h_2 = "A coin that always alternates heads and tails", h_3 = "A coin that mostly comes up heads", and h_4 = "A coin that always comes up heads". The orders of both sequences and hypotheses were randomized across subjects. Representativeness judgments were made on a scale of 1-7.

Bayesian model. While people could construct an arbitrarily large hypothesis space for this task, we make the simplifying assumption that their hypothesis space can be approximated by just the four hypotheses that they are asked to make judgments about. We constructed simple probabilistic models for each hypothesis h_i to generate the necessary likelihoods $P(d_j\ h_i)$. Priors for all hypotheses were assumed to be equal. To model h_1, "a fair coin", all likelihoods were set equal to their true values of 1 2^8. To model h_3, "mostly heads", and h_4, "always heads", we used binomial distributions with $p = 0.85$ and $p = 0.99$, respectively. In some sense, these p values represent free parameters of the model, but their values are strongly constrained by the meaning of the words "mostly" and "always". Their exact values are not crucial to the model's performance, as long as "always" is taken to mean something like "almost but not quite always" (i.e. $p < 1.0$). To model h_4, "always alternates heads and tails", we used a binomial distribution over the seven possible state transitions in each sequence, again with "always" translated into probability as $p = 0.99$. All model predictions were then given by Equation 4.

Likelihood model. This model treats representativeness judgments simply as $P(d_j\ h_i)$, as specified above.

Similarity model. We defined a simple similarity-based model in terms of two intuitively relevant features for comparing sequences: the number of heads in each sequence and the number of alternations in each sequence. Let α_j be the number of heads in sequence j, and β_j be the number of alternations. Then the similarity of sequences d_i and d_j is defined to be

$$sim(d_i, d_j) = \exp\left(-w_\alpha\ \alpha_i - \alpha_j\ - w_\beta\ \beta_i - \beta_j\ \right), \quad (6)$$

where w_α and w_β are the weights given to these two features. To compute similarity between a sequence and a generating hypothesis, we construct a prototype for each hypothesis based on the mean values of α and β over the whole distribution of sequences generated by that hypothesis. For example, for h_2, $\alpha = 4$ and $\beta = 7$; for h_3 (again assuming "mostly" means with probability 0.85), α 6.8 and β 1.8. Lastly, we define the representativeness of sequence i for hypothesis j as $R(d_i, h_j) = sim(d_i, h_j)\ \sum_k sim(d_i, h_k)$. The dimensional weights w_α and w_β are free parameters optimized to fit the data, giving $w_\alpha = 1$, $w_\beta = 0.4$.

Results. To compensate for nonlinear transformations that might affect the 1-7 rating scale used by subjects, the predictions of each model were first transformed according to a power function with a power γ chosen to optimize each model's fit, and then mapped onto the same interval spanned by the data. This gives both the likelihood model and the Bayesian model one free parameter plus two constrained parameters (corresponding to the meanings of "mostly" and "always"), while the similarity model has three free parameters (w_α, w_β, and γ) and the same two constrained parameters. All three models correlate highly with subjects' representativeness judgments, although the Bayesian model has a slight edge with $r = 0.94$, versus 0.87 for the likelihood model and 0.92 for the similarity model. Figure 2 presents an item-by-item analysis, showing that the Bayesian model captures virtually all of the salient patterns in the data.

Animals

Methods. We used data reported by Osherson, Smith et al. (1990; Tables 3 and 4) in a study of category-based induction. They asked one group of subjects to judge pairwise similarities for a set of 10 mammals, and a second group of subjects to judge the strengths of 45 arguments of the form x_1 has property P, x_2 has property P, x_3 has property P, therefore all mammals have property P , where x_1, x_2 and x_3 are three different kinds of mammals and P is a blank biological predicate. Such judgments of argument strength are not the same thing as judgments of representativeness, but for now we take them as a reasonable proxy for how representative the sample $X = \ x_1, x_2, x_3\ $ is of the set of all mammals.

Bayesian model. We assume that people's hypothesis space includes the category of all mammals (h_M), as well as an infinite number of alternative hypotheses. For simplicity, we model all hypotheses as Gaussian distributions in a two-dimensional feature space obtained from a multidimensional scaling (MDS) analysis of the similarity judgments in Osherson et al. (1990). This allows us to apply essentially the same analysis used in the previous section to compute the representativeness of a sample from a Gaussian distribution (Equation 5), and also parallels the original approach to modeling category-based induction of Rips (1975). The MDS space for animals is shown in Figure 3. The large gray oval indicates the one-standard-deviation contour line of h_M, which we take to be the best fitting Gaussian distribution for the set of all ten mammals. We assume the set H of alternative hypotheses includes all Gaussians in this two-dimensions

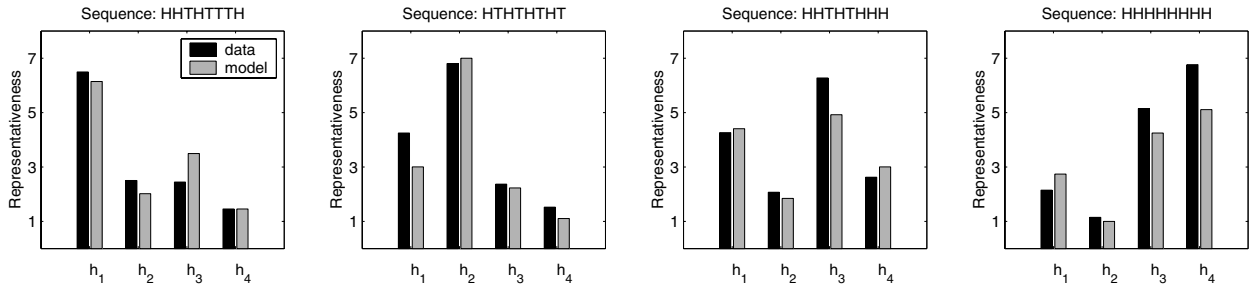

Figure 2: Representativeness judgments for coin flip sequences. Each panel shows subjects' mean judgments and the Bayesian model predictions for the representativeness of one sequence with respect to four different generating hypotheses: h_1 = "A fair coin", h_2 = "A coin that always alternates heads and tails", h_3 = "A coin that mostly comes up heads", and h_4 = "A coin that always comes up heads".

space, and we again use the uninformative Jeffreys' prior $P(h)$ (Minka, 1998; Equation 3). How representative a sample X (e.g. horse, cow, squirrel) is of all mammals can then be computed from a multidimensional version of Equation 5 (ignoring terms equal for all samples):

$$R(X,h_m) = N\log|\mathbf{S}| - N(\mathbf{m}-\mu)^{\mathrm{T}}\mathbf{V}^{-1}(\mathbf{m}-\mu) - \mathrm{trace}(\mathbf{S}\mathbf{V}^{-1}), \quad (7)$$

where m is the mean of X, $\mathbf{S} = \sum_i(\mathbf{x}_i-\mathbf{m})^{\mathrm{T}}(\mathbf{x}_i-\mathbf{m})$, $\mathbf{x}_i$ are the MDS coordinates of example i, N is the number of examples in X, and μ and $\mathbf{V}$ are the mean and covariance matrix of h_M (Minka, 1998). Equation 7 measures the representativeness of any sample X of N mammals in terms of the distance between the best fitting Gaussian for the sample (mean $\mathbf{m}$, covariance $\mathbf{S}$/N) and the best fitting Gaussian for the set of all mammals (mean μ, covariance $\mathbf{V}$). Figure 3 illustrates this graphically, by plotting one-standard-deviation contours for three samples that vary in how representative they are of the set of all mammals. Observe that the more representative the sample, the greater the overlap between its best-fitting Gaussian and the best-fitting Gaussian for the whole set.

Similarity-based models. Osherson et al. (1990) report pairwise similarity judgments for the animals, but to construct a similarity-based model of this representativeness task, we need to define a setwise measure of similarity between any sample of three animals and the set of all mammals. The similarity-coverage model proposed by Osherson et al. defines this quantity as the sum of each category instance's maximal similarity to the sample: $R(X,h_M) = \sum_j \max_i sim(i,j)$, where j ranges over all mammals and i ranges over just those in the sample X. A more traditional similarity-based model might replace the maximum with a sum: $R(X,h_M) = \sum_j\sum_i sim(i,j)$. Osherson et al. (1990) consider both max-similarity and sum-similarity models but favor the former as it is more consistent with their phenomena. However, there seems to be little a priori reason to prefer max-similarity, and indeed most similarity-based models of classification are closer to sum-similarity, so we consider both here.

Other models. We also compare the predictions of a simple likelihood model, which equates representativeness with $P(X\ h_M)$, and Sloman's (1993) feature-based model. Heit (1998) also presented a Bayesian model of category-based induction tasks, but because his model depends heavily on the choice of priors, it does not make strong quantitative predictions that can be evaluated here.

Results. Figure 3 plots the argument strength judgments for 45 arguments versus the representativeness predictions of the probabilistic and similarity-based models. Both the Bayesian and max-similarity models predict the data reasonably well ($r = 0.80$ vs. $r = 0.88$), with no significant difference between them ($p > .2$). Neither of these models has any free numerical parameters. With one free parameter, the feature-based model performs slightly worse ($r = 0.71$). Interestingly, both the likelihood and sum-similarity models show a weak *negative* correlation with the data ($r = -.31$, $r = -.26$). This discrepancy directly embodies the insight of Figure 1: high likelihood can yield low representativeness when the sample is tightly clustered near the mean, as in the sample of horse, cow, rhino (ellipse **C** in Figure 3). Sum-similarity performs as poorly as likelihood because it is essentially a nonparametric estimate of likelihood; likewise, max-similarity performs well because it correlates highly with Bayesian representativeness.

Discussion

Overall, the Bayesian models provide the most satisfying account of these two data sets. On the coinflip data, not only does Bayes obtain the highest correlation, but it does so with the minimal number of free parameters. On the animals data, Bayes obtains a correlation competitive with the best of the other models, max-similarity, even though it is based on less than half as much input data (20 MDS coordinates versus 45 raw similarity judgments) and may be hindered by information lost in the MDS preprocessing step. Most importantly, the Bayesian models are based on a rational analysis, which provides a single principled definition of representativeness applicable across the two quite different domains of coinflips and

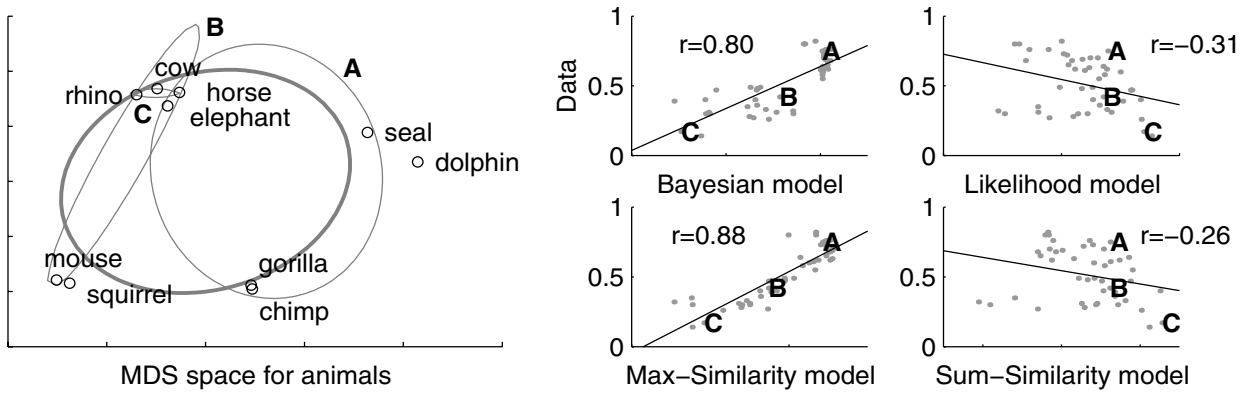

Figure 3: Modeling representativeness for sets of mammals. Ellipses in the MDS space of animals (left) mark one-standard-deviation contours for the set of all mammals (thick), a representative sample (horse, chimp, seal , **A**), a somewhat representative sample (horse, mouse, rhino , **B**), and a less representative sample (horse, cow, rhino , **C**). Scatter plots (right) compare strength judgments for 45 arguments with the predictions of four models (see text).

animals. In contrast, the similarity-based models have no rational grounding and take on very different forms in the two domains. They achieve high correlations, but only through the introduction of multiple free parameters, such as the feature weights on the coin flip data, or ad hoc assumptions, such as the choice of max-similarity over sum-similarity on the animal data. On the other hand, similarity-based models do have the advantage of requiring only simple computations. Thus both Bayesian and similarity-based models may have something to offer, but at different levels of analysis. Similarity may provide a reasonable way to describe the psychological mechanisms of representativeness, while a Bayesian analysis may provide the best explanation of why those mechanisms work the way they do: why different features of sequences are weighted as they are in the coinflip example, or why max-similarity provides a better model for inductive reasoning than does sum-similarity.

Conclusion

We have argued that representativeness is best understood as a Bayesian computation, rather than as a judgment of similarity or likelihood. Our analysis makes precise one core sense of representativeness – the extent to which something is a good example of a category or process – and exposes its underlying rational basis. Rational models have been successfully applied to a number of cognitive capacities (Shepard, 1987; Anderson, 1990; Oaksford & Chater, 1998) but not previously to analyzing representativeness, which is traditionally thought of as an alternative to normative probabilistic judgment. By clarifying the relation between our intuitive sense of representativeness and normative principles of statistical inference, our analysis may lead to a better understanding of those conditions under which human reasoning may actually be rational or close to rational, as well as those situations in which it truly deviates from a rational norm.

Abstract

We present the first developmental computational model of metaphor comprehension, which seeks to relate the emergence of a distinction between literal and non-literal similarity in young children to the development of semantic representations. The model gradually learns to distinguish literal from metaphorical semantic juxtapositions as it acquires more knowledge about the vehicle domain. In accordance with Keil (1986), the separation of literal from metaphorical comparisons is found to depend on the maturity of the vehicle concept stored within the network. The model generates a number of explicit novel predictions.

Introduction

Despite the highly imaginative and figurative way in which children often describe the world, somewhat surprisingly it has been claimed that children are unable to understand figurative or metaphorical speech until they are quite old (Piaget, 1962; see Gibbs, 1994, for a complete review of this position). A likely explanation of this disparity is that adult usage of figurative devices such as metaphor involves several skills. For metaphor, these may include the perception of similarity and of anomaly in comprehending metaphors, the invention of similarities in generating metaphors, an understanding of the role of context in constraining possible meanings, an understanding of speaker intentions, and a metalinguistic ability to justify metaphor use based on specific cross-domain similarities (see e.g., Dowker, 1999). Moreover, it is possible that these skills have different developmental trajectories. Thus Dowker (1999) argues that age variations in similarity recognition and invention may be due to limited domain knowledge which serve to restrict the types of similarity employed by young children to mainly perceptual information. On the other hand, the temporary reduction found in the prevalence of metaphor in the language of children around the age of 6 to 7 (Gardner, Winner, Becchoffer, & Wolf, 1978; Winner, 1988) may be due to age variations in recognition of anomaly.

The idea that conceptual knowledge constrains the ability to use language figuratively is supported by evidence that metaphor usage in children is more prevalent in domains with which they are more familiar (Gottfried, 1997). Indeed Keil (1986) argued that metaphor usage closely shadows the development of conceptual categories. Similar arguments have been made in the related field of analogical reasoning, where it was also initially maintained that the relevant skills appear late in childhood (Piaget, 1962). However, when analogical reasoning was tested in more familiar domains, skills were found at a much earlier age. This implies that limitations in analogical reasoning arise from differences in the knowledge available to children as a basis for exercising this skill (Goswami, in press).

How, then, are we to interpret the apparent presence of metaphor in young children, for example, when a child aged 3 years and 5 months refers to a green carpet as 'grass' (Billow, 1981)? Putting aside the possibility of renaming in symbolic play (which need not involve any similarity between label and assigned referent), and the possibility that this is a case of over-extension (which can be ruled out by checking that the child knows the actual name for a carpet; see Gardner et al., 1978), the juxtaposition would qualify as metaphoric only under the following conditions: the child had not only spotted the similarity between the carpet and grass, but was also aware that carpet and grass fall into separate categories, so that the similarity between them was understood to be *non-literal*. Several authors have suggested that fuzziness in categorization could explain children's early use of apparently figurative language (Hakes, 1982; Marschark & Nall, 1985). If a child's conceptual knowledge has not formed into neat clusters, then there will be some overlap between categories. A sentence that appears figurative to adults may be interpreted as literal by the child.

Evidence to support this position can be found in a study by Vosniadou and Ortony (1983). In their investigations of

the emergence of the distinction between literal, metaphorical, and anomalous comparisons, these authors found evidence that, although 3-year-olds could produce metaphorical completions to target sentences, they were unable to reliably identify that the concepts juxtaposed in these sentences fell into separate categories. However, by four years of age, children who produced metaphors also showed an understanding that metaphorical statements involved concepts from different conventional categories. Both the 3- and 4-year-olds were able to identify anomalous from literal and metaphorical comparisons (see also Pearson, 1990). Vosniadou and Ortony interpreted these data as suggesting that children start with an undifferentiated notion of similarity, which at about the age of four becomes differentiated into literal and non-literal similarity. They suggested that the latter type forms the basis of metaphorical language comprehension.

In this paper, we describe the first computational model explaining the emergence of the distinction between literal and metaphorical similarity, based on an existing connectionist model of simple metaphor comprehension (Thomas & Mareschal, 2001). The importance of this model is that it directly relates the development of metaphor comprehension to the development of semantic representations. The structure of this paper is as follows. We begin by briefly reviewing connectionist approaches to metaphor comprehension. Second, we describe the main tenets of the Metaphor by Pattern Completion (MPC) model on which the developmental account is based. Third, we chart the development of category-specific representations that support metaphor comprehension and the distinction between literal and figurative statements within the MPC model. Finally, we discuss implications for the order of acquisition of such distinctions by young children.

Connectionist models of metaphor processing

First of all, it is important to point out that, although previous computational models have been proposed for the comprehension of metaphor, all of these models have related to the adult state, and none have contained a developmental component.

Previous models of metaphor comprehension have exploited the soft multiple constraint satisfaction abilities of connectionist networks to capture the interactions of conceptual domains when they are juxtaposed in comparisons. One class of models has focused on the potential of microfeature or vector representations of concepts to capture subtle interactions between knowledge bases (e.g., Chandler, 1991; Sun, 1995; Thomas & Mareschal, 2001). A second class of models has focused on structural mapping accounts of analogy formation, whereby target and vehicle domains are compared via the alignment of their relational structure, as well as evaluation of shared attributes (e.g., Holyoak & Thagard, 1989; Hummel & Holyoak, 1997). Why have computational models of metaphor comprehension been silent on developmental phenomena? The answer is that both classes of model have tended to include extensively pre-structured, domain-specific representations, which prevent them from exploring how representations (and their comparison) may emerge as a function of development.

In the present work, we will focus only on attribute mapping, which is readily captured by microfeature models, and put to one side problems of structural alignment. Although this limits the scope of the metaphors to which the model can be applied, it nevertheless makes the first initial steps towards exploring the developmental dimension of metaphor processing, and specifically, to investigating the ways in which metaphor comprehension can be linked to the development of semantic representations.

The MPC model

A full description of the MPC model can be found in Thomas and Mareschal (2001), along with an evaluation of its main assumptions. Here we provide a brief outline. In broad terms, the model suggests that, when presented with a metaphor such as *Richard is a lion*, the listener indeed attempts to fit the concept *Richard* into the category of *lion*; in so doing, an outcome of the categorization process is to alter the representation of *Richard* to make him more consistent with the features of a lion.

More specifically, metaphor comprehension is construed as a two-stage process. Consistent with Glucksberg and Keysar's (1990) view of metaphor comprehension as a type of categorization process, the first stage comprises *mis-classification* of a semantic input. A metaphor <A is B>, where A is the *topic* and B the *vehicle*, is comprehended by applying a representation of the first term (A) to a semantic memory network storing knowledge about the second term (B). Categorization is evaluated via the accuracy of reproduction of (A)'s representation in an autoassociator network trained on exemplars of (B). The degree of semantic distortion of (A) is a measure of the semantic similarity of concept A to domain B (Thomas & Mareschal, 2001).

However, the result of applying (A) to the network storing knowledge about (B) is a representation of (A) transformed to make it more consistent with the (B) knowledge base. In particular, there is an interaction in which features of (A) key into covariant structure between features in (B). If (A) shares some features of such covariant structures, it inherits further features by a process of *pattern completion*. Such feature inheritance depends on both terms, and provides an implementation of Black's (1979) well-known interaction theory of metaphor comprehension. However, enhancement of the features of (A) does not complete the process. In a second stage, the degree of meaning change of the topic is compared to the expected level of change given the current discourse context (Vosniadou, 1989). If the threshold is high, the statement is taken as literal and the full change in meaning is accepted. If it is at an intermediate level, only enhanced feature changes are accepted as the

communicative intent of a metaphor. If the threshold is at a low level, the sentence is rejected as anomalous.

Thomas & Mareschal (2001) evaluated the model's performance in comparing highly simplified domains to illustrate this process. Plausible metaphorical comparisons such as "the apple is a ball" were contrasted with anomalous comparisons such as "the apple is a fork". The model was able to account for a number of empirical phenomena, including the non-reversibility of comparisons and the predictability of interactions between topic and vehicle.

However, the degree to which metaphorical semantic transformations will occur depends not only on the similarity of (A) and (B), but also on the amount and quality of the knowledge stored in knowledge base B. In this way, metaphor comprehension can be linked to semantic development.

In the next section, we take a single vehicle knowledge domain and trace the development of metaphorical comprehension as the knowledge in the base network increases with learning. For simplicity, the sample knowledge base comprises information about *types of ball*, and performance is compared on literal comparisons ("the football is a ball") against metaphorical comparisons ("the pumpkin is a ball") and anomalous comparisons ("the kite is a ball").

The developmental model is intended to be illustrative: we make no claims about children's specific abilities to compare objects to balls at specific ages. Rather, we are interested in evaluating the effect of emerging semantic structure on the delineation of different types of similarity, and the consequent qualitative changes in the nature of metaphor comprehension during development.

Modeling the development of metaphor comprehension

Autoassociation is at the heart of the MPC mechanism. In the original model (Thomas & Mareschal, 2001), multiple parallel knowledge bases were available for different comparisons. However, in the present article and in the interest of clarity, we discuss only results obtained with a single autoassociator network.

A network with 16 input units, 16 output units, and 10 hidden units was trained to autoassociate a set of input patterns that defined the semantic knowledge of the vehicle domain. The number of hidden units was chosen to allow good training performance but also to encourage generalization. All units in the network used sigmoid activation functions.

The autoassociation network was trained for 500 presentations of the complete training set. At each epoch the training set was presented in a different random order. The learning rate and momentum were set to 0.05 and 0.0 respectively. Metaphor comprehension performance was evaluated at 0, 1, 2, 3, 4, 5, 7, 10, 15, 20, 30, 45, 70, 110, 200, and 500 epochs of training. The results reflect an average over n=12 replications with different initial random seeds.

The training set was constructed around 8 prototypes of various balls, constituting the 'ball' knowledge base. Prototypes were defined over 5 clusters of features: color (red, green brown, white), shape (round, irregular), consistency (soft, hard), size (small, large), weight (heavy, light), and associated action (thrown, kicked, hit, eaten), for a total of 16 semantic features. The last feature was included to permit anomalous and metaphorical comparisons. We assume that all concepts can be described by the same large feature set, and that the organization of knowledge into different categories happens within the hidden unit representations through learning. Feature values ranged between 0 and 1, so that the higher the activation, the more prominent the feature. Opposite feature values (e.g., small & large) were encoded on separate inputs to allow the coding of an absence of knowledge. From each prototype, 10 exemplars were generated by adding Gaussian noise (with standard deviation of 0.35) to the prototype pattern. The final training set thus constituted 8x10 = 80 exemplars of balls. The training prototypes are listed in Table 1, upper section.

Assessing different semantic comparisons

A comparison is evaluated by applying a novel input to the network and seeing how well it is reproduced on the output units. The more accurate the reproduction, the greater the similarity of the novel item to the knowledge stored within the network. Nine novel comparisons were created using the semantic features described above. These fell into three classes: (1) literal comparisons, (2) metaphorical comparisons, and (3) anomalous comparisons.

Literal comparisons involved novel exemplars of balls near the prototypical values. Metaphorical comparisons involved inputs that shared some properties with balls, but differed on other properties. Anomalous comparisons involved inputs constructed so that the inputs shared few features with balls in general.

The input vectors for the different classes of comparisons were constructed by comparing the novel input with the ball prototype vectors used to generate the knowledge training set. This was achieved by computing the angle between the two vectors in semantic space and selecting the closest match. For the literal comparisons, the angle had to be to be less than 10 degrees, for the metaphorical comparisons, it had to be between 40 and 45 degrees, and for the anomalous comparisons, it had to be between 60 and 66 degrees. (An angle of 90 degrees would constitute a novel pattern orthogonal to, or completely different from, all the prototypes used to generate the exemplars in the knowledge base.) Novel comparisons are shown in Table 1, lower section. A perfect reproduction of the input at the output indicates a similarity of 1.0 (self-similarity). The transformation similarity (*S*) of each novel comparison to the ball knowledge base was defined as:

$$S = 1 - RMS\ Error \quad (1)$$

An RMS error of 0 would give a similarity of S=1. High similarity implies low semantic distortion (as expected in a literal comparison), moderate similarity implies moderate semantic distortion (as expected in a metaphorical comparison), and low similarity implies high semantic distortion (as expected in an anomalous comparison). The similarity of novel comparisons was evaluated at different points during training. Principal Component Analyses of the hidden unit activations were also carried out during training to chart the development of the internal representations.

Results

Figure 1 shows S for each of the three types of comparison as learning progresses. Initially, there is little difference between literal, metaphorical and anomalous comparisons. However, even very early in learning a marked separation of the anomalous comparisons from the literal and metaphorical comparisons appears. The metaphorical and literal comparisons continue to be treated in a similar fashion for a further 5 presentations of the training set. At this point, metaphorical and literal similarities diverge. In the remaining epochs of training, the similarities from the three different types of comparisons separate into distinct bands. After an initial period of treating literal and metaphorical statements identically, the network has learnt to separate them out.

The process that underlies the development of this distinction can be better understood by examining the developing structure of the network knowledge base (Fig.2). Principal Components Analysis of the hidden unit activation space shows how the internal representations pull apart the different types of ball during training, according to their input characteristics.

In general, anomalous patterns fall in-between clusters, while metaphorical comparisons lie at the edge of clusters, and literal comparisons lie within the clusters. Once the clusters are sufficiently delineated from each other, an item that bears a metaphorical relation to a given category is distinguished from members of that category.

Novel inputs to the network are transformed in an attempt to classify them. Within the model, the transformed semantic representation corresponds to the meaning enhancement that is the outcome the comparison. Focusing on the metaphorical comparisons alone, examination of this enhancement yields three distinct phases during training. First, there is poor pattern completion, linked to an immature vehicle knowledge base. Next, with the initial emergence of semantic structure, metaphorical comparisons such as “the pumpkin is a ball” and “the apple is a ball” lead to enhancement of some of the target’s features. For example, ‘pumpkins’ and ‘apples’ are not associated with being ‘thrown’, ‘hit’, or ‘kicked’. The effect of each metaphor is to transfer such features from vehicle to topic. However, initially enhancement occurs according to an early, prototypical notion of ball, a notion that averages over all exemplars of balls, and corresponds to what one might call the *basic level* of the category. On average, most balls are ‘hit’ rather than ‘kicked’ or ‘thrown’. During this second phase, the ‘hit’ enhancement is inherited by all round, firm targets such as ‘apple’ and ‘pumpkin’. However, in the third phase, as further training produces delineation of the knowledge base, transfer now occurs according to the type of ball *most similar* to the particular target, according to

Table 1: Upper section: Prototypical patterns forming the ball knowledge base. Adding noise to the prototypes creates training sets. Lower section: Novel patterns used in literal, metaphorical, and anomalous comparisons.

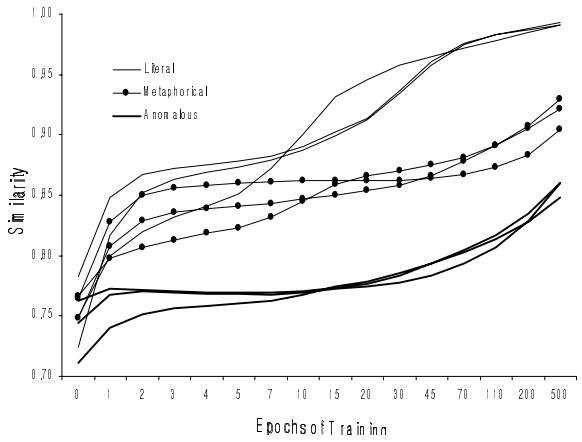

Figure 1. Similarity (*S*) of novel comparisons to the ball knowledge base during training. Three examples from each comparison type are plotted.

what one might call the *subordinate level* of the vehicle category. Table 2 shows that at 4 epochs 'apple' and 'pumpkin' have similar activation levels for the action features, loading maximally on 'hit', whereas at 500 epochs, 'apple' and 'pumpkin' now load on different features. Apples are now viewed as likely to be hit, and pumpkins to be kicked, according to their differing sizes. The model thus generates an explicit and testable prediction: *attribute inheritance will move from basic to subordinate level during development*.

Moreover, since there is variability within the internal structure of categories, not all literal comparisons will be equivalent. The more atypical the literal comparison, the more it will resemble a metaphor. This leads to a second explicit and testable prediction: *the recognition of atypical literal statements as distinct from metaphorical statements should lag behind the recognition of typical literal statements as distinct from metaphorical statements during development.*

Discussion

A common characterization of conceptual development views young children's knowledge as being assimilated into broad groups; as children develop, they make finer and finer distinctions until there are many different categories (e.g., Carey, 1985; Keil, 1986). Because the comprehension of metaphor requires the deliberate deconstruction of

Table 2: Attribute transfer from *basic* (4 epochs) and *subordinate* (500 epochs) category levels. Scores show the transformed feature values for action features Thrown (T), Hit (H) and Kicked (K) in the topic.

categories, the way knowledge is categorized will have a large effect on metaphor comprehension. The model we have described above provides a concrete implementation of Marschark and Nall's (1985) account of metaphor use in young children. Literal, metaphorical, and anomalous comparisons fall onto a conceptual space undergoing refinement. The process of refinement leads to the emergence of a notion of non-literal similarity.

Clearly this simple model does not capture all aspects of the development of metaphor comprehension. The metaphors we have dealt with are predominantly perceptual. Importantly, the model fails to capture the emerging use of structural information in children's metaphors (Gentner, 1988). However, existing computational models have not addressed develop-mental phenomena at all, let alone the relational shift. The next step for the MPC model will be an extension to structured representations, possibly via the inclusion of synchrony binding (see Hummel & Holyoak, 1997), while retaining the mechanism of pattern completion as a powerful tool for explaining the transfer of attributes in metaphorical comparisons. Despite its simplicity, the importance of the current model is its demonstration that the emergence of non-literal similarity can be driven by emerging semantic structure, and the explicit testable hypotheses it generates to progress our understanding of the development of metaphor comprehension in young children.

A New Model of Graph and Visualization Usage

J. Gregory Trafton

Abstract

We propose that current models of graph comprehension do not adequately capture how people use graphs and complex visualizations. To investigate this hypothesis, we examined 3 sessions of scientists using an *in vivo* methodology. We found that in order to obtain information from their graphs, scientists not only read off information directly from their visualizations (as current theories predict), but they also used a great deal of mental imagery (which we call spatial transformations). We propose an extension to the current model of visualization comprehension and usage to account for this data.

Introduction

If a person looks at a standard stock market graph or a meteorologist is examining a complex meteorological visualization, how is information extracted from these graphs? The most influential research on graph and visualization comprehension is Bertin's (1983) task analysis that suggests three main processes in graph and visualization comprehension:

1. Encode visual elements of the display: For example, identify lines and axes. This stage is influenced by pre-attentive processes and is affected by the discriminability of shapes.

2. Translate the elements into patterns: For example, notice that one bar is taller than another or the slope of a line. This stage is affected by distortions of perception and limitations of working memory.

3. Map the patterns to the labels to interpret the specific relationships communicated by the graph. For example, determine the value of a bar graph.

Most of the work done on graph comprehension has examined the encoding, perception, and representation of graphs. Cleveland and McGill, for example, have examined the psychophysical aspects of graphical perception (Cleveland & McGill, 1984, 1986). Similarly, Pinker's theory of graph comprehension, while quite broad, focuses on the encoding and understanding of graphs (Pinker, 1990). Kosslyn's work emphasizes the cognitive processes that make a graph more or less difficult to read. Kosslyn's syntactic and semantic (and to a lesser degree pragmatic) level of analysis focuses on encoding, perception, and representation of graphs (Kosslyn, 1989). Recent work by Carpenter and Shah (1998) shows that people switch between looking at the graph and the axes in order to comprehend the visualization.

This scheme seems to work very well when the graph contains all the information the user needs (i.e., when the information is explicitly represented in one form or another). Thus, when an undergraduate is asked to extract specific information from a bar-graph, the above process seems to hold. However, graph usage outside the laboratory is probably not simply a series of information extractions. For example, when looking at a stock market graph, the goal may not be just to determine the current or past price of the stock, but perhaps to determine what the price of the stock will be sometime in the future. A weather forecaster looking at a meteorological visualization is frequently trying to predict what the weather will be in the future, as well as what the current visualization shows (Trafton, Kirschenbaum, Tsui, Miyamoto, Ballas, & Raymond, 2000). A scientist examining results from a recent experiment can not always display the available information in a way that perfectly shows the answer to her hypotheses.

How do current theories of graph comprehension hold up when a graph or visualization does not contain the exact information needed? Unfortunately, the theories do not say anything about this situation. In fact, there are no specifications in any theory of graph comprehension about how information could or would be extracted from a visualization where that information is not represented in some form. If a graph does not contain the information needed by the user, the graph is often labeled "bad" or "useless" (Kosslyn, 1989; Pinker, 1990).

Current graph comprehension theories do not have a great deal to say about what to do when a graph does not explicitly show the needed information for a variety of reasons. The main reason is probably that most graph comprehension studies have used fairly simple graphs for which no particular domain knowledge is required (e.g., Carter, 1947; Lohse, 1993; Pinker, 1990). However, in real-world situations, people use complex visualizations that require a great deal of domain knowledge, and all the needed information would probably not be explicitly represented in the graph. This study will thus try to answer two questions about graph comprehension. Do expert users of visualizations ever need information that is not on a specific graph they are using? If so, how do they extract that information from the graph?

There are several possible things that users could do when trying to extract information from a graph. In the simplest case, the information is explicitly available, and they can simply read off the information from the visualization. What do they do when information they need is not available on the visualization? They could create a completely new visualization that does show the information. They could also collect more data or consult another source. They could create an explicit plan to look for more data or run another experiment.

What do they do when the visualization is all they have to work with? What kind of mental operations could users perform on graphs and visualizations in order to extract information that is not explicit? One possibility is that people use some sort of visual imagery to extract information that is not explicitly represented on a graph or visualization. For example, a weather forecaster may mentally imagine a front moving east over the next several days (Trafton et al., 2000), or a stock analyst may mentally extend a line on a graph and think that a stock will continue to rise. We have developed a framework for coding and working with these kinds of graphs and visualizations called *Spatial Transformations* that will be used to investigate these issues. We will argue that spatial transformations are a fundamental aspect of complex visualization usage.

Spatial Transformations are cognitive operations that a scientist performs on a visualization. Sample spatial transformations are mental rotation (e.g., Shepard & Metzler, 1971), creating a mental image, modifying that mental image by adding or deleting features to or from it, animating an aspect of a visualization (Hegarty, 1992) time series progression prediction, mentally moving an object, mentally transforming a 2D view into a 3D view (or vice versa), comparisons between different views (Kosslyn, Sukel, & Bly, 1999; Trafton, Trickett, & Mintz, 2001), and anything else a scientist mentally does to a visualization in order to understand it or facilitate problem solving. Also note that a spatial transformation can be done on either an internal (i.e., mental) image or an external image (i.e., a scientific visualization on a computer-generated image). What all spatial transformations have in common is that they involve the use of mental imagery. A more complete description of spatial transformations can be found at `http://iota.gmu.edu/users/trafton/405st.html`.

We will examine the number of times that users needed information from a visualization. If all or most of the information is available explicitly on the visualization, we should see primarily read-offs (Kosslyn, 1989; Pinker, 1990). If, however, a particular visualization does not explicitly display particular information that a scientist wants, we will examine how the scientist goes about obtaining that information. We expect that in complex visualizations, there is a great deal of information that is needed in addition to what is displayed, and we expect scientists to use spatial transformations to retrieve that information.

Method

In order to investigate the issues discussed above, we have adapted Dunbar's in vivo methodology (Dunbar, 1995, 1996; Trickett, Trafton, & Schunn, 2000b). This approach offers several advantages. First, it allows the observation of experts, who are thus able to use their domain knowledge to guide their strategy selection. Second, it allows the collection of "on-line" measures of thinking, which allow the investigation of the scientists' reasoning as it occurs (Ericsson & Simon, 1993). Finally, the tasks (experiment design, data analysis, etc.) conducted by the scientists, as well as the tools they use, are fully authentic.

Two sets of scientists were videotaped while conducting their own research. All the scientists were experts, having earned their Ph.D.s more than 6 years previously. In the first set, two astronomers, one a tenured professor at a university, the other a fellow at a research institute, worked collaboratively to investigate computer-generated visual representations of a new set of observational data. At the time of this study, one astronomer had approximately 20 publications in this general area, and the other approximately 10. The astronomers have been collaborating for some years, although they do not frequently work at the same computer screen and the same time to examine data.

In the second dataset, a physicist with expertise in computational fluid dynamics worked alone to inspect the results of a computational model he had built and run. Two related sessions were recorded with this scientist over consecutive days. He works as a research scientists at a major U.S. scientific research facility, and had earned his Ph.D. over 20 years previously. He had inspected the data previously but had made some adjustments to the physics parameters underlying the model and was therefore revisiting the data.

Both sets of scientists were instructed to carry out their work as though no camera were present and without explanation to the experimenter (Ericsson & Simon, 1993). The relevant part of the astronomy session lasted about 53 minutes, and the two physics sessions each lasted approximately 15 minutes. All utterances were later transcribed and segmented according to complete thought. All segments were coded by 2 coders as on-task (pertaining to data analysis) or off-task (e.g., jokes, phone call interruptions, etc.). Inter-rater reliability for this coding was more than 95%. Off-task segments were excluded from further analysis. On-task segments (N = 649 for the astronomy dataset and N = 189 for the first physics dataset and N = 176 for the second physics dataset) were further coded as described below.

The Tasks and the Data

Astronomy The astronomical data under analysis were optical and radio data of a ring galaxy. The astronomers' high-level goal was to understand its evolution and structure by understanding the flow of gas in the galaxy. In order to understand the flow of gas, the astronomers must make inferences about the velocity field, represented by

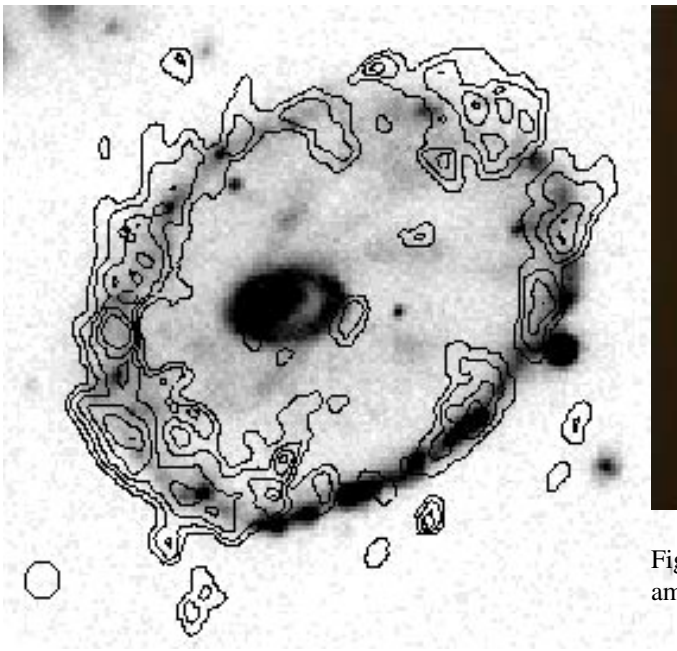

Figure 1: An example of the kind of visualizations examined by the astronomers.

contour lines on the 2-dimensional display. The astronomers' task was made difficult by two characteristics of their data. First, the data were one- or at best 2-dimensional, whereas the structure they were attempting to understand is 3-dimensional. Second, the data were noisy, and there was no easy way to distinguish between noise and real phenomena. Figure 1 shows a screen snapshot of the type of data the astronomers were examining. In order to make their inferences, the astronomers used different types of image, representing different phenomena (e.g., different forms of gas), which represent different information about the structure and dynamics of the galaxy. Some of these images could be overlaid on each other. In addition, the astronomers could choose from images created by different processing algorithms, each with advantages and disadvantages (e.g., more or less resolution). Finally, they could adjust different features of the display, such as contrast or false color. A more complete description of this dataset can be found in Trickett, Fu, Schunn, and Trafton (2000a) and Trickett, Trafton, and Schunn (2000b).

Physics The physicist was working to evaluate how deep into a pellet a laser light will go before being reflected. His high-level goal was to understand the fundamental physics underlying the reaction, an understanding that hinged on an understanding of the relative importance and growth rates of different modes. The physicist had built a model of the reaction; other scientists had independently conducted experiments in which lasers were fired at pellets and the reactions recorded. A close match between model and empirical data would indicate a good understanding of the underlying theory. Although the physicist had been in conversation with the experimentalist, he had not viewed the empirical data, and in this session he was investigating only the results of his computational model. However, he believed the model to be correct (i.e., he had strong expectations about what he would see), and in this sense, this session may be considered confirmatory.

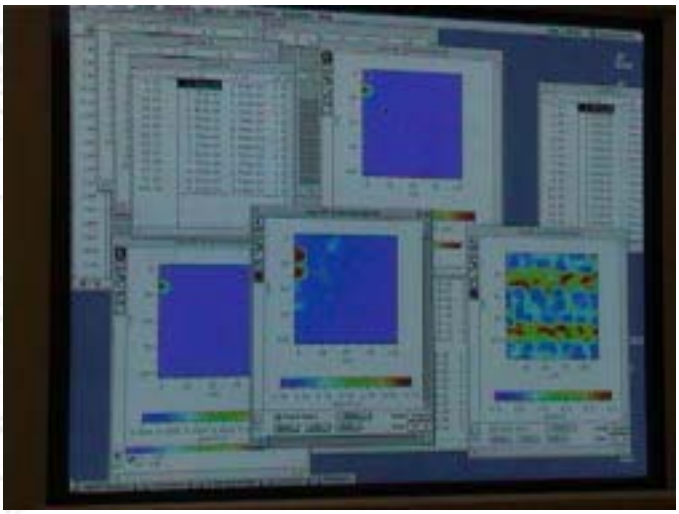

Figure 2: An example of the kind of visualizations examined by the physicist.

The data consisted of two different kinds of representation of the different modes, shown over time (nanoseconds). The physicist was able to view either a Fourier decomposition of the modes or a representation of the "raw" data.

Figure 2 shows an example of the physicist's data. He could choose from black-and-white or a variety of color representations, and could adjust the scales of the displayed image, as well as some other features. He was able to open numerous views simultaneously.

Coding Scheme

Our goals in this research are first, to determine if complex visualizations contain all the information needed by the scientists, and, if not, to investigate what happens when they do not have all the information they need. We propose that spatial transformations are a major portion of extracting information from a visualization when the data is not explicitly represented. Consequently, we identified every situation where a scientist wanted to extract information from a visualization. Next, we coded what the scientist did to extract information, including reading off the information directly from the graph, spatial transformations, changing the visualization, plans or discussions about getting more data, and abandoning their attempt to get the information. We now describe and provide examples of this coding scheme in detail.

Example	Explanation
After all, it is ten to the minus six...	Scientist is looking at a line and extracting the y-axis value
I mean, the fact you see such a strong concentration of gas in the ring, um...	Scientist is reading off the amount of gas in the ring
That's about 220 km/sec, which is the velocity spread of a normal galaxy.	Scientist is reading off the velocity spread

Table 1: Examples of information that is read off the visualizations.

Spatial Transformation	Example	Explanation
Create Mental Image	I mean, in a perfect, in a perfect world, in a perfect sort of spider diagram...	Scientist is creating a mental image of a spider diagram; there is no spider diagram displayed.
Modify Image	So that [line] would be below the black line	Scientist is adding a new (hypothesizied) line to a current visualization
Modify Image	If there was no streaming motion or sort of piling of gas	Scientist has imaged a previous mental image and is now removing the streaming motions from his mental image
Comparison:	Maybe it's a projection effect, although if that's true, there should be a very large velocity dispersion.	Scientist is comparing a current image to a previously created mental image.

Table 2: Examples of spatial transformations.

Desire to extract information A scientist would frequently want to extract some amount of information from a visualization. Comments varied from the very general ("What do we see?") to the very specific ("Let's see, how does oh-three versus three-oh [look]?").

Read-Off A scientist would be able to read-off information directly from the graph. Information that was read off a visualization was explicitly on the graph and the scientist simply had to read-off a particular value. For every utterance, we evaluated whether a value was read off the visualization. Table 1 shows several examples of information that was read off of the visualization.

Spatial Transformations As discussed earlier, spatial transformations are cognitive operations that a scientist performs on a visualization. For every utterance in each protocol we evaluated whether there was a spatial transformation. Spatial transformations were further coded as Create Image, Modify Image, or Comparison. Table 1 shows examples of each category of spatial transformation (note that these utterances are independent of one another and do not represent a sequence). Table 2 shows several examples of spatial transformations that were used by the scientists.

Changing the Visualization The scientists were using their own tools and were able to change the visualization to a completely different representation. For example, a scientist could change the data display from the raw data to a Fourier mode display). Alternatively, the scientists could "tweak" the current representation (from black and white to color, for example). We coded the visualization changes where the scientists were looking for additional information. If they simply made a mistake and tweaked the visualization, we did not count that visualization change. For example, while looking at a particularly compressed visualization, one of the scientists said "Where's three-oh at? Don't see three [oh]. That's what I figured, I was gonna get spaghetti. Let's do a re-plot." and then replotted the data with a reduced dataset.

Plans to gather more data Occasionally, the scientists wanted or needed to gather more data. We coded every time they made a plan to gather more data. For example, one scientist said "So that means that this guy is in fact between him and him, which is exactly what the experimentalist believes he saw. Now, somewhere along the line I have to get their results."

Abandoning their attempt to get information Sometimes the scientists either could not decide what data to get or simply abandoned their quest for a specific information. We coded every time the scientists abandoned their attempt to get information. For example, one scientist, unable to explain a particular feature after extensive investigation of the image, said "Yeah well, [let's] gloss over it."

Results

Our two goals in this paper are to explore whether scientists are able to directly extract the amount of information they need from the visualizations they examine and if not, to explore how they do get the information that is needed.

How often is needed information directly available?

Of the 1014 total utterances in the three sessions, almost half (481) involved some form of information gathering.

As Figure 3 shows, approximately half of those information gathering instances were read-off, suggesting that the scientist did use the visualization a great deal to extract information. However, there were many times when the scientists needed information from a visualization but it was not available directly from the visualization. Thus, the visualizations seem to be good, but far from perfect from an information gathering point of view.

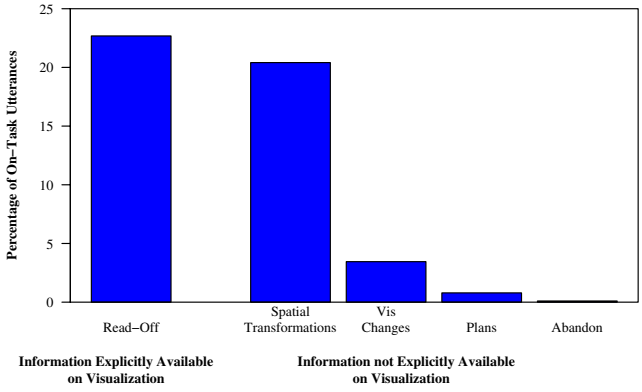

Figure 3: The number of read-offs, spatial transformations, visualization changes, plans to collect future data, and decisions to abandon the attempt to get more data for all datasets.

How was needed information extracted if it was not simply read off? As Figure 3 shows, the vast majority of information that was not read off was gathered by using spatial transformations. In fact, there was no statistical difference between the number of times that the scientists read off information directly from the graph and the number of spatial transformations, $\chi^2(1) = 1.21, p > .20$.

Additionally, scientists chose to use a spatial transformation to get needed information from a visualization rather than changing the visualization, $\chi^2(1) = 122.25, p < .001$, making plans to gather more data $\chi^2(1) = 184.19, p < .001$, or abandoning their attempt to answer their question, $\chi^2(1) = 204.02, p < .001$.[1]

[1] All χ^2's used the Bonferroni adjustment.

General Discussion

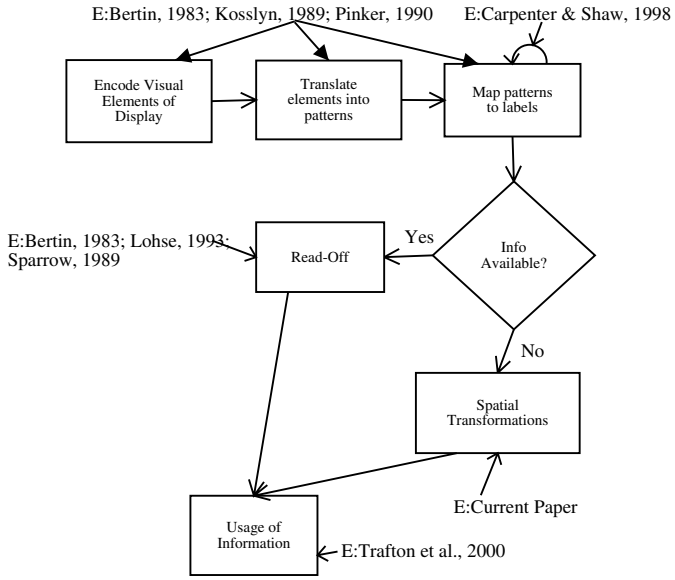

Figure 4: Our current theoretical model of complex visualization usage. The "E:" shows evidence for each stage of the model.

We have conducted a detailed analysis of expert scientists at work in their own laboratories, analyzing data that they have collected themselves. Our results show that these scientists do extract a great deal of information from the visualizations. However, these visualizations do not provide the scientists with all the information they need to answer their questions. We found that when they needed information that was not explicitly provided by the visualization, they tended to perform spatial transformations to answer their questions.

It is interesting that the scientists did not simply change the visualization more frequently to get the needed information. There was some evidence in the protocols that it was not easy to create new visualizations. For example, some of the visualizations had to be re-done because of an error that was made in the display (i.e., needed data was not included in the plot or the plot was not presented logarithmically when it should have been). However, this problem did not seem to have prevented the scientists from trying to make the changes: there were no instances of a scientist saying the visualization tool was too complicated or difficult to work with (though these tools could no doubt be improved). Thus, the scientists' use of spatial transformations do not seem to be a substitute for "bad" graphs, but rather a strategy to understand the data more thoroughly.

As suggested earlier, current theories of graph comprehension can not account for this pattern of results. Current theories (e.g., Bertin, 1983; Kosslyn, 1989; Pinker, 1990) deal primarily with how users extract information that is explicitly available on a graph or vi-

sualization. In this study, we have shown that users do not simply extract information that is explicitly shown on a visualization; rather, they extract information and use mental imagery to create similar visualizations, modify those mental images, and compare their mental results to on-screen results. These spatial transformation seem to be used for a variety of reasons, including hypothesis testing and understanding their own mental representation through a process of aligning various mental images (Trafton et al., 2001).

How can we integrate these new results into current theories? We believe that the current theoretical model should be expanded to include spatial transformations as part of the cognitive processes that users go through to interpret and use visualizations. Figure 4 shows our current model of graph comprehension, along with evidence that supports each stage of this model.

We believe, as Figure 4 shows, that when people use graphs or visualizations, they initially go through a process to understand the graph itself. Then, when they need to extract information, they can either read off that information directly from the visualization or, if that information is not available, perform a spatial transformation to get the needed information.[2] Finally, that information is actually used by the user.

Abstract

We use an *in vivo* methodology to investigate the responses of scientists to anomalies. Protocols of 3 scientists performing data analysis in 2 domains were analyzed. We found that the scientists noticed anomalies and paid more attention to them than to expected data. This attention took the form of proposing a hypothesis and then elaborating that hypothesis by reference to other data in the visual display, rather than to the scientists theoretical domain knowledge.

Introduction

How do scientists deal with anomalous or unexpected data? Philosophers of science (e.g., Kuhn, 1962; Lakatos, 1976) have argued that anomalies play a crucial role in moving science forward. Scientists themselves have claimed that investigating anomalies lies at the heart of scientific innovation (e.g., Knorr, 1980).

Psychologists have been interested in the cognition underlying how scientists deal with anomalies. There have been two general approaches to the study of anomalies. One approach focuses on response to negative evidence in concept identification tasks (Wason, 1960). Several studies have found that people are likely to seek confirming evidence for their theories (e.g., Mynatt, Doherty, & Tweney, 1977).

Surprisingly, studies from this tradition have found that scientists are also very susceptible to confirmation bias (e.g., Mahoney & DeMonbreun, 1977). One criticism of this approach is that the tasks are abstractions of the hypothesis-testing cycle and therefore do not allow the participants to make use of their extensive domain knowledge (e.g., Chinn & Malhotra, 2001). However, sociological studies (e.g., interviews) of practicing scientists have also found that scientists appear to display confirmation bias (Mitroff, 1974).

A second approach investigates scientists' response to anomalies as they perform analyses of authentic scientific data. This approach includes both historical studies of scientific discovery (Chinn & Brewer, 1992; Kulkarni & Simon, 1988; Nersessian, 1999) and *in vivo* observations of contemporary practicing scientists (Dunbar, 1997; Trickett, Trafton, & Schunn, 2000). Chinn and Brewer have developed a taxonomy of responses, from ignoring the anomaly to changing the theory. They have found evidence for the whole range of responses in historical records of science. Yet the results of other studies suggest that scientists do pay attention to anomalies. For example, Dunbar (1997) found that individual scientists were quick to discard a hypothesis when faced with results that were inconsistent with it, and Kulkarni and Simon (1988) identified an "attend to surprising result" heuristic as crucial to Hans Krebs' discovery of the urea cycle.

Recently, Alberdi, Sleeman and Korpi (2000) have brought together these two approaches to the study of anomalies in scientific thinking. They conducted a psychological study of expert botanists performing a categorization task in the domain of plant taxonomy. As participants formed hypotheses about the category into which a current set of plants would fall, they were presented with a "rogue," or anomalous, item that belied their expectations. Alberdi and his colleagues found that participants did indeed pay attention to the anomalies. Furthermore, they identified a number of strategies by which participants attempted to resolve the anomalous data. Key among these was the "instantiate" strategy, in which participants searched their theoretical domain knowledge for a new hypothesis that would accommodate the anomaly.

Although categorization is an important task in many areas of science, there are many other situations in which scientists might encounter anomalies. For example, to name a few, experimental results might fail to match a prediction, a computational model might yield a different output from expectation, or empirical data might contain puzzling phenomena hard to explain by means of current theoretical understanding. Thus, many questions remain about other circumstances under which a scientist encounters an anomaly in the course of his or her own research.

The goal of this paper is to investigate scientists' response to anomalies they discover as they analyze their own data. Our first question concerns the extent to which scientists attend to anomalous data. One can imagine a range of possible responses, from ignoring the anomaly to attempting to give a full accounting of it (Chinn and Brewer, 1992). Do practicing scientists tend to ignore anomalies as suggested by Mitroff (1974) or do they attend to anomalies as suggested by Dunbar (1997) and Alberdi et al. (2000)? Our second question concerns the processes and strategies by which scien-

tists deal with anomalies when they encounter them. Do they take a theoretical approach, as found by Alberdi et al (2000) or focus on the data itself? Alternatively, additional strategies might emerge from observing scientists at work. We investigate all these possibilities.

Method

In order to investigate the issues discussed above, we have adapted Dunbar s in vivo methodology (Dunbar, 1997; Trickett, Trafton & Schunn, 2000). This approach offers several advantages. It allows observation of experts, who can use their domain knowledge to guide their strategy selection. It also allows the collection of "on-line" measures of thinking, so that the scientists' thought processes can be examined as they occur. Finally, the tasks the scientists do are fully authentic.

Two sets of scientists were videotaped while conducting their own research. All the scientists were experts, having earned their Ph.D.s more than 6 years previously. In the first set, two astronomers, one a tenured professor at a university, the other a fellow at a research institute, worked collaboratively to investigate computer-generated visual representations of a new set of observational data. At the time of this study, one astronomer had approximately 20 publications in this general area, and the other approximately 10. The astronomers have been collaborating for some years, although they do not frequently work at the same computer screen and the same time to examine data.

In the second dataset, a physicist with expertise in computational fluid dynamics worked alone to inspect the results of a computational model he had built and run. He works as a research scientist at a major U.S. scientific research facility and had earned his Ph.D. 23 years ago. He had inspected the data earlier but made some adjustments to the physics parameters underlying the model and was therefore revisiting the data.

Both sets of scientists were instructed to carry out their work as though no camera were present and without explanation to the experimenter (Ericsson & Simon, 1993). The relevant part of the astronomy session lasted about 53 minutes, and the physics session, 15 minutes. All utterances were later transcribed and segmented according to complete thought. All segments were coded by 2 coders as on-task (pertaining to data analysis) or off-task (e.g., jokes, phone interruptions, etc.). Inter-rater reliability for this coding was more than 95%. Off-task segments were excluded from further analysis. On-task segments (N = 649 for astronomy and N = 176 for physics) were then grouped into episodes (N = 19 for astronomy and N = 9 for physics). Episodes began with the scientists' focus on a phenomenon and lasted until attention switched to another feature or theoretical issue. This grouping of the protocol into episodes allowed us to focus on the more immediate reaction to anomalies.

The Tasks and the Data

Astronomy The data under analysis were optical and radio data of a ring galaxy. The astronomers high-level goal was to understand its evolution and structure by understanding the flow of gas in the galaxy. In order to understand the gas flow, the astronomers must make inferences about the velocity field, represented by contour lines on the 2-dimensional display.

The astronomers task was made difficult by two characteristics of their data. First, the data were one- or at best 2-dimensional, whereas the structure they were attempting to understand was 3-dimensional. Second, the data were noisy, with no easy way to separate noise from real phenomena. Figure 1 shows a screen snapshot of the type of data the astronomers were examining. In order to make their inferences, the astronomers used different types of image, representing different phenomena (e.g., different forms of gas), which contain different information about the structure and dynamics of the galaxy. In addition, they could choose from images created by different processing algorithms, each with advantages and disadvantages (e.g., more or less resolution). Finally, they could adjust some features of the display, such as contrast or false color.

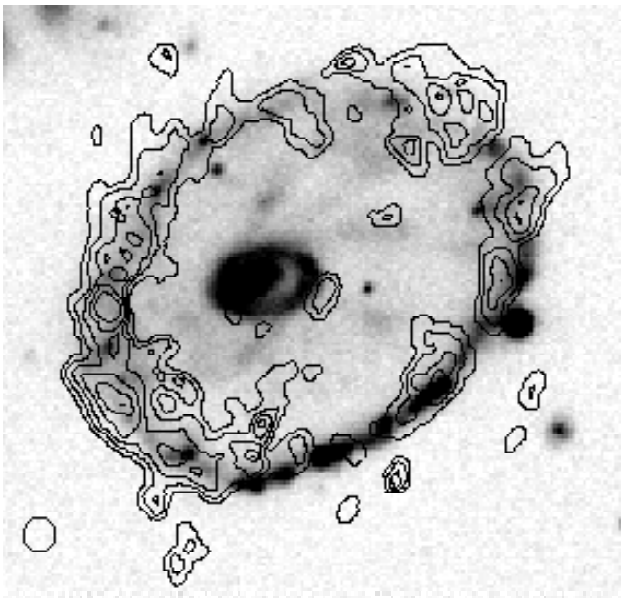

Figure 1: Example of data examined by astronomers. Radio data (contour lines) are laid over optical data.

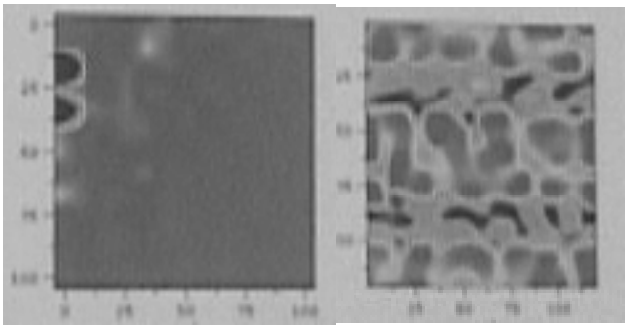
Physics The physicist was working to evaluate how deep into a pellet a laser light will go before being reflected. His high-level goal was to understand the fundamental physics underlying the reaction, an understanding that hinged on comprehending the relative importance and growth rates of different modes. The physicist had built a model of the reaction; other scientists had independently conducted experiments in which lasers were fired at pellets and the reactions recorded. A

close match between model and empirical data would indicate a good understanding of the underlying theory. Although the physicist had been in conversation with the experimentalist, he had not viewed the empirical data, and in this session he was investigating only the results of his computational model. However, he believed the model to be correct (i.e., he had strong expectations about what he would see), and in this sense, this session may be considered confirmatory.

The data consisted of two different kinds of representation of the different modes, shown over time (nanoseconds). The physicist was able to view either a Fourier decomposition of the modes or a representation of the raw data. Figure 2 shows an example of the physicist's data. He could choose from black-and-white or a variety of color representations, and could adjust the scales of the displayed image, as well as some other features. He was able to open numerous views simultaneously. A large part of his task was comparing images, both different types of representation of the same data and different time slices represented in the same way.

Figure 2: Example of data examined by physicist
Fourier modes (left) and raw data (right)



Coding Scheme

Our goal in this research was to investigate scientists' response to anomalous data. First, we wanted to establish whether and to what extent the scientists noticed and attended to anomalies. Second, we wanted to investigate the processes by which they respond.

Both protocols were coded independently by 2 different coders. Initial inter-rater reliability for each code was greater than 85%. Disagreements were resolved by discussion. Any coding disagreements that could not be resolved were excluded from further analysis.

Noticings In order to establish which phenomena unusual or not the scientists attended to, we first coded for the scientists' *noticing* phenomena in the data. A noticing could involve merely some surface feature of the display, such as a line, shape, or color, or it could involve some interpretation, for example, identifying an area of star formation or the implied presence of a mode. Only the first reference to a phenomenon was coded as a noticing; coding of subsequent references to the same phenomenon is discussed below.

Because our investigation focused on the extent to which the scientists attended to anomalies in the data, we further coded these noticings as either "anomalous" or "expected," according to one or more of the following criteria: a) in some cases the scientist made explicit verbal reference to the fact that something was anomalous or expected; b) if there was no explicit reference, domain knowledge was used to determine whether a noticing was anomalous or not;[1] c) a phenomenon might be associated with (i.e., identified as like) another phenomenon that had already been established as anomalous or not; d) a phenomenon might be contrasted with (i.e., identified as unlike) a phenomenon that had already been established as anomalous or not; e) a scientist might question a feature, thus implying that it is unexpected. Table 1 illustrates these codes.

Criterion	Code	Example
Explicit	Anomalous	What's *that funky thing* That's odd
Domain Knowledge	Expected	You can see that *all the H1* is concentrated in the ring
Association	Anomalous	You see *similar kinds of intrusions* along here
Contrast	Expected	That's odd As opposed to *these things*, which are just the lower contours down here
Question	Anomalous	I still wonder why *we don't see any H1 up here* in this sort of northern ring segment?

Table 1: Noticings (in italics): anomalous or expected

Subsequent References One of our questions was the extent to which the scientists attended to anomalies. The coding of noticings captured only the first reference to a phenomenon of interest; we needed to establish how frequently they made subsequent reference to each noticing. Consequently, all subsequent references were also identified and coded.[2] Not all subsequent references immediately followed a noticing; frequently, the scientists returned to a phenomenon after investigating other features of the data. Subsequent references were identified both within the episode in which the noticing had occurred and across later episodes.

The rest of the coding scheme addresses *how* the scientists responded to the anomalies, in particular imme-

[1] The coders domain knowledge came from textbooks and interviews with the scientists.

[2] In the astronomy dataset, because the scientists shared a computer monitor, frequently the first interaction between them after a noticing was to make sure they were both looking at the same thing. Subsequent references that served purely to establish identity were *not* included in the analyses.

diately after they notice the anomalies. To investigate the scientists immediate response to their anomalous findings, we coded 10 utterances following each noticing, whether anomalous or expected (minus utterances establishing which phenomenon was under discussion, in the astronomy dataset). We anticipated that scientists would attempt to produce hypotheses for the anomalies, and that some of these hypotheses would be discussed further. Based on the results reported by Alberdi, et al. (2000), we investigated the extent to which elaboration of hypotheses was grounded in theory or in the visual display of the data. We also anticipated the use of additional strategies and inspected the data to identify strategies that emerged, as discussed below.

Hypotheses Statements that attempted to provide a possible explanation for the data were coded as hypotheses. All hypotheses were further coded as *elaborated* or *unelaborated*. Elaboration consisted of one or more statements that either supported or opposed the hypothesis. Hypotheses that were not discussed after they were proposed were coded as unelaborated.

When a hypothesis was elaborated, we coded whether the elaboration was *theoretical* or *visual*. When evidence for or against a hypothesis was grounded in theoretical domain knowledge, elaboration was coded as theoretical; when evidence came from the display, it was coded as visual.

Place in context A strategy that emerged from our examination of the data was considering the noticing in relation to other data. Thus we coded whether or not the scientist placed the noticing in context, and whether that context was another part of the dataset (*local*) or the scientist's own theoretical knowledge (*global*).

Results and Discussion

Noticing Anomalies

Our first question was did the scientists notice anomalies in the data?[3] Recall that a noticing is a first-time reference to a phenomenon of interest. Table 2 presents the total number of noticings for each dataset and the percentages of anomalous and expected phenomena. As Table 2 shows, at least one-third of the phenomena the astronomers identified and almost one-half the physicist identified were unusual in some way. It appears then that the scientists *did* notice anomalies in their data.

	Total Noticing	Anomalous	Expected	Not coded
Astronomy	27	33%	48%	19%
Physics	9	44%	44%	12%

Table 2: Frequency of anomalies and expected noticings

[3] We presented a more detailed discussion of a subset of the results for the astronomy dataset in Trickett et al. (2000).

Attention to Anomalies

Once the scientists had identified something unusual in the data, what did they do with this observation? There are several possible reactions: they could pursue the anomaly in order to try to account for it, they might temporarily disregard it but return to it later, or they might move on to explore some other, better understood, aspect of the data. A related question is whether their response to anomalies was different from their response to expected phenomena.

We investigated this issue by counting how often the scientists made subsequent reference to a noticing immediately upon identifying it. If anomalies and expected phenomena are of equal interest, we would expect them to make a similar number of references to both the anomalous and expected patterns. However, if anomalies play a more important role in their efforts to understand the data, we would expect them to pay more attention (measured by the number of subsequent references) to anomalies than to expected observations.

As Table 3 shows, for both the astronomy and physics datasets, scientists paid more attention to anomalies than expected phenomena, $t(28)=2.33$, $p<.05$. In the case of astronomy, the anomalies received over 3 times as many subsequent references within the same episode as the expected phenomena. The physics dataset follows a similar pattern, with more than twice as many references to anomalies as expected phenomena. The results are in stark contrast to the findings of the confirmation bias literature.

	Anomalies	Expected
Astronomy	7.6	1.5
Physics	3.0	1.25

Table 3: Mean number of subsequent references per noticed object to anomalies and expected phenomena

Immediate Response to Anomalies

We have shown that when the scientists noticed an anomaly, they immediately attended to it, but we have not analyzed the content of that attention to anomalies. In order to understand what kind of the scientists made, we now turn to the results of the second part of our coding scheme, which was applied to the 10 utterances that immediately followed the initial noticing of anomalies and expected phenomena.

Identify Features As Figure 3 shows, the scientists were only slightly (and nonsignificantly) more likely to identify specific features of the anomalies as the expected noticings, and this pattern held for both domains.

Propose Hypothesis As Figure 4 shows, the scientists were much more likely to propose a hypothesis for the

anomalies than the expected noticings $\chi^2(1) = 7.5$, $p<.05$, and this pattern was very strong in both domains.

Figure 3: Percentage of noticings for which scientists identified features.

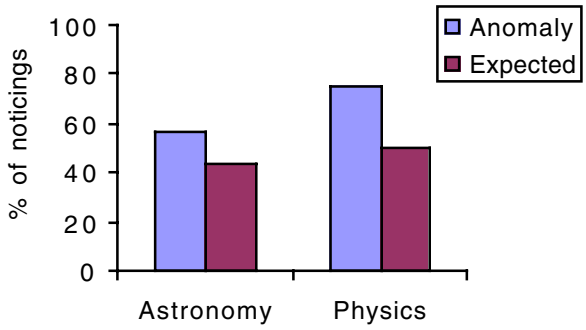


Figure 4: Percentage of noticings with hypotheses

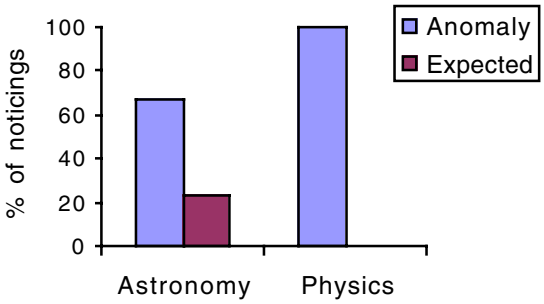
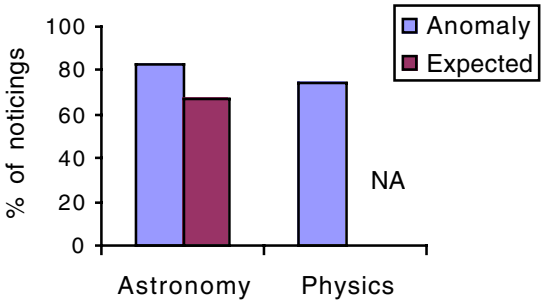


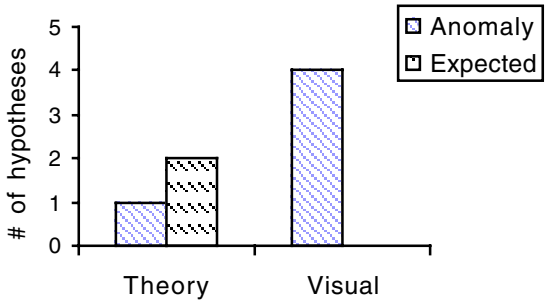
Elaborated Hypothesis Once the scientists had proposed a hypothesis (primarily about the anomalies), in most cases they elaborated that hypothesis. Figure 5 presents the proportion of hypotheses that were elaborated within each domain for expected and anomalous noticings. In most cases, scientists attempted to elaborate the hypotheses, for both expected and anomalous noticings (note that there were no hypotheses to elaborate in the expected physics case).

Figure 5: Percentage of noticings that were elaborated



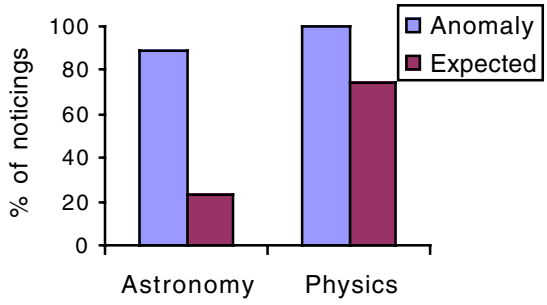
Source of Elaboration For the physics dataset, there were not enough elaborated hypotheses to analyze further. For the astronomy data, evidence about 4 of the 5 hypotheses about anomalies came from the visual display. The 2 hypotheses about expected noticings were developed theoretically. Figure 4 shows this result.

Figure 6: Elaboration type for hypotheses (astronomy)



Place in Context In addition to (or instead of) developing hypotheses about the noticings, the scientists also might consider the noticing in relation to other information, either theoretical information in memory (global context) or information about the current dataset (local context), or they might not place it in either context. In fact, none of the noticings was considered in the context of the scientists' theoretical knowledge (global). However, the scientists considered the noticings in the context of the current dataset (local), and this sequence occurred more frequently for the anomalies than for the expected phenomena, especially in the astronomy dataset (see Figure 7), $\chi^2(1) = 9.21$, $p<.01$.

Figure 7: Percentage of noticings put in local context



General Discussion and Conclusion

We examined the behavior of scientists at work, analyzing their own data. Our results show that these scientists not only notice anomalies in the data, but also attend to them, contrary to the confirmation bias literature, but similar to the findings of Dunbar (1997) and Alberdi et al. (2000).

The scientists we observed not only notice and attend to anomalies, but also do so in a particular way. Furthermore, this pattern is quite different from the pattern that results from their observation of expected phenomena. When they notice an expected phenomenon, after identifying or describing its features, the scientists are likely to engage in no further elaboration of the phenomenon. On the rare occasions when they do attempt to account for it by proposing a hypothesis, they seek evidence in their own theoretical knowledge, rather than in the visually displayed data. By contrast, however, for anomalous noticings, the scientists attempt to account for the anomaly by proposing a hypothesis. They then elaborate the hypothesis, primarily by seeking evidence in the visual display, and finally consider how the anomaly relates to neighboring phenomena within the same display.

Our results mesh in part with those of other researcher, in that they provide further evidence for the important role played by anomalies as scientists analyze and reason about data. However, our results differ from those of Alberdi et al. (2000) in some significant ways. When the botanists in their study encountered an anomaly, they were most likely to use a strategy of theory-driven search for an explanation. The scientists in our study, however, sought support for hypotheses in the visually displayed data, and attempted to place the anomaly in the local context of neighboring phenomena. Only hypotheses about expected phenomena were developed at a theoretical level.

There are several possible explanations for this difference. Situational differences in the tasks performed by the participants in these two studies might affect their strategy. For the botanists, categorization was the goal *per se.* Although the astronomers and physicist were performing some categorization tasks, this was done in service of understanding the data as a whole, in order to build a mechanistic theory. The difference in their goals might account for the different strategies they used. Another possibility is that the botanists were getting immediate feedback on their hypotheses, whereas the other scientists had to generate their own feedback. In this sense, the botanists' task is similar to a supervised learning task, whereas the astronomers and physicist were in a situation where learning was unsupervised (Hertz, Krogh, & Palmer, 1991). It is plausible that the uncertainties inherent in this situation can account for the fact that these scientists sought feedback in the empirical data in the display rather than jumping immediately to their theoretical domain knowledge.

Spoken Language Comprehension Improves the Efficiency of Visual Search

Abstract

Much recent eye-tracking research has demonstrated that visual perception plays an integral part in on-line spoken language comprehension, in environments that closely mimic our normal interaction with our physical environment and other humans. To test for the inverse, an influence of language on visual processing, we modified the standard visual search task by introducing spoken linguistic input. In classic visual search tasks, targets defined by only one feature appear to "pop-out" regardless of the number of distractors, suggesting a parallel search process. In contrast, when the target is defined by a conjunction of features, the number of distractors in the display causes a highly linear increase in search time, suggesting a more serial search process. However, we found that when a conjunction target was identified by a spoken instruction presented concurrently with the visual display, the effect of set size on search time was dramatically reduced. These results suggest that the incremental linguistic processing of the two spoken target features allows the visual search process to, essentially, conduct two nested single-feature parallel searches instead of one serial conjunction search.

Introduction

For a psycholinguist studying spoken language comprehension, the visual environment would be considered "context". However, for a vision researcher, the visual environment is the primary target of study, and auditory/linguistic information would be considered the "context". Clearly, this variable use of the label "context" is due to differences in perspective, not due to any objective differences between language and vision. In everyday perceptual/communicative circumstances, humans must integrate visual and linguistic information extremely rapidly for even the simplest of exercises. Consider the real-time dance of linguistic, visual, and even gestural events that takes place during a conversation about the weather. This continuous coreferencing between visual and linguistic signals may render the very idea of labeling something as "context" arbitrary at best, and perhaps even misleading.

The problem of "context" has traditionally been dealt with in a rather drastic fashion: researchers forcibly ignore it. If context does not influence the primary functions of the process of interest (be it in language, vision, memory, reasoning, or action), then that process can be thought of as an encapsulated module which will permit dissection via a nicely limited set of theoretical and methodological tools. For example, prominent theories of visual perception and attention posit that the visual system is functionally independent of other cognitive processes (Pylyshyn, 1999; Zeki, 1993). This kind of modularity thesis has been applied to accounts of language processing as well (Chomsky, 1965; Fodor, 1983). As a result, a great deal of progress has been made toward developing first approximations of how vision may function and how language may function.

However, recent eye-tracking studies have shown evidence that visual perception constrains real-time spoken language comprehension. For example, temporary ambiguities in word recognition and in syntactic parsing are quickly resolved by information in the visual context (Allopenna, Magnuson, & Tanenhaus, 1998; Spivey & Marian, 1998; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). Findings like these are difficult for modular theories of language to accommodate.

The present experiment demonstrates the converse: that language processing can constrain visual perception. In a standard visual search task, a target object is typically defined by a conjunction of features, and reaction time increases linearly with the number of distractors, often in the range of 15-25 milliseconds per item (Duncan & Humphreys, 1989; Treisman & Gelade, 1980; Wolfe, 1994). However, when we presented the visual display first, and then provided the spoken target features incrementally, we found that reaction time was considerably less sensitive to the number of distractors.

With conjunction search displays, increased reaction times as a linear function of set size were originally interpreted as evidence for serial processing of the objects in the display, and contrasted with the near-flat function of reaction time by set size observed with

feature search displays -- where a single feature is sufficient to identify the target object. It was argued that the early stages of the visual system process individual features independently and in parallel (Livingstone & Hubel, 1988), allowing the target object to "pop out" in the display if it is discriminable by a single feature, but requiring application of an attentional window to the individual objects, one at a time, if the target object is discriminable only by a conjunction of features (Treisman & Gelade, 1980). This categorical distinction between parallel search of single feature displays and serial search of conjunction displays has been supported by PET scan evidence for a region in the superior parietal cortex that is active during conjunction search for motion and color, but not during single feature search for motion or for color (Corbetta, Shulman, Miezin, & Petersen, 1995).

However, several studies have discovered particular conjunctions of features that do not produce steeply sloped reaction-time functions by set size (e.g., McLeod, Driver & Crisp, 1988; Nakayama & Silverman, 1986). Additionally, it is possible to observe the phenomenology of 'pop-out' while still obtaining a significant (albeit, small) effect of set size on reaction time (Bridgeman & Aiken, 1994). Moreover, it has been argued that steeply sloped reaction-time functions may not reflect serial processing of objects in the display, but rather noise in the human visual system (Eckstein, 1998; Palmer, Verghese, & Pavel, 2000). Overall, a wide range of studies have suggested that the distinction between putatively "serial" and "parallel" search functions is continuous rather than discrete, and should be considered extremes on a continuum of search difficulty (Duncan & Humphreys, 1989; Nakayama & Joseph, 1998; Olds, Cowan, Jolicoeur, 2000; Wolfe, 1994, 1998).

In a recent study, Spivey, Tyler, Eberhard, and Tanenhaus (in press b) demonstrated that the incremental processing of linguistic information could, essentially, convert a difficult conjunction search into a pair of easier searches. When target identity was provided via recorded speech presented concurrently with the visual display, displays that typically produced search slopes of 19 ms per item produced search slopes of 8 ms per item. It was argued that if a spoken noun phrase such as "the red vertical" is processed incrementally (cf. Altmann, & Kamide, 1999; Eberhard, Spivey-Knowlton, Sedivy, & Tanenhaus, 1995; Marslen-Wilson, 1973, 1975), and there is extremely rapid integration between partial linguistic and visual representations, then one might predict that the listener should be able to search items with the first-mentioned feature before even hearing the second one. If the observer can immediately attend to the subset of objects sharing that first-mentioned feature, such as the target color (Egeth, Virzi, & Garbart, 1984; Friedman-Hill & Wolfe, 1995; Motter & Holsapple, 2000), and subsequently search for the target object in that subset upon hearing the second-mentioned feature, then this initial immediate group selection should reduce the effective set size to only those objects in the display that share the first-mentioned feature – effectively cutting the search slope in half.

At least two concerns remain before this basic finding can be extended and tested in the many different variations of visual search displays. First, since a slope of 8 ms per item is clearly in the range of what has traditionally been considered “parallel search”, it is somewhat unclear whether the result is in fact a *halving* of the effective set size or a near *elimination* of the effect of set size. Essentially, the question is whether the first feature extraction is a genuine “pop-out” effect and the second is a genuine serial search of those “popped out” objects (half of the set size), or are both searches “practically parallel”. A replication of the study may provide some insight into this question. Second, the experiments reported by Spivey et al. (in press b) ran participants in separate blocks of control trials and trials with concurrent auditory/visual input. It is in principle possible that practice was somehow more effective in the auditory/visual concurrent condition, or that subjects developed some unusual strategy in that condition that they didn’t use in the control condition. To be confident in the result, it is necessary to replicate it with a mixed (instead of blocked) design, where the control trials and the A/V concurrent trials are randomly interspersed.

Experiment

Method

Participants Eighteen Cornell undergraduate students were recruited from various Psychology classes. Participants were reimbursed 1 point of course extra credit for participating in the study.

Procedure The experiment was composed of two types of trials presented in random mixed order within one continuous block of 192 trials. Participants were instructed to take breaks between trials when they felt it was necessary. In one type of trial, the participant was auditorily informed of the target identity *before* presentation of the visual display (‘Auditory First’ control condition). In the other type of trial, the participant was auditorily informed of the two defining feature words of the target *concurrently with* the onset of the visual display (‘A/V Concurrent’ condition) (see Figure 1) Of the 192 trials, 96 were ‘Auditory First’, and 96 were ‘A/V concurrent.’

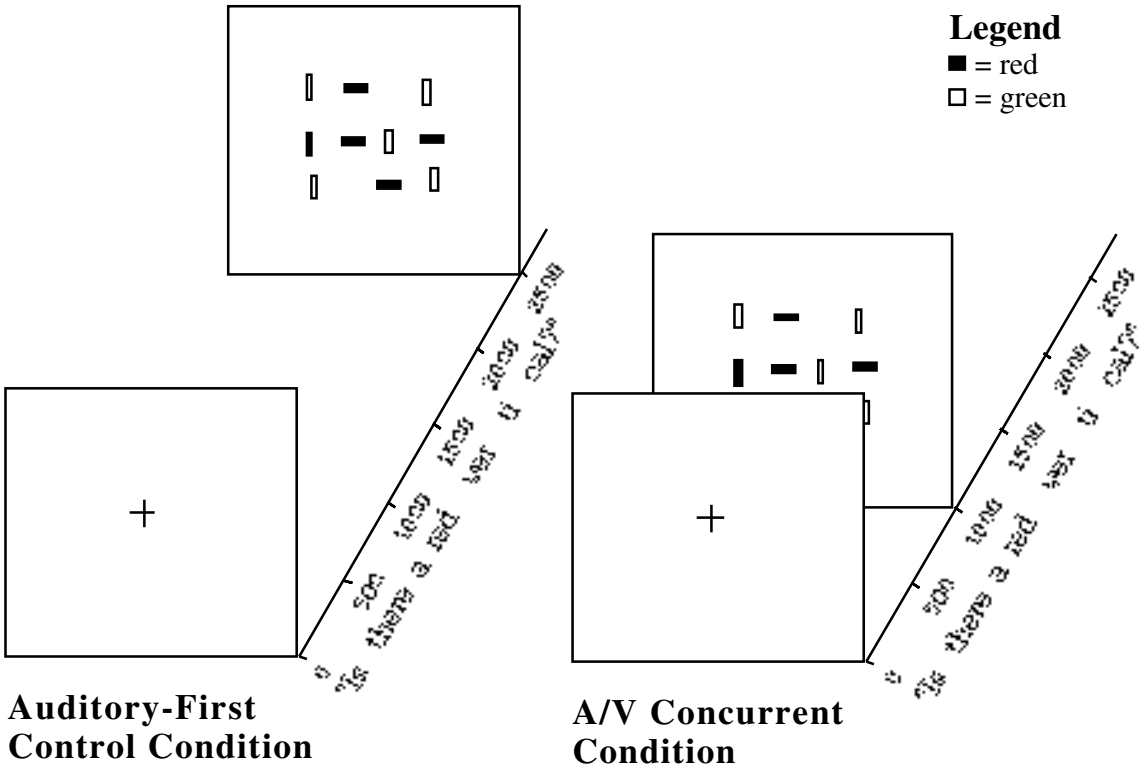

Figure 1. Schematic diagram of the two conditions. In the Auditory-First condition, the search display is presented after the entire spoken query is heard, whereas in the A/V Concurrent condition, the search display is presented immediately before the two target features are heard. Reaction time is measured from the point of display onset.

Trials began with a question delivered in the format of a speech file. The same female speaker recorded all speech files with the same preamble recording, "Is there a…" being spliced onto the beginning of each of the four types of target query types ("…red vertical?", "…red horizontal?", "…green vertical?", and "…green horizontal?"). Each of the four types of speech files were edited to be almost identical in length, and with almost identical auditory spacing of defining feature words. Participants were instructed to press a 'yes' key on a computer keyboard if the queried object was present in the display, and the 'no' key if it was absent. It was stressed to participants that they should do this as quickly and accurately as possible. An initial fixation cross preceded the onset of the visual display in order to direct participants' gaze to the central region of the display. Each stimulus bar subtended 2.8 degrees X 0.4 degrees of visual angle, and neighboring bars were separated from one another by an average of 2 degrees of visual angle. Trials with red vertical bars as targets and trials with green vertical bars as targets, as well as red and green horizontal bars as targets, were equally and randomly distributed throughout the session. All participants had normal or corrected-to-normal vision, and all had normal color perception. The objects comprising the visual display appeared in a grid-like arrangement positioned centrally in the screen (see Figure 1). Set sizes of objects comprising the visual displays were 5, 10, 15, and 20.

Results

Mean accuracy was 95% and did not differ across conditions. Figure 2 shows the reaction time by set size functions for target-present trials (filled symbols) and target-absent trials (open symbols) in the A/V Concurrent condition and the Auditory-First condition. The best-fit linear equations are accompanied by their r^2 values indicating the percentage of variance accounted for by the linear regression.

Overall mean reaction time was slower in the A/V Concurrent condition as a result of the complete auditory notification of target identity being delayed by approximately 1.5 seconds relative to the Auditory-First control condition. However, since spoken word recognition is incremental, participants were able to begin processing before both target feature words had been presented, and overall reaction time was only delayed by about 600 milliseconds.

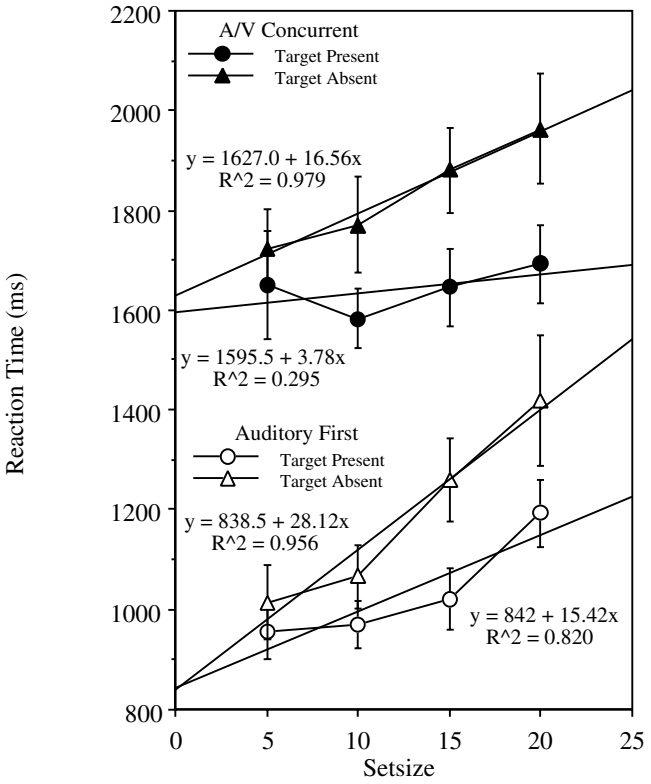

Figure 2: Reaction time as a function of set size.

Repeated-measures analysis of variance revealed significant main effects of Condition [F(1, 16)=230.27, p<.01], Target Presence/Absence [F(1,16)=27.97, p<.01], and Set Size [F(3, 48)=22.83, p<.01]. The effect of Condition was simply that overall reaction times were slower when the delivery of target identity was delayed in the A/V Concurrent condition. The effect of Target Presence/Absence was the common finding that it takes longer to determine that the target is absent than to determine that it is present. Essentially, the target-present case involves something akin to a self-terminating search, and the target-absent case requires something like an exhaustive search. The main effect of Set Size simply showed that, when Condition and Target Presence/Absence are ignored, having more distractors increased reaction time. There was also an interaction between Set Size and Target Presence/Absence, showing that the effect of Set Size was more pronounced in the target-absent trials than in the target-present trials [F(3,48)=4.36, p<.01].

The important result for the purposes of our inquiry was the significant interaction between Condition and Set Size, indicating that the effect of Set Size was more pronounced in the Auditory-First control condition than in the A/V Concurrent condition [F(3, 48)=4.92, p<.01]. Despite the fact that the visual displays were identical, results indicated shallower slopes for reaction-time functions in the A/V Concurrent condition compared to the Auditory-First control condition (Figure 2).

To specifically test whether the mean slope was significantly shallower in the A/V Concurrent condition, participants' individual set size slopes from the two conditions were compared via paired t-tests, and revealed significantly shallower slopes for the A/V Concurrent condition in target-present trials [3.78 vs. 15.42 ms per item; t(16)=2.09, P<.05] and in target-absent trials [16.56 vs. 28.12 ms per item; t(16)=3.39, P<.01]. These results indicate that adjusting the timing of the spoken query (e.g., "Is there a red vertical?"), such that the two target feature words were presented while the visual display was visible, allowed participants to find the target object in a manner that was substantially less affected by the total number of distractors. In fact, the mean slope of 3.78 ms per item in the target-present trials of the A/V Concurrent condition was not significantly greater than zero [t(16)=1.12, p>.25], whereas the mean slope of 15.42 ms per item in the target-present trials of the Auditory-First control condition was robustly greater than zero [t(16)=4.47, p<.001].

Hence it appears that, in the Auditory-First condition, the search process may employ a conjunction template to find the target, thus forcing a serial-like process akin to sequentially comparing each object to the target template. However, in the A/V concurrent condition, it appears that the incremental nature of the speech input allows the search process to begin when only a single feature of the target identity has been heard. This initial single-feature search proceeds in a more parallel fashion (with the second-mentioned target feature being used to find the target amidst the attended subset), thus dramatically improving the efficiency of search.

Discussion

The results suggest that, due to the incremental nature of spoken language comprehension (Allopenna et al., 1998; Altmann & Kamide, 1999; Cooper, 1974; Eberhard et al., 1995; Marslen-Wilson, 1973, 1975; Tanenhaus et al., 1995) the listener/observer can selectively attend to the subset of objects that exhibit the target feature which is mentioned first in the speech stream. Upon hearing even just a portion of the second-mentioned target feature a few hundred milliseconds later, the observer can then locate the conjunction target object amidst this attended (spatially noncontiguous) subset. These results highlight the incremental processing of spoken language comprehension, and demonstrate the human brain's ability to seamlessly cross-index partial linguistic representations (of a noun phrase, for example) with partial visual representations (of a cluttered visual display).

A more detailed question remains, concerning whether the improved efficiency in visual search is due to the first-mentioned target feature initiating an instantaneous parallel search and the second-mentioned target feature initiating a serial search among the attended items (thus cutting the search slope in half) or to both spoken target features initiating parallel searches (causing the search slope to look like that of a single-feature search). In Spivey et al. (in press b, Experiments 1 and 2), the target-present search slopes of 7.7 and 8.9 ms per item in the A/V Concurrent conditions were roughly consistent with both of those interpretations. When parallel and serial search were conceived of as discrete categories, any set-size function of less than 10 ms per item was generally interpreted as "parallel search." However, Spivey et al.'s target-present Auditory First conditions produced search slopes of 19.8 and 18.6 ms per item -- approximately twice the A/V Concurrent slopes.

The present results, with a target-present search slope of 3.78 ms per item in the A/V Concurrent condition, appear to support the "two parallel searches" alternative. However, in all likelihood, the two alternatives outlined above rely too much on the discrete distinction between "parallel" and "serial" search. If there is indeed a continuum of search efficiency (Duncan & Humphreys, 1989; Nakayama & Joseph, 1998; Olds, Cowan, Jolicoeur, 2000; Wolfe, 1994, 1998), and conjunction search is not quite accurately described as an object-by-object serial process (Eckstein, 1998; Palmer, Verghese, & Pavel, 2000), then it might be safest to conclude that each spoken target feature initiates a "relatively efficient" search that is not quite parallel and not quite serial. Importantly, the second search appears to be able to work selectively on the output of the first one -- compelling evidence for the continuous incrementality with which linguistic and visual processing can coordinate.

Until now, there has been little or no evidence for real-time visual perception being influenced by linguistic context. However, there is considerable work reporting demonstrations of real-time language processing being influenced by visual context (e.g., Allopenna, Magnuson, & Tanenhaus, 1998; McGurk & MacDonald, 1976; Spivey & Marian, 1998; Tanenhaus et al., 1995). Recent eyetracking research has shown in a number of circumstances that the resolution of temporary ambiguities is immediately biased by information in the visual array. For example, when participants were instructed to "pick up the candy", they often looked first at a *candle* before then fixating the candy (Tanenhaus et al., 1995). A precise timing analysis of the eye movements suggested that, when the candle and candy are in the visual display, participants had mental representations for both 'candle' and 'candy' equally partially active during the first couple hundred milliseconds of the word (Allopenna et al., 1998). When only the candy was in the display, the eye-movement data suggested that word recognition was faster, involving less competition from partially active alternatives.

Similar findings were reported for syntactic ambiguity resolution. When the visual context contained a referential ambiguity (e.g., two apples for the instruction "Put the apple…") that was best resolved by pursuing the correct parse of a syntactic ambiguity ("Put the apple on the towel in the box."), participants eye-movement patterns suggested a fast and correct interpretation of the instruction. When there was no such referential ambiguity (e.g., only one apple), participants produced eye-movement patterns indicating a mis-parse of the instruction (Spivey, Tanenhaus, Eberhard, & Sedivy, in press a; Tanenhaus et al., 1995).

Those effects of visual context immediately influencing language comprehension were initially met with considerable resistance from a substantial portion of psycholinguists. However, when we would discuss those findings with vision researchers, they were often appreciative but not terribly impressed. To them, it made perfect sense that the visual system was important and powerful enough to occasionally tell the language system what to do very quickly. We are curious to see the reaction of the vision research community to the present results.

Returning to our discussion of the notion of "context", which began this paper, it seems that the rapidity with which the visual system and the language system can coordinate their representations suggests that any attempt to label some signal as "context" is doomed to be an arbitrary choice – a choice that risks marginalizing important information sources as well as opaquely lumping discriminable information sources. Essentially, the less we assume encapsulated modular processes in language and in vision, the less use we have for the notion of "context" in language and in vision. Instead of visual processing and linguistic processing, perhaps a considerable portion of our daily mental life is made up of visuolinguistic processing.

Since the human brain is neither a psycholinguist nor a vision researcher (indeed, it is much more than even the two of them combined), it is not susceptible to the biased perspectives they exhibit. As far as the brain is concerned, no one incoming signal is the "primary signal" with the others being "context". Each time slice of perceptual experience is a rich tapestry of multi-modal environmental inputs, all of which the brain integrates and incorporates simultaneously. Our results suggest that, across the domains of language and vision, it is surprisingly good at doing that job immediately and continuously.

"Two" Many Optimalities

Gran de Gràcia, 127, 2-1; 08012 Barcelona, Spain

Abstract

In evolutionary biology a trait is said to be optimal if it maximizes the fitness of the organism, that is, if the trait allows the organism to survive and reproduce better than any other competing trait. In engineering, a design is said to be optimal if it complies with its functional requirements as best as possible. Cognitive science is both a biological and engineering discipline and hence it uses both notions of optimality. Unfortunately, the lack of a clear methodological stance on this issue has made it common for researchers to conflate these two kinds of optimality. In this paper I argue that a strict distinction must be kept in order to avoid inaccurate assumptions.

Cognitive Explanations

Contemporary biological explanations are teleonomic explanations. Teleonomic explanations are those explanations that treat biological traits as adaptations. Adaptations are innovations that make a difference between alternative biological designs embodied in different individuals. Such designs are "chosen" from among alternative designs on the basis of how well they perform in a given environment.

The phenotype of an organism is therefore understood as a collection of functionalities that were added and maintained (i.e., copied over generations) in the design features of a given species *because* these functionalities had the consequence of solving problems that promoted, in some way or other, survival and reproduction (Millikan, 1984). A complete teleonomic explanation would then consist of a step-by-step process in which the scientist must:

(A) Teleonomic Explanation

1. Identify the trait that is likely to be under selection.
2. Identify the adaptive problem that the trait is supposed to solve.
3. Show:

(a) that the trait is specialized for solving the adaptive problem;
(b) that it is unlikely to have arisen by chance alone; and
(c) that it is not better explained as the by-product of mechanisms designed to solve some alternative adaptive problem.

4. Establish the fitness value of the trait in the population.[1]

This sort of story could be the general strategy for *any* discipline which required teleonomic explanations. However, cognitive science has certain particularities that change this methodology. In explaining the cognitive mechanisms of biological organisms, the cognitive scientist may attempt to identify the adaptive problem that the brain is supposed to solve. In reality, however, this turns out to be quite difficult, because the trait—that is, the specialized device within the brain that is responsible for solving the adaptive problem—is not as self-evident as, say, an eye, a liver or a wing. Specialized cognitive mechanisms lie within the circuitry of the brain in such a way that makes them not as obvious as one would like (Barkow, Cosmides & Tooby, 1992).

In order to overcome this problem, cognitive scientists usually invert the first and second steps of the algorithm above:

(B) Cognitive Explanation

1. Identify the adaptive problem that the organism is supposed to solve.
2. Presuppose the trait that is likely to be under selection.
3. Show:

(a) that the trait is specialized for solving the adaptive problem;
(b) that it is unlikely to have arisen by chance alone; and
(c) that it is not better explained as the by-product of mechanisms designed to solve some alternative adaptive problem.

4. Establish the fitness value of the trait in the population.

Inverting the two first steps of algorithm (A) cannot be without consequences. The most obvious is the fact that identifying the function of a trait, such as a wing

[1] In other words, the theorist must establish that the distribution of the trait in the population contributes to the evolutionary notion of fitness, which for present purposes means simply the capacity to survive and reproduce.

or an eye, is much easier when the trait has been identified rather than presupposing the trait when we only know its function. In the first case we can simply observe the trait at work or determine if it is rarely used, etc., or perhaps we might test it under all imaginable circumstances just to see what it does. Cognitive scientists face a much more difficult enterprise, however, since we have to "imagine" the design features of the trait. This is where the reverse-engineering strategy comes in.

Optimality in Reverse-Engineering

Dennett (1995) is perhaps one of the most adamant about defending the reverse engineering strategy in cognitive science. This strategy can be defined as the interpretation of an already existing intelligent artifact or system through an analysis of the design considerations that must have governed its creation. Logically, this overidealizes the design problem, because it presupposes that the trait is *optimally* executed by the cognitive machinery. Thus, reverse-engineering takes cognitive systems to be systems that are designed to solve the problem identified by the theorist; otherwise, the analysis could not get off the ground. As Dennett observes, if cognitive scientists cannot assume that there is a good rationale for the features they observe in cognizers, they cannot even begin their task. Optimality must be the default assumption in cognitive explanations.

A standard way of advancing the reverse-engineering strategy is to resort to Cummins' notion (1983) of functional analysis. Basically, a functional analysis amounts to:

1. System S performs F
2. F can be broken down into $f_1, f_2, f_3 \ldots f_n$
3. S implements $f_1, f_2, f_3 \ldots f_n$

The first step is therefore to establish F, that is, what the system does. The usual way in which one characterizes F is to call upon the computational theory proposed by Marr (1982). In this framework, the theorist must provide an abstract formulation of the information-processing task that defines a given cognitive ability. Peacocke (1986), for example, describes such formulations as characterizations of the information state that the system draws upon.

Now, the notion of "information drawn upon" can be spelled out as follows:

> A state draws upon some information whenever such state carries the information which is causally influential in the operation of the algorithm or mechanism. (Peacocke, 1989, p.102).

Given this definition, explanations based on Peacocke's notion can be seen as a fully causal. For instance, facts about the meaning, syntactic structure, and phonetic form of linguistic expressions are causally explained by facts about the information drawn upon by algorithms or mechanisms in the language-user (ibid., p.113). Thus, if a system draws upon the correct information, then the explanation of system is correct regardless of the detailed algorithm that the system uses.

Be this as it may, the computational characterization of a problem determines the specifications by which the reverse-engineering must proceed. These specifications are taken at face value and are considered sufficient to establish the design features of the mechanism. Cummins (1983) further argues that such characterizations should proceed by decomposing them into a set of simpler capacities that are to be explained by subsumption. The overall capacity is thus explained in terms of the contributing capacities of parts of the system, and the function of a given item is its contribution to the overall capacity. Such design theories of functions define the function of a mechanism or process in terms of the roles they might play, that is, in terms of their contribution to some capacity of the system to which the process or mechanism belongs. In short, design theories relativize functions to capacities of containing systems.

Optimality in Evolutionary Biology

The previous sense of optimality must be distinguished from the notion of optimality that is used in evolutionary biology. To begin with, the biological notion of an optimum does not imply an optimal design, as it does in engineering. Rather, it refers to a solution to a given adaptive problem that maximizes the fitness of the organism in the adaptive situation.

A biological optimum can be said to be the point at which the difference between costs and benefits of environmental and genetic variables (e.g., amount of food, energy requirements, distribution of the trait, alternative phenotypes, etc.) is maximized (see Figure 1). Thus, the role of a trait as an adaptation must be established by considering the manner in which such a trait contributes to the optimum. This makes the notion of optimality in biology and engineering orthogonal to one another:

Biological optimality: Natural selection favors the trait that maximizes the organism's *fitness*.

Reverse-engineering optimality: A mechanism is *designed* to comply with its function.

The fact of the matter is that a trait need not be optimally designed to be adaptive: what is optimal is the fitness value of the trait, not its design characteristics. Evolutionary solutions must, on this view, only be "selectively efficient," that is, they need only to comply with adaptive requirements. It follows, then, that the notion of optimal design should be detached from the notion of fitness value.

That natural selection is only susceptible to the fitness-value maximizations is anything but surprising: evolution by natural selection only requires that biological systems be minimally effective (stay alive and leave offspring) with respect to their of adaptive problems. Hence, rather than actively designing and building organisms that are well-adapted to the world, nature eliminates

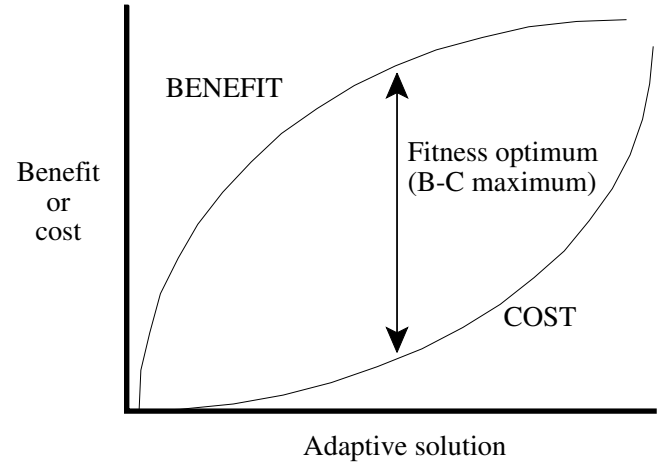

Figure 1: The optimum for a given adaptive solution is the point in which the benefit/cost relationship is maximized.

those that are too ill-suited for survival and reproduction. In other words, biological systems are simply not designed by engineers. Design and evolution are different precisely because they have different strategies open to them. An engineer may build a system out of an analysis of the problem, and thus may go from the problem to the solution. This is not a possibility for biological systems: biological systems are blind to the solution until they have stumbled upon it.

The bottom line, then, is that we should explain how cognitive systems are selected for and maintained by taking into account not only the adaptive problem itself, but also their resources and the environment in which they are evolving.

Conflating the Two Optimalities

The previous discussion makes it advisable to maintain the engineering and the biological optimalities separate. However, some cognitive scientists (e.g., Barkow, Cosmides & Tooby, 1992) seem to conflate both notions. According to these theorists, what must guide the design specifications of cognitive mechanisms is a computational characterization (Marr, 1982) of the adaptive problems that these mechanisms were meant to solve. These specifications are considered sufficient to establish the design features of the mechanism:

> In effect, knowledge of the adaptive problems humans faced, described in explicitly computational terms, can function as a kind of Rosetta Stone: It allows the bewildering array of contents effects that cognitive psychologists routinely encounter—and usually disregard—to be translated into meaningful statements about the structure of the mind. (Cosmides & Tooby, 1992, p.221)

In other words, these theorists take the brain to be the seat of specialized mechanisms that are optimally designed, in an engineering sense, to solve specific adaptive problems.

It is of course possible for engineering and biological characterizations to coincide for a given trait and a given organism. Nonetheless, counterexamples abound (e.g., Ullman, 1996; Steels, 1994; Dehaene, 1997; Cooper & Munger, 1993;). Consider the well-known example of the sight-strike-feed mechanism of the frog (Gilman, 1996). Frogs catch flies by way of a strike with their tongue. It is assumed that mediating between the environmental presence of a fly and the motor response of the tongue strike there is some sort of mechanism that registers the fly's presence in the vicinity of the frog. That is, the presence of the fly causes the relevant mechanism to go into state *S*, and its being in state *S* causes the tongue to strike.

This story goes on to assume that the information drawn upon by state *S* is that of "fly", "fly, there," or "edible bug, there," since this information can be derived from that the fact that the function of the frog's sight-strike-feed mechanism mechanism is to detect the presence of flies. Yet, an analysis of the frog's cognitive system indicates that the best account of the system's function is in fact detecting "little ambient black things." Specifically, the function of the mechanism is to mediate between little ambient black things and the frog's tongue strike.

This means that the frog's mechanism is functioning optimally even when the frog strikes at a little ambient black thing that is not a fly but a BB-gun pellet that happens to be in the vicinity. To be sure, from a reverse-engineering point of view, the system is not optimally designed to catch flies. However, from a biological point of view, it might be the optimal system. The reason is quite simple. The cost of "fly-detecting" mechanism may outweigh the cost of eating, say, lead pellets. The guarantee that a frog with such an less-than-perfect mechanism could have survived and reproduced is provided

by the contingent fact that, during natural selection, a sufficient number of little ambient black things in the frog's environment were flies (or edible bugs). The combination of the benefits (which should include adequate feeding) with the costs (which should include design-building costs) shows that a better design need not mean better fitness, which is what would be predicted if only design were considered. Accordingly, in some situations a better design can actually mean a drop in fitness.

It might be objected that the fact that frogs also flick their tongues out at little black things that happen not to be flies is an empirical discovery and, hence, either sense of optimality could have been wrong about what frogs would do when confronted with BB-gun pellets. For example, an evolutionary biologist might predict that natural selection would favor the trait if the trait were specifically tailored to fly catching, since this would maximize fitness. Yet this prediction would have been wrong. A reverse-engineering perspective, by contrast, might well have made the correct prediction: striking at little black things that are not flies might be seen as an acceptable amount of noise, and not necessarily an unoptimally designed fly-catching mechanism. Such being the case, the problem, it might be argued, does not really have anything to do with the two different notions of optimality, but rather with the claims one is making about a particular trait and what sort of evidence should be used in evaluating those claims.

It seems to me that such an objection would miss the point of the argument, which is to uncover two different methodological strategies, and not competence in hypothesis formation. I will illustrate the problem with another example. Peacocke (1993) has argued that the use of particular kinds of physical principles is constitutive of the capacity of normal mature subjects to reason about and predict object motions. Such a constitutive basis is held to underlie the remarkable precision of our perceptual systems in extracting and using the motion of objects in space. Examples of this capacity include our ability to anticipate the trajectories of objects in order to intercept, follow, or avoid them.

As is well known, two general types of information are used in classical physics to describe the behavior of moving objects. On the one hand, kinematic information describes the pure motion of bodies without regard to mass (i.e., the position, velocity and acceleration of an object). On the other, dynamics describes the forces causing movement or acting on objects with mass. According to Peacocke (ibid.), in order to qualify as being able to reason about objects, we must attribute to humans the capacity to reason according to dynamic principles. This would correspond to what I have described as the task characterization, which is a normative description: it is what the system must do in order for its behavior to be selectively efficient (e.g., avoid falling stones).

If we employ a reverse-engineering strategy, the task characterization of reasoning and predicting object motions (*qua* dynamic computation) will be all that we need to analyze the system that accounts for such a capacity. If, on the other hand, we employ an evolutionary strategy, then we will have to develop a model of adaptation (see, for example, Parker & Maynard Smith, 1990). Such a model will have to consider competing alternatives that exist in an adaptive scenario. For instance, we can assume that we should evaluate the performance of a system that predicts object motion according to kinematic variables, and another according to dynamic variables. This comparison should establish the performance of each system, not in isolation but as a part of the whole organism-environment interaction. Once this is done we will be able to consider the costs of either system, in terms of design and computation.

It is very conceivable that this model might yield an outcome that is very different from the reverse-engineering analysis. It could, for example, provide the hypothesis that the kinematic system is the most adaptive solution because it satisfies the task of predicting object trajectories in a way that outweighs the cost of a much more complex, yet more optimally designed, computational system that computes dynamic variables. Among other things, the errors induced by a kinematic system may not be unacceptably gross and may be easily compensated by the continuous activation of the perceptual system. This would be congruent with empirical research such as Cooper and Munger (1993).

The point, then, is this: if we had relied the reverse-engineering strategy we would not have reached the correct analysis. This is not because we would have assumed an incorrect claim but because we simply would have employed the wrong optimality strategy.

Having said this, it is no doubt true that the distinction between the engineering and biological optimalities might not be an easy matter, at least not at first blush. On the one hand, the functionality of the system (e.g., detecting flies) is amenable to both reverse-engineering and ecological analyses; on the other, it is not always clear how to establish the parameters of the fitness-maximization process that constrains adaptive cognitive traits. The latter might not be impossible to establish in cognitive science (Vilarroya, 2001). The former requires changes in algorithm (B).

Cognitive Explanation Revisited

In my opinion the explanatory strategy of cognitive science cannot be simply an inversion of the first steps of the teleonomic explanation. It is not enough to identify the adaptive problem and then infer the mechanism. Rather, we need to complement the assumption about a trait's design with a characterization of how the adaptation might have appeared over evolutionary time. Fortunately, we have the elements to proceed to the different steps necessary to complete a cognitive explanation. In order to do that, we should divide the first step of algorithm (B) into two substeps, namely:

(B′) Cognitive Explanation

1. Characterize:

(a) the adaptive problem that the organism is supposed to solve; and
(b) the fitness-maximization process.

2. Presuppose the trait that is likely to be under selection.
3. Show:

(a) that the trait is specialized for solving the adaptive problem;
(b) that it is unlikely to have arisen by chance alone; and
(c) that it is not better explained as the by-product of mechanisms designed to solve some alternative adaptive problem.

4. Establish the fitness value of the trait in the population.

The explanation should proceed as follows. The first sub-step should yield the informational-theoretic characterization (Marr, 1982) of the functional requirements needed to satisfy the adaptive problem. Specifically, we need to indicate the requirement imposed by the adaptive problem that the system should satisfy in an idealized situation.

Once this characterization has been established, then the theorist must proceed to characterize the fitness-maximization process (including the adaptive requirements that are to be satisfied by the organism in such a process). Then, the theorist should verify whether the computational characterization of the adaptive problem is compatible with the optimum established in the fitness-maximization process. If both draw upon the same information, then the characterization of the adaptive problem can be used in conjunction with reverse-engineering methodology. This should yield the assumed design specifications for the trait. If, on the other hand, the the adaptive problem's computational characterization is not compatible with the fitness-maximization optimum, then the functional requirements of the fitness-maximization process should guide the design assumptions. As the case of the frog has shown, the fitness-maximization account allowed the assumption that the trait should be designed to detect "little ambient black things," rather the one offered by the adaptive problem which would have been "fly-there."

The characterization of the fitness-maximization process in cognitive science is, unfortunately, not a straightforward operation, as I have shown elsewhere (Vilarroya, in press). It is actually a complex process because, among other things, there is an essentially open-ended set of factors that influence just where the cost-benefit curve reaches its maximum. What allows an individual, or a group of individuals, to survive and leave offspring depends precisely on their biological constitution and the exact characteristics of the surrounding environment with which they interact.

Nonetheless, the elements in this characterization are objective. Therefore one can hope to make them explicit, and thus provide an adaptive characterization of the trade-off between the costs as well as the benefits of available solutions. This will (or should) eventually yield a description of the functional account of the cognitive system, if the analyst takes into account: (a) the nature of the adaptive problem itself, (b) the analysis of the system's resources, (c) the environment and interaction with competitors, as well as (d) the way in which all these elements interact.

How can we apply this characterization in the case of the frog? I believe that there is a way to account for the paradox that the cognitive system of the frog accords with a characterization of the adaptive problem, even though it is not the characterization of the mechanisms that accounts for the adaptive capacity. For one thing, we already have an account of the adaptive problem that the system has to solve: identify flies. This is a normative description; it is what the system must do in order for its behavior to be selectively efficient. For another, we have the functional requirements that the fitness-maximization process imposes: identify "little ambient black things." The evolutionary rationale behind this solution is consistent with the assumption that the extra computational cost of taking only flies into account (over and above other small dark ambient things) arguably outweighs the small increase in accuracy that would be gained from doing so.

In sum, a system may seem to accord with a certain functionality (e.g., identifying flies) that is, in actuality, different from the description of the structure of the cognitive system (e.g., identifying "little ambient black things"). Accordingly, such a system may in fact take advantage of mechanisms that are not specifically designed to deal the problem at hand. This does not mean that the solution is somehow deficient. The fact that the fly-catching mechanism of the frog is not sensitive only to flies does not mean that it cannot identify flies. It can and it does.

Conclusion

Cognitive science uses two distinct notions of optimality: engineering optimality and biological optimality. In engineering, optimality refers to design ideals whereas, in biology, optimality refers to fitness maximization. While conflation of the two concepts is understandable, neglecting the distinction entails incurring risk of arriving at a mistaken conclusion. Fitness value and designs are therefore best analyzed separately.

Abstract

In this paper we examine Elman's position (1999) on generalization in simple recurrent networks. Elman's simulation is a response to Marcus et al.'s (1999) experiment with infants; specifically their ability to differentiate between novel sequences of syllables of the form ABA and ABB. Elman contends that SRNs can learn to generalize to novel stimuli, just as Marcus et al's infants did. However, we believe that Elman's conclusions are overstated. Specifically, we performed large batch experiments involving simple recurrent networks with differing data sets. Our results showed that SRNs are much less successful than Elman asserted, although there is a weak tendency for networks to respond meaningfully, rather than randomly, to input stimuli.

Introduction

In a recent paper, Elman (1999) casts doubt upon the widely noted results of Marcus et al. (1999). In the Marcus et al.'s experiment, 7-month old infants were habituated to sequences of syllables of the form ABA or ABB (e.g., "we di we" or "le di di"). Marcus et al. found that infants showed an attentional preference for novel test sequences of syllables (which we call "sentences"), which differed from the habituation stimuli[1]. Marcus et al. argue that the reason for this behavior is the fact that infants extracted "algebra-like rules that represent relationships between placeholders (variables)" (1999). They also concluded that simple recurrent networks (and, in general, all networks whose training is based on backpropagation of error) were not able to display this kind of behavior because they could not generalize outside the training space.

The issue of generalization outside the training space was previously addressed in Niklasson and van Gelder (1994), and Marcus (1998). In essence, the training space represents the n-dimensional hyperplane delimited by the set of training vectors. We say that a connectionist model generalizes to novel stimuli when correct output is reliably produced for an input item that was not included in the training set (i.e., the network was never trained on that stimulus in any position within its input layer). Marcus maintains that a neural network trained with the backpropagation algorithm (or any variant of it) is not able to display such a behavior, because the innate structure of the backpropagation algorithm[2] precludes the network from generalizing to nodes that have not been specifically trained.

Elman agrees that the Marcus experiment does "indicate that infants discriminated the difference between the two types of sequences" (1999), but he believes that this result may be explained by the relationship between the last two syllables: infants were able to distinguish that in one case the last two syllables were identical (ABB), and in the other case the last two syllables were different (ABA). Moreover, Elman maintains that it is feasible for a simple recurrent network to perform this same task, provided the network is presented with the same background knowledge as infants have (in particular, an exposure to a wide range of syllables that infants have before participating in the experiment).

Having said that, Elman performs an experiment involving an SRN that aims to simulate the Marcus et al.'s experiment. There are three phases in Elman's simulation: 1) the pre-training period, corresponding to the prior experience of the infants in learning to recognize syllables; 2) a second phase corresponding to the habituation task that infants encountered (presenting ABA and ABB sentences); 3) a testing phase involving novel stimuli, as in the infants' experiment. At the end of his simulation, Elman concludes that his results "clearly indicate that the network learned to extend the ABA vs. ABB generalization to novel stimuli" (1999).

Granting Elman's basic assumptions, we constructed an experiment that mimics his simulation. We did not

[1] For example, after habituated to ABA sequences, the infants spent more time recognizing novel test sequences of the form ABB than did for ABA sequences, and vice versa.

[2] The weights connecting a given output node are trained independently of the weights connecting any other output node. Consequently, the set of weights connecting one output unit to its input units is entirely independent of the set of weights feeding all other output units. This is called input-output independence, and it is believed to be the major weak point of backpropagation neural networks. It is less clear that the problem arises for competitive learning networks, however. See Hadley et al (1998) for details.

have access to all Elman's data, but we used the same Plunkett and Marchman's (1993) distinctive feature notation of consonants and vowels that Elman employed in his experiment. However, since the results we obtained led us to a different conclusion than Elman's, in order to have a more complete picture of the performances of simple recurrent networks, we created a variety of data sets by changing the degree of overlapping units in the training/testing vectors. Also, to be sure that the results were not obtained by chance, we performed batch training, i.e., at least 64 different training-test sessions were carried out for each individual training corpus (i.e., 64 or 128 different weight initializations were assigned to the basic configuration, resulting in 64 or 128 separate networks trained on each data set).

Basic structure of Elman's and our experiments

A simple recurrent network architecture was used for all experiments. The input layer contains 12 or 24 units (depending on the experiment; see details below). The number of hidden/context units was varied between 10 and 40. The output layer contains two units; one was used only during the pre-training phase, while the other unit was only used during the sentence habituation and testing phases.

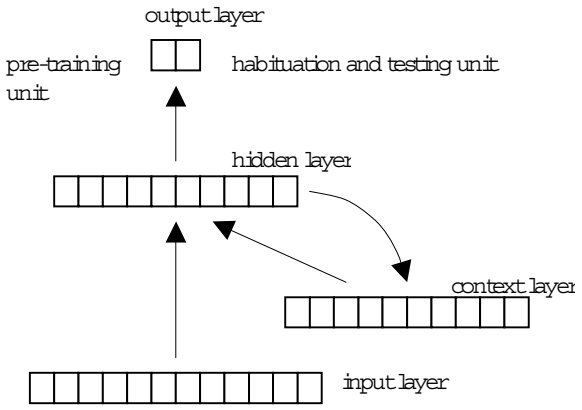

Fig. 1. Architecture of the network

The data set deployed in the pre-training phase contained 50,000 syllables (separate tokens) from the full set of 120 possible types. Each syllable was presented to the network, one at a time, and the SRN was trained to distinguish between the current syllable and the previous one (whether or not they are identical). Only one of the two output units was used during this supervised training.

The habituation phase followed the pre-training phase. During this phase the same network was presented with 32 distinct sentences formed with 8 different syllables (these 8 syllables also occurred in the set of 120 types of syllables employed in the pre-training set). The 32 sentences were generated from the ABA and ABB grammars (16 ABA sentences, and 16 ABB sentences). Each sentence was presented to the network, one syllable at a time. Following the last syllable of a sentence, the network was trained to output a 0 in the case of ABA sentences, and a 1 in the case of ABB sentences. During this training phase only the second output unit was used (the one not used during pre-training). Interestingly, the weights were modified only after the last syllable of the current sentence was presented (no training occurred following the first two syllables). This was done in order to ensure that the network would learn to make discriminations the same way as the infants presumably would, using similar stimuli.

For testing, four sentences were used, formed with 4 "relevantly novel" syllables (i.e., these syllables appeared in the 120-syllable pre-training set, but not in the training corpus). Two sentences had the form ABA, and the other two had the form ABB. Again, the second output unit was used to monitor the network's responses.

Before presenting our results, we would like to clarify the following issues:

1) Because we were not able to have exactly the data set that Elman used, we generated our patterns based on Plunkett & Marchman's (1993) feature representation of consonants and vowels. Since Elman encoded his stimuli using the same notation, we believe that the difference between our data set and Elman's is minimal and arguably insignificant to the outcome of the experiment.
2) Elman's main objective was to challenge Marcus' assertion that SRNs are not able to generalize outside the training space. However, we believe his claims are overstated. Although a minority of sessions in our batch jobs was as good as Elman's, in general, we found that the SRN did not perform as well as Elman maintains.

As noted above, all experiments were based on Elman's simulation. Between our experiments and Elman's there were a few differences, however. These consisted in the way in which the data sets were created and the way the results were computed. Our first data set very closely resembles Elman's representation of vectors, both corpora being based on the same distributed representation of syllables. Since the results we obtained for this first data set offered only little evidence to support Elman's position, we have created a second corpus of patterns, by changing Elman's original vectors in order to have a more uniform and more overlapping data set (see below the description of Experiment 2). Lastly, our third data set employs completely non-overlapping vectors, i.e. we used a localist representation of input patterns.

Experiment 1

The input corpus for this experiment was very close to the Elman's data set. We used distributed representations to create the patterns: each syllable had 12 phonetic features, each syllable being made up from a consonant followed by a vowel. All the syllables were generated randomly using the whole set of letters, and the patterns were created based on Plunkett & Marchman's (1993) notation of each letter[3]. We created 120 vectors this way. All of these patterns were used in the pre-training phase, while 8 of them were employed during training and other 4 vectors were used for testing.

For example, here are 2 of the 8 training syllables and 2 of 4 testing syllables:

training

```
mo -1  1 -1 -1  1  1 -1  1 -1  1 -1  1
wu -1  1 -1  1  1  1  1  1  1  1 -1  1
```

testing

```
za -1  1  1 -1 -1  1  1  1  1  1 -1 -1
fe -1 -1  1 -1  1  1  1  1 -1 -1  1 -1
```

We tried to generate as diverse and random data set as possible, like infants are presumably exposed to prior to participating in the Marcus et al's experiment. However, our results showed that these patterns were not very "friendly" to our SRNs, and the networks were not nearly as successful as infants in discriminating those sentences.

One of the characteristics of this data set was that, because of the randomness of patterns, many of the testing vectors were very different from the vectors employed in training. For instance, the average distance[4] among training vectors was about 3-4 bits, while the difference between training and testing patterns exceeded 6-7 bits. In our opinion, this contrast among patterns is responsible for making the testing session difficult.

Experiment 2

Since the results based on the first data set failed to prove Elman's strong claims, we generated a different corpus of stimuli, trying to make the training process successful. Consequently, we have manually created 12 vectors (8 vectors are used in training, the other 4 in testing). The remainder of 108 vectors have been generated randomly. All these patterns have been distributed uniformly between the two sets of stimuli (training and testing). In this way, the distance among vectors within the same set of stimuli (whether training or testing) was similar to the distance between vectors found in the different corpora.

For example, here are a few of the vectors used in this experiment:

training

```
-1 -1 -1  1  1 -1 -1  1 -1  1  1  1
 1 -1 -1  1  1 -1 -1  1  1 -1 -1  1
```

testing

```
 1 -1  1 -1  1 -1  1 -1  1 -1  1 -1
-1 -1  1  1 -1 -1  1  1 -1 -1  1  1
```

In this case, the average difference among the vectors within the same corpora is about 4-6 bits. This value is close to the difference between training stimuli and testing stimuli (6-7 bits). Because the patterns are uniformly spread across the training and testing sets, this represented a training advantage for networks. However, this tactic further reduces the novelty of the test "sentences".

Experiment 3

The third experiment involved a rather different data set. This employed completely non-overlapping vectors. As a result, the vectors were larger (24 bits, instead of 12).

For example, here are 4 of 12 training/testing vectors (the rest of the 108 vectors used during pre-training were generated randomly):

```
1) 1 -1  1 -1 -1 -1 -1 -1 -1 -1 -1 -1
-1  1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1
2)-1  1 -1  1 -1 -1 -1 -1 -1 -1 -1 -1
-1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1
3)-1 -1 -1 -1  1 -1  1 -1 -1 -1 -1 -1
-1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1
4)-1 -1 -1 -1 -1  1 -1  1 -1 -1 -1 -1
-1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1 -1
```

As it may be seen, the patterns were generated by moving a 4-bit frame [1 -1 1 -1] along the 24 bit vectors. In this way, the resulting vectors do not overlap, and the distance among all vectors is the same (4 bits).

Although this corpus of stimuli had little in common with Elman's data, we wanted to examine the performance of SRNs in the case of non-overlapping vectors and to address Marcus' issue about generalization to genuinely novel items.

Results

The performances of SRNs (and, in general, any network using the backpropagation algorithm) are influenced by several training parameters, such as initial weights, learning rate, etc. Usually, the initialization of weights is performed randomly and if training parameters are not chosen properly (especially the learning rate), the network may end up in a region of local minimum of the error function. One way to

[3] For example, the pattern for syllable "da" was a 12-bit vector created by concatenating the 6-bit feature representation of "d" with the 6-bit feature representation of "a".

[4] The distance between two vectors is given by the number of bits by which the two vectors differ.

reduce this liability is to perform a batch experiment, to test the network with a large number of different weight initializations and training parameters. Another advantage of this approach is that at the end of the batch sessions we will have a more precise picture of the behavior of the networks, and also know whether or not the results are generated accidentally.

Significantly, in a series of preliminary experiments, we found that, very often, the weight initializations we used determined poor results for networks, regardless of training parameters (including hidden layer size). Therefore, we decided to perform at least 64 different training-test sessions for each of our 3 experimental designs, each session using a different weight initialization (there were 64 sessions for the first two experiments, and 128 different sessions for the third experiment). In this way, we generated at least 64 separate trained networks for each batch experiment[5].

We chose to use two criteria in order to evaluate the results:

(1) Our first criterion was simply based on the percentage of "acceptable" results. We say that a network generates acceptable results when it grammatically categorizes each presented test sentence within 30% of its target value. Since there are 4 test sentences (2 ABA sentences, and 2 ABB sentences), we have 4 output values to record for each of the 64 networks (let's say, A, B, C, D are the network outputs for the 4 test sentences). Having 0 as the target value for A and B, and 1 as the target value for C and D, an acceptable result is an output value less than .3 for A and B, and greater than .7 for C and D.

(2) Although the above-mentioned criterion is very tolerant, Elman's results would not be counted as acceptable in conformity with this criterion (one of Elman's responses is about .6, outside the 30% error margin; see below for more details). However, not to reject Elman's approach on a-priori grounds, we adopted a second, more forgiving criterion: we consider a result as "acceptable" if only 3 of the 4 responses are within 30% of their target values, while the remaining response is within 45% of its target value.

Since our extensive set of training-test results were significantly different from Elman's isolated result, we tried to see whether, at least, they were better than mere chance. For the first criterion, the chance value is given by the probability that all 4 test sentences are fortuitously, correctly classified, i.e., the network outputs are within 30% of the target values. Clearly, the chance probability that the network outputs a value in the target range, for any of the 4 test sentences, is .3. Therefore, the probability that all 4 sentences are correctly recognized is .0081 (= .3 x .3 x .3 x .3), or .81%. This represents the "chance" value, which we compared all our results to. For the second criterion, the chance value is slightly different. Here, in order to correctly categorize purely by chance, networks should report output values within 30% of the target values for 3 sentences, and within 45% for the 4th sentence. Consequently, the probability for that happening is .01215 (= .3 x .3 x .3 x .45), or 1.215%.

[5] One could metaphorically regard these trained networks as the infants involved in the Marcus et al.'s experiment.

Experiment 1

This experiment is closest to Elman's simulation. Results reported by Elman (1999) were as follows:

	response	target		response	target
A	0.004	0	C	0.853	1
B	0.008	0	D	0.622	1

Even though the network's response for the last sentence was very close to the chance value of .5, Elman asserted, "these responses clearly indicate that the network learned to extend the ABA vs. ABB generalization to novel stimuli" (1999). In our view, based only on these results, Elman overstates the facts. In accord with our first evaluation criterion, his result would not even have been considered acceptable. We devised the second criterion, even more lenient than the first one, in order to cover Elman's result. In any case, in our extended series of experiments, we found that the responses of our networks were highly dependent on weight initializations.

We performed numerous batch experiments, systematically varying, in all combinations, the available parameters values: learning rate (between 0.01 and 0.1), the number of hidden/context units (between 10 and 40), the momentum (0 and 0.5), weight initialization (within the interval [-1, 1], or [-0.1, 0.1]). The best results were obtained for 30 hidden/context units, a learning rate of 0.01, momentum 0 and weight initialization within [-1, 1].

Specifically, for this first experiment, our results were:

(1) of the 64 trained networks, 15 generated acceptable results in conformity to the first evaluation criterion; thus, the percentage of acceptable results is 15/64 x 100 = 23.43%;

(2) evaluating with the second, more lenient, criterion, the percentage of acceptable results is 23/64 x 100 = 35.93%;

We believe the results lend, at best, weak support to Elmans claims. A percentage of good results around 30% cannot lead us to the conclusion that "the network learned to extend the ABA vs. ABB generalization to novel stimuli", as Elman asserted (1999). Granted, the results are significantly larger than the chance values (.81% for the first criterion, and 1.215% for the second one), which means that there is a tendency for the networks to train in such a fashion that they give meaningful, rather than random results.

As noted earlier, these results might be partially explained by the randomness of patterns used in this

experiment. There were instances when the training vectors were very different from the vectors used for testing (up to 90% of the bits were different).

To prove that a different corpus of stimuli can generate better results, we performed a second set of tests, making the data set more uniform and decreasing the distance between training and testing patterns. Here are the details:

Experiment 2

As noted earlier, most part of the 120 patterns used in this second experiment were created randomly, except the 12 vectors employed in the training (habituation) and testing phases. These 12 vectors were generated manually and distributed uniformly over the training and testing sets in order to have a similar distance among all the vectors.

In this case, the average difference between training and testing vectors is about 6 bits, close to the distance among vectors within the same set (whether training or testing), which is about 7 bits.

We varied many training parameters in this case too, and we obtained the best result for 40 hidden/context units, a learning rate of 0.1 and momentum 0.5.

As expected, the results were substantially better:

(1) there were 40 trained networks (out of 64) whose responses were acceptable in conformity with the first evaluation criterion; thus, the percentage of acceptable results is 40/64 x 100 = 62.5% ;

(2) there were 42 trained networks that responded acceptably in accord with the second criterion; the percentage of acceptable results is: 42/64 = 65.62% ;

Noteworthy, these results were obtained for a number of 40 hidden/context units. When using 10 hidden/context units (as Elman presumably did), the results were worse: 29.68% in accord with the first criterion, and 34.37% evaluating with the second criterion.

Although the percentages of 62.5% or 65.62% of successfully trained networks are not impressive, in contrast with the chance value of .81% (and 1.215% respectively), they represent a significant result (the probability to respond acceptably, in conformity to our criteria, is 80 times greater than the probability by mere chance). Therefore, this experiment demonstrates more convincingly what we noted earlier: there clearly is a tendency for the networks to train in such a fashion that they give meaningful, rather than random results. However, we must bear in mind that the training regime now under consideration does not satisfy the conditions for generalization outside the training space.

Experiment 3

The third experiment differs from the first two with respect to the type of the vectors involved: here we used completely non-overlapping vectors, because we wanted to address Marcus' challenge of generalization outside the training space. Thus, we tried to discover whether simple recurrent networks are indeed able to generalize to novel stimuli.

Initially, it would seem that our testing patterns were not novel to the network (since they also appeared in the pre-training set). But, there are two arguments behind our assumption that the testing vectors are actually novel:

- the output unit used during pre-training is different from the output unit used during habituation (second training). Since the representation of patterns is localist and the training algorithm is backpropagation, these two output units are purportedly independent: the training of one unit should not influence the other unit, as Marcus argued (1998).
- the training regimes used during the pre-training and habituation phases are different (one algorithm teaches the network to determine whether or not consecutive syllables are identical, while the other one teaches the network to differentiate between ABA and ABB sentences). Since the testing vectors do not appear in the training data set used during sentence habituation, they are novel to the network in the relevant sense.

For this experiment we performed two sets of tests, both involving 128 separate training/testing sessions. Although 64 trained networks are presumably enough to form a complete picture of the behavior of networks, we wanted to see whether or not the general tendency noted previously was repeatable for a substantially larger batch experiment. The answer was affirmative.

The first set of experiments employed a test corpus of 4 sentences, exactly the same number of sentences used by Elman, and by us in the experiments 1 and 2. The results were as follows:

(1) there were 8 successfully trained networks (out of 128); thus, the percentage of well-trained networks was, in conformity with the first criterion, 8/128 = 6.25% ;

(2) there were 14 trained networks which responded acceptably in accord with the second criterion; the percentage of acceptable results is: 14/128 = 10.93% ;

Although these values are much less impressive than those of the previous experiment, they still are better than chance. Of course, the absolute percentage of successful networks (6.25, or even 10.93) is small, indicating that SRNs have problems dealing with novel stimuli. However, it is still substantially greater than .81 (or 1.215 for the second criterion), which would have been obtained by pure chance.

However, for the second set of tests we expanded the test corpus to 30 sentences. In this case, none of the 128 trained networks output good results in accord with any of the two criteria. This result was consistent for different training parameters, such as learning rate and number of hidden/context units.

Discussion

In the three experiments described herein, we have systematically varied a wide range of parameters. Indeed, in the case of Experiment 1, were Elman's data set is very closely approximated, we have parametrically varied not only the learning rate and weight initialization range, but also the hidden layer size (which Elman did not do). On the basis of all three experiments described above, we believe it is fair to say that Elman's case has been substantially overstated.

On the other hand, certain of our results may lend some modest confirmation to Elman's position, at least with respect to the very simple syntax employed in the Marcus et al experiment. To be sure, in the case of Experiment 1, which most closely approximated Elman's training data, the percentage of successfully trained networks was only 23.43%. However, this percentage is far above the purely chance values that we have cited. In addition, we have shown that even when all input vectors within a given training corpus are completely non-overlapping (Experiment 3), as many as 6% of trained networks satisfy our "least forgiving" criterion of success, at least when the test corpus contained just 4 sentences (as in Elman's case). Significantly, though, when the test corpus for Experiment 3 was expanded to contain 30 novel sentences, no positive results whatsoever were obtained even when our more lenient "success criterion" was used. This outcome lends clear support to Marcus' claims on "generalization outside the training space" -- at least with respect to the infant learning experiment described by Marcus et al (1999).

Finally, we must also emphasize that, except in Experiment 2 (where we modified the syllable vectors to ensure that training and test input vectors were much more similar), the preponderance of trained networks failed to satisfy even the most forgiving success-criterion adopted here. More importantly, we have replicated the design of Experiment 1 using two modestly more complex grammars, and have obtained only negative results. In particular, when the grammars (ABCA vs. ABCB) and ABCDA vs. ABCDB) were employed, we were unable to train even a single network successfully (from a batch of 64 networks). This strongly suggests that the SRN architecture deployed in Elman's "refutation" of Marcus is incapable of abstracting the underlying structure of anything but the very simplest of grammars. Our view is that the "grammar" deployed by Marcus et al (1999) is perhaps too simple to present a useful challenge to eliminative connectionist networks. A desirable step for future research would be to repeat the "human infant experiment" using the modestly more complex grammars just cited.

Abstract

People generate counterfactual alternatives to reality when they think about how things might have happened differently, 'if only…'. There are considerable regularities in the sorts of past events that people mentally undo, for example, they tend to mentally undo the most recent event in an independent sequence. Consider a game in which two contestants will win £1000 if they both pick cards from the same color suite. The first player picks black and the second red and they lose. Most people spontaneously undo the outcome by thinking, if only the second player had picked black. We describe a computational model that simulates our theory of the mental representations and cognitive processes underlying this temporal order effect. The computer model is corroborated by tests of the novel predictions of our theory: it should be possible to reverse the temporal order effect by manipulating the way in which the winning conditions are described.

Counterfactual Thinking

When people reflect on past events, they tend to think not only about the events that actually happened but also about how those events might have happened differently. This tendency to construct imaginary alternatives to reality is called counterfactual thinking (e.g., Kahneman & Tversky, 1982). For example, if your car breaks down and you are late, you might think that you would have been on time if you had had the car serviced or if you had taken the train.

Counterfactuals have been studied in philosophy (e.g., Lewis, 1973; Stalnaker, 1968), psychology (e.g., Kahneman & Miller, 1986) and artificial intelligence (e.g., Costello & McCarthy, 1999; Ginsberg, 1986). Counterfactual thinking has been implicated in many aspects of cognition and emotion. It may play a role in formulating counterexamples in reasoning (Johnson-Laird & Byrne, 1991) and in formulating sub-goals in problem-solving (Ginsberg, 1986). Counterfactuals may allow us to learn (e.g., Roese, 1994). The sorts of counterfactuals that are useful to people may also be useful to learning algorithms in artificial intelligence systems (Costello & McCarthy, 1999). Counterfactual thinking has also been linked to a range of emotions and social judgements, including blame and regret, both in the laboratory and in real-life settings.

Yet little is known about the mental representations and cognitive processes that underlie the generation of counterfactuals. Our goal in this paper is to describe a computational model that simulates a theory of the processes underlying counterfactual thinking and some experimental results that corroborate this theory.

Psychological studies of the sorts of counterfactuals that people generate indicate considerable regularities, despite the infinite number of ways that past events could have happened differently (e.g., Kahneman & Miller, 1986). People are more likely to undo exceptional than routine events (e.g., Kahneman & Tversky, 1982), actions than inactions (e.g., Byrne & McEleney, 2000), controllable than uncontrollable events (e.g., Girotto, Legrenzi & Rizzo, 1991; McCloy & Byrne, 2000) and the first event in a causal chain (e.g., Wells, Taylor & Turtle, 1987). In this paper we will focus on one important factor that influences the mutability of an event, that is, its temporal order in relation to other events, to which we now turn.

The Temporal Order Effect

Research has shown that when a series of events are independent of each other, people tend to mutate the most recent event (Byrne, Segura, Culhane, Tasso & Berrocal, 2000; Miller & Gunasegaram, 1990; Spellman, 1997). Consider a game in which two individuals are given a shuffled deck of cards, and each one picks a card from their own deck. If the two cards they pick are of the same color (i.e., both red or both black), each individual wins £1,000. Otherwise, neither individual wins anything. John goes first and picks a red card from his deck; Michael goes next and picks a black card from his deck. Thus the outcome is that neither individual wins anything (from Byrne et al, 2000). Participants tend to undo the second event, e.g., if only Michael had picked red too, when they are asked

to imagine that one of the card selections came out differently so that the players won, and this finding has been termed the temporal order effect. In addition, the second player, Michael, is usually expected to experience more guilt and to be blamed more by John. This effect has also been demonstrated in a number of practical situations, such as in judgements of fairness in an exam context (Miller and Gunasegaram, 1990) and in ranking team performance in a league (Sherman & McConnell, 1986

One possible explanation is that causality is assigned by the relative change in probability before and after an event (Spellman, 1997) although this account cannot explain the shift in focus which arises when an explicit alternative to the first event is provided (Byrne et al, 2000). An alternative explanation is that the first event in an independent sequence may be relatively immutable because it is presupposed (Miller & Gunasegaram, 1990), acting as a background against which later events are perceived (Sherman & McConnell, 1996), and playing an important contextualising role in constructing a mental representation of a factual situation (Byrne et al., 2000). Our aim is to explain why the first event is presupposed or perceived as immutable, and to do so, we will focus on the mental representation not only of the facts, but also of the counterfactual alternatives to the facts.

People may understand the card scenario by constructing a set of mental models (Johnson-Laird & Byrne, 1991), that is, mental representations that correspond to the structure of the world, and their models may represent certain aspects of the factual situation explicitly:

John red Michael black Lose

where 'John red' represents 'John picked a red card', 'Michael black' represents 'Michael picked a black card', and 'Lose' represents the outcome (Byrne et al., 2000). They may generate their counterfactual models by mutating aspects of the factual model. The fully explicit set of models is as follows:

Factual:	John red	Michael black	Lose
Counterfactual:	John red	Michael red	Win
	John black	Michael black	Win
	John black	Michael red	Lose

where separate possibilities are represented on separate lines of the diagram, and the models may be annotated to keep track of their epistemic status (Byrne & Tasso, 1999; Johnson-Laird & Byrne, 1991). The temporal order effect indicates that people construct just a subset of the possible counterfactual models:

Factual:	John red	Michael black	Lose
Counterfactual:	John red	Michael red	Win

. . .

where the three dots represents an implicit model which may be fleshed out to be more explicit if need be. Our aim is to explain why people construct this counterfactual model more than others.

TempCounterFacts: A Computational Model of the Temporal Order Effect

We will describe a computational model, called TempCounterFacts, which simulates the primary tenets of our theory of the mental representation and cognitive processes underlying the temporal order effect in counterfactual thinking (see Walsh & Byrne, 2001, for details). The program is written in LISP and it takes as input a set of facts about the card selection game (e.g., John picked red and Michael picked black) and a description of the winning conditions (e.g., if they both pick red or both pick black they win) and it generates a counterfactual alternative about how the outcome could have turned out differently (e.g., they would have won if Michael had picked red).

We suggest that the counterfactual context, that is, the representation of the conditions leading to a counterfactual outcome, such as the conditions under which a contestant would have won or lost a card game, can in themselves provide an explicit alternative to a factual event. This possibility has not been explored systematically before. Our suggestion is that people imagine a counterfactual scenario by changing their model of the facts to fit with their model of the winning conditions. They may select the first element of the factual model, e.g., John picks red, and find a match for it in the winning models. They may consider only this model as a possible counterfactual and conclude that if Michael had picked red they would have won. We suggest that the generation of a counterfactual alternative is driven not only by the 'bottom-up' facts of the actual situation but also by 'top-down' expectations derived from the counterfactual context. The program consists of three suites of functions.

1: Representing Facts and Counterfactual Context

The program begins by constructing a representation of the facts in a FactModel:

Factual: John Red Michael Black Outcome Lose

It also takes as input a set of winning conditions and it constructs the Counterfactmodels or set of models of the winning conditions:

John Red Michael Red Outcome Win
John Black Michael Black Outcome Win

These initial models represent the conditions under which the protagonists can win. Because of working memory constraints people may represent as little information as possible (Johnson-Laird & Byrne, 1991). For example, they may not explicitly represent the conditions under which the protagonists can lose (Byrne, 1997).

The program constructs models for different conditions which may be specific events, e.g., 'John picks a red card' or not, e.g., 'both players pick a red card'. It accepts four connectives: and, or (unspecified disjunction), ori (inclusive disjunction) and ore (exclusive disjunction).

2: Matching Facts and Counterfactual Context

The program attempts to match the FactModel to the set of CounterfactModels. It selects the first fact, e.g., John picked a red card, and it attempts to find a match for this event in the CounterfactModels. If an explicit match is found then it selects this model. If not, then it looks for a model which contains the negation of the first fact, e.g., John picks not-red. In the current example, it finds a match in the first model of the CounterfactModels:

John Red Michael Red Outcome Win

Once a match is found the program checks to see if the selected model is fully explicit, that is, it contains explicit information about both card selections. If the selected model is not fully explicit then the program fleshes out the models to be explicit (for details on fleshing out models and other technicalities, see Walsh & Byrne, 2001.)

The program then compares the FactModel and the selected CounterfactModel. If they match entirely then the FactModel is a winning instance. If there is only one item that is different then it uses this model to generate a new CounterAlternative model. If there is more than one difference, then the program continutes to search through the remaining CounterfactModels to find one which is more similar to the FactModel. In this way, the program ensures that minimal changes are made (see, e.g., Byrne, 1997).

3: Generating a Counterfactual Alternative

Once a counterfactual model has been selected, the program identifies the events in this model which are different from the FactModel. In the current example, it is Michael's card. It then generates a new CounterAlternative model by taking the FactModel and replacing the FactModel events with the CounterfactModel events, i.e., Michael picked Black is replaced with Michael picked Red. It describes the newly constructed CounterAlternative by generating a counterfactual conditional of the following form:

If it had been the case that: (Replaced event)
then it would have been the case that:
(Outcome Win).

The program simulates the temporal order effect, that is, it mutates the second event, when it is given the scenario in the current example, which is typical of scenarios used in such studies. However, the program also produces a novel reversal of the temporal order effect when it is given certain descriptions, as we will now describe.

Performance of the model on novel descriptions

We tested the performance of the model on several novel scenarios, with different sorts of winning conditions and different sorts of facts (see Walsh & Byrne, 2001, for full details). For example, we gave the model descriptions of a card game in which the winning conditions required the players to pick *different* colour cards and the fully explicit set of models for the winning conditions were as follows:

John Red Michael Black Win
John Black Michael Red Win

In each case, we presented the program with the same facts, i.e., John picks a black card and Michael picks a black card and they lose, and it produces the FactModel:

Factual: John black Michael Black Outcome Lose

We varied the way in which we described the winning conditions. Given the following 'black' disjunction, to describe the winning conditions:

If one or the other but not both pick a card from a black suit, each individual wins £1,000

the program constructs the following initial models:

John Black Win
Michael Black Win

and produces the temporal order effect. When one of the CounterfactModels contains an explicit match for the first fact, as in the models of the 'Black' disjunction the program selects this model. If it is not fully explicit then the program fleshes it out, relying on the footnotes to indicate how to do so. The program compares the fleshed out model to the FactModel and if the second event is different, as it is in the example, then the program uses this event to generate a new CounterAlternative model and to produce the counterfactual conditional:

If it had been the case that: (Michael not-Black)
then it would have been the case that:
(Outcome Win).

Given instead the following 'red' disjunction, to describe the winning conditions:

If one or the other but not both pick a card from a red suit, each individual wins £1,000

The program produces the following initial models:

John Red Win
Michael Red Win

and it produces a *reversal* of the temporal order effect, that is, it constructs a counterfactual scenario that undoes the first event rather than the second event. When the CounterfactModels do not contain an explicit match for the first fact, as in the models of the 'Red' disjunction, the program selects instead a model which contains the negation of the first fact, John picks not-black (which in the binary context of the color card

game, the program recognises as red). It repeats the same process described above, however in this case it is the first event which is different in the FactModel and CounterfactModel. As a result, this event is used to generate the CounterAlternative model and the conditional:

If it had been the case that: (John Red)
then it would have been the case that:
(Outcome Win).

The winning conditions are identical in both descriptions, and the facts are identical, but the description differs. As a result, the program constructs different sorts of initial models. The program simulates the assumption of the model theory that reasoners rarely construct a fully explicit set of models and their initial set of models makes some information explicit and some implicit (see Johnson-Laird & Byrne, 1991). One novel prediction of our theory is that it should be possible to reverse the temporal order effect if the way in which the winning conditions are described ensures that people construct an initial model that does not contain an explicit match to the first event. We turn now to some experimental results that corroborate this novel prediction.

Experimental Results on Temporal Order

We constructed a scenario based on the color card scenario (from Byrne et al., 2000). In a series of experiments, the facts of the players' selections remained the same: John goes first and selects a black card, Michael goes second and the card that he selects is also black, and the outcome is that both players lose. The winning conditions were also identical in each of the experiments: the players would win if they each picked different cards. We varied the description of these winning conditions (see Walsh & Byrne, 2001, for details). The experiments test our predictions that people hold this *counterfactual context* in mind from the outset and they use it to help them construct an appropriate counterfactual model.

In one experiment, we described the winning conditions as a disjunction of red cards:

If one or the other but not both pick a card from a red suit, each individual wins £1,000

and we compared it to a control description designed to eliminate the temporal order effect (see Walsh & Byrne, 2001 for details). In the experiment, the facts were that John picked black and Michael picked black and so they both lost. The two descriptions referred to exactly the same set of winning conditions, but for the 'red' disjunction, people cannot readily match the fact about the first player, John picked black, to their explicit thoughts about how the players can win. Instead the availability of an explicit alternative to the first fact, should lead them to mutate the first fact.

We tested 148 undergraduate students from different departments in the University of Dublin, Trinity College in several large groups. They took part voluntarily and were randomly assigned to the control or 'red' disjunction condition in a between subjects design. (Five participants were eliminated because they failed to follow the instructions.) Participants completed the following counterfactual mutation task:

> Please complete the following sentence. John and Michael could each have won £1,000 if only one of them had picked a different card, for instance if...

followed by several other related tasks (for details see Walsh & Byrne, 2001).

As our theory predicts, and as our cognitive model simulates, the 'red' disjunction reversed the temporal order effect. As Table 1 shows, the results indicated that for participants who mutated a single event, more mutated the first event (40%) than the second event (24%), and this difference was reliable (binomial n = 61, z = 1.79, 1-tailed $p < .04$), whereas when the same set of winning conditions were described in the control condition, the temporal order effect was eliminated. In the control condition, as many participants mutated the first event (32%) as the second event (36%, binomial n = 32, z = .18, p = .86), as we had expected (see Walsh & Byrne, 2001, for further details).

Table 1: The percentages of mutations in Experiment 1

	Control (n = 47)	Disjunction (n = 96)
Mutations		
First only	**32**	**40**
First and then Second	15	24
Second only	**36**	**24**
Second and then First	2	1
Neither	15	11

The experiment provides the first demonstration that the typical temporal order effect can be reversed, that is, participants mutate the first event in the sequence, rather than mutating the second event. The reversal depends not on the facts or on the nature of the winning conditions but on the way the winning conditions are described. Our explanation is that this description makes some information explicitly available in the mental models that reasoners construct, and renders other information implicit in the representation. An alternative to the first player's choice was made explicitly available and as a result, the temporal order effect was reversed.

Is it possible that the results show simply that the temporal order effect does not occur when the players

must pick different cards? The original temporal order effect may be an artifact of the constraint that both players must choose the same card. However in a further experiment in this series, we ruled out this possibility (see Walsh & Byrne, 2001). We showed that the temporal order effect can be observed even when players must pick different cards. We used the same scenario as described in the experiment here except that we changed the conditionals. We described the winning conditions as a disjunction of black cards:

If one or the other but not both pick a card from a black suit, each individual wins £1,000

Participants given this 'black' disjunction exhibited the standard temporal order effect. For both the 'red' and the 'black' disjunction conditions, the facts were the same: Both players picked black. The winning conditions were also the same (the contestants would have won if they picked different colored cards). The logical form of the description was the same, in that it was an exclusive disjunction. The only difference was in the reference to the color of the suit, black or red. This small difference in wording created a large difference in mutation patterns: mutations of the first event versus mutations of the second event. Our explanation is that reasoners represent the winning conditions not in a fully explicit set of models but in an initial set of models that makes some information explicit and keeps some implicit. We have called this mental representation of the winning conditions, the counterfactual context.

General Discussion

This paper provides one of the first computational simulations of counterfactual thinking. The model simulates our theory of the mental representations and cognitive processes that underlie counterfactual thinking, in the domain of the temporal order effect. One widely held view is that the mental representation of the facts are important in the generation of counterfactual alternatives. Our model makes use not only of the representation of the facts, but also of the representation of the winning conditions, which we have called the *counterfactual context*. It constructs representations that make some information explicit and leave other information implicit.

The program simulates the robust temporal order effect. However, our theory also led to a novel prediction about the reversal of the temporal order effect. In a series of experiments, we corroborated the predictions (see Walsh & Byrne, 2001). Our experiments showed that the temporal order effect can be reversed, eliminated or observed. The experiments provide the first demonstration that the temporal order effect can be reversed and that the nature of the description of the winning conditions can influence the mutability of events.

The Semantic Modulation of Deductive Premises

Abstract

Two experiments examined how the mental models of premises influence deductive reasoning. Experiment 1 showed that individuals draw different conclusions from the same information depending on whether it is expressed in conditional assertions or disjunctions. It also showed that co-reference within the premises can speed up more difficult inferences. Experiment 2 corroborated these results and also showed that the failure to represent what is false can lead people to draw illusory inferences, i.e., systematic but compelling fallacies.

Introduction

The ability to reason deductively is central to human intelligence. Our goal is to examine how the nature of mental representations can influence this ability. Several factors should influence the process. First, the verbal formulation of premises should lead to different representations of the same underlying information. In turn, these representations should lead reasoners to draw different conclusions. Second, the semantic content of premises should influence the process of deductive reasoning. It should eliminate certain possibilities, and, in the case of co-reference from one clause to another, it may yield more concise representations. In this paper, we examine how these different factors impact on deductive reasoning.

Mental Models and Deductive Reasoning

The theory of mental models postulates that individuals who have no training in logic represent the meaning of assertions in mental models (Johnson-Laird and Byrne, 1991). Each mental model represents a possibility. But, the limitations of working memory force individuals to abide by the *principle of truth:* mental models represent only true possibilities and within them the constituent propositions in premises only when they are true. For example, an exclusive disjunction such as:

Either Mary is in Brussels or Gino is in Rome, but not both.

elicits two mental models of the alternative possibilities:

Mary-Brussels

Gino-Rome

where "Mary-Brussels" denotes a model of Mary in Brussels, and "Gino-Rome" denotes a model of Gino in Rome. Mental models of possibilities do not represent the falsity of the clauses in the disjunction, e.g., that Gino is not in Rome in the first possibility. One consequence is that mental models should give rise to illusory inferences, i.e., fallacies that most individuals make. Recent studies have corroborated their occurrence (e.g. Johnson-Laird and Savary, 1999). In one experiment, participants were given the following problem:

If there is a king in the hand then there is an ace in the hand, or else if there is not a king in the hand then there is an ace in the hand.
There is an king in the hand.
What follows?

All the participants drew the conclusion that there is an ace in the hand. Mental models yield this conclusion, but it is wrong. In fact, the sentential connective or else implies that one of the conditionals could be false. But, if the first conditional is false, then there isn't an ace in the hand even though there is a king in the hand.

The meanings of clauses, their co-referential relations, and background knowledge, can all *modulate* the basic meanings of sentential connectives (Johnson-Laird and Byrne, 2001). One way modulation can occur is when background knowledge prevents the construction of a model. Consider, for example, the conditional:

If she played a game, then she didn't play soccer.

The basic interpretation of a conditional allows the possibility that she doesn't play a game but that she plays soccer. This possibility, however, is eliminated by the knowledge that soccer *is* a game.

A second example of modulation, in our view, is Bouquet and Warglien's (1999) discovery that

reasoning from disjunctions was more accurate when the clauses were co-referential, e.g.:

Either Gino is in Brussels or Gino is in Rome, but not both. Gino is not in Rome. What follows?

Premises of this sort yielded a greater proportion of valid conclusions, e.g.: Gino is in Brussels, than premises that did not refer to the same individual in both clauses. Co-reference may enable people to construct representations that are more concise. The aim of Experiment 1 was to examine this possibility.

Experiment 1: Co-reference in reasoning

Our conjecture is that co-reference may allow reasoners to build a more concise representation of the premises, thereby reducing the load on working memory. We predicted that such representations should facilitate performance in reasoning tasks particularly if the demands on working memory are high. In addition, the form of the premises - whether they are based on a disjunction or a conditional - should make different information available. Hence, each sort of premise should make some inferences easier and some more difficult to draw.

Each participant carried out 32 inferences in a different random order. The inferences concerned people carrying out various actions. For half the inferences, the first premise was an exclusive disjunction, e.g.:

Rachel is climbing up the stairs or David is cooking at the stove but not both

which should elicit the mental models:

Rachel-climbing

David-cooking

For half the inferences, the same information was expressed as a biconditional, e.g.:

If and only if Rachel is not climbing up the stairs then David is cooking at the stove.

which should elicit the mental models:

¬ Rachel-climbing David-cooking

. . .

where "¬" denotes negation, and the ellipsis denotes an implicit model, which acts as a "place holder" for the possibilities in which the antecedent is false. If necessary, it can be fleshed out explicitly.

The second premise was a categorical assertion or categorical denial of either the first or second proposition in the preceding premise. There were accordingly 8 forms of inference.

In order to manipulate co-reference, there were four types of semantic content:

1. Two persons do two different actions (two-actions).
2. Two persons do one action, which they cannot perform simultaneously (exclusive-action, e.g. "sit on the stool").
3. Two persons do one action, which they can perform simultaneously (inclusive-action, e.g., "sit on the sofa").
4. One person does two different actions, which cannot be performed simultaneously (one-person).

The eight forms of inferences with the four sorts of content yielded the 32 different inferences.

The problems were presented on a computer. The participants drew their own conclusion about what followed from the premises. They responded by typing their answer, and their latencies were measured from the presentation of the premises to the first key press. They were not told that their responses were being timed. We tested 30 undergraduates from Princeton University in return for course credit.

Results and Discussion

Table 1 presents the percentages of correct responses to the eight forms of inference (collapsing over their contents). As the Table shows, the participants were more accurate when the categorical premise matched an event that was represented explicitly in the models of the first premise. When the categorical premise was negative and concerned the first event in the preceding premise, Not-A, the participants were more accurate in reasoning from the biconditional (91%) than the disjunction (68%). But, when the categorical premise was affirmative, A, they were more accurate in reasoning from the disjunction (94%) than from the biconditional (78%; McNemar tests, chi-squared = 17.36 $p < .0001$; chi-squared = 15.04, $p < .0001$ respectively). Participants performed equally well on both descriptions when the categorical premise affirmed the second proposition, B, (94% for both, McNemar Test, chi-squared = 0.07 $p = 1$). We predicted these results in terms of mental models, but they might reflect the surface matching of clauses in the premises. One result, however, is more readily explained in terms of models. When the categorical premise negated the second proposition, not-B, participants were more accurate in reasoning from the disjunction (68%) than from the biconditional (46%; McNemar Test, chi-squared = 13.8, $p < .0002$). Not-B mismatches the clauses in both sorts of premises. It is also not represented explicitly in the initial models of either premise. But, reasoners may find it easier to flesh out the disjunction, which already contains two mental models, than to flesh out the conditional which is represented by just one explicit mental model.

Table 1
The percentages of correct responses to the eight forms of inference in Experiment 1

	First Premise	
Categorical Premise	*Iff not-A then B*	*A or else B*
A	78	94
Not-A	91	68
B	94	94
Not-B	46	68

The co-referential manipulation had no effect on accuracy. Yet, it did affect the latencies of correct responses. The principal results were that responses to exclusive-action problems (10.93 secs) and to inclusive-action (10.18 secs) were faster than those to two-action problems (11.58 secs; Wilcoxon test $z = 2.33, 2.81$, $p < .01$, $p < .003$, respectively, excluding the results of two outliers). In other words, co-reference can help the process of reasoning. In particular, problems in which two persons carry out one action, whether or not they can perform it at the same time, elicited faster responses than problems in which two persons carry out two different actions. Reference to a common action may yield more parsimonious models of the premises, and it may help reasoners to avoid confusion about which action a particular individual was carrying out. Such confusions are more likely in the case of a disjunction, which, unlike a biconditional, demands that reasoners model two explicit possibilities. The shared referent in a disjunction is common to two alternative models whereas in a biconditional it occurs within one model. That, perhaps, is why the referential effects were stronger for disjunctions (exclusive-action 9.0 secs vs two-action problems 10.7 secs, inclusive-action 8.7 secs vs two-action problems 10.6 secs, Wilcoxon test $z = 2.76, 2.44$, $p < .003, .01$ respectively), than biconditionals (exclusive-action 11.8 secs vs two-action problems 12.3 secs, inclusive-action 11.7 secs vs two-action problems 12.0 secs, Wilcoxon test $z = 0.68, 1.47$, $p < .25, .07$ respectively). We followed up these phenomena in a second experiment.

Experiment 2: Illusory inferences and co-reference

The aims of the experiment were twofold. The first aim was to examine what inferences people make from an exclusive disjunction of the form:

Either P and Q or otherwise R and S.

The disjunction was paired with a categorical premise, either asserting or denying its first proposition, P. The participants had to evaluate the validity of a one-clause conclusion, either Q or R. There were accordingly four forms of inference.

The model theory predicts that the failure to make certain information explicit in the models of the disjunction should lead people to make invalid inferences. According to the principle of truth, reasoners should construct two mental models of such a premise:

P Q
R S

It follows that given the categorical premise P, reasoners should infer that Q and not-R follow. Similarly, given the categorical premise not-P they should infer that not-Q follows. These inferences, however, are illusions. When falsity is taken into account, the disjunctive premise is consistent with six different possibilities, which we present here in *fully explicit* models:

P Q ¬ R S
P Q R ¬ S
P Q ¬ R ¬ S
¬ P Q R S
P ¬ Q R S
¬ P ¬ Q R S

These models show that the three previous inferences are invalid. Given the premise, P, for instance, Q and not-Q are both possible, and likewise R and not-R are both possible. In contrast, given the categorical premise, not-P, participants should correctly infer that R follows: this conclusion follows from the mental models above, but it also follows from the fully explicit models.

Our second aim was to examine the effects of co-reference on these inferences. Experiment 1 showed that co-reference reduced response times, at least for certain inferences. The present experiment followed up this effect and the semantic modulation of the premises.

Table 2 presents the five sorts of semantic contents, which manipulated the number of shared referents (i.e., people carrying out actions) contained in the first premise, and whether the co-referential relations occurred within or between models. We predicted that co-reference would again facilitate performance and that this facilitation would be greater as the number of shared referents increased. We also predicted that facilitation would be greater for problems requiring a greater working memory load.

Table 2: The five sorts of semantic content in Experiment 2, and the number of fully explicit models compatible with each content.

1. *Four persons act: six models*

Either Jane is kneeling by the fire and Sean is looking at the TV or otherwise Mark is standing at the window and Pat is peering into the garden.

2. Two persons, one per clause: six models

Either Jane is kneeling by the fire and she is looking at the TV or otherwise Mark is standing at the window and he is peering into the garden.

3. Two persons do inclusive actions: six models

Either Jane is kneeling by the fire and Mark is standing at the window or otherwise Jane is looking at the TV and Mark is peering into the garden.

4. Two persons do exclusive actions: two models

Either Jane is kneeling by the fire and Mark is looking at the TV or otherwise Jane is standing at the window and Mark is peering into the garden.

5. One person: two models

Either Jane is kneeling by the fire and she is looking at the TV or otherwise she is standing at the window and she is peering into the garden.

The first three sorts of content in Table 2 are consistent with all six of the fully explicit models above. However, in the other two cases, the exclusive actions rule out the models in which P and R occur together, and Q and S occur together. The premise is therefore consistent with just two fully explicit models:

P	Q	¬ R	¬ S
¬ P	¬ Q	R	S

These models yield the same conclusions as the mental models described above, but these conclusions are no longer illusions, but correct.

We tested individually 35 participants (25 paid members of the public and 10 postgraduate volunteers from the University of Dublin, Trinity College). They acted as their own controls and carried out the 20 inferences in different random orders. We constructed 20 sets of materials, each of which contained the same number of words. The materials were rotated so that they were presented equally often with each of the five sorts of semantic content.

The problems were presented on a computer screen. For each problem, the premises and questions were presented one-by-one on the screen. Participants responded to the question by pressing one of three keys: yes, no or cannot tell. The program recorded separately the time that it took participants to read each of the premises and to answer the question. The participants were not told that their responses were being timed.

Results and Discussion

Table 3 presents the percentages of the "Yes" and "No" responses to the main sorts of problems. As the table shows, the participants succumbed to the illusory (six model) problems (10% correct), but performed well the (six-model) control problem (78% correct). Of the 35 participants, 34 were less accurate on the illusions than on the control problems (Sign Test, $p < 1$ in 900 million). The pattern of responses was comparable for the two model problems, and so we suspect that the participants constructed just two models for the six-model and the two-model problems. A similar pattern of results occurred in the participants' responses to the first problem that they encountered. They were more accurate with the two-model problems (81% correct) than with the six-model problems (31% correct). This result suggests that the illusions occurred spontaneously and not as a result of the development of a mental set.

Table 3: The percentages of the "Yes" and "No" responses in Experiment 2. The balance of the responses (around 10% per problem) were "can't tell". The predicted responses are shown in bold, and underlined where they are illusory.

	Six models		Two models	
1. P & Q, or R & S	Yes	No	Yes	No
P				
∴ Q	**87**	4	**84**	6
2. P & Q, or R & S				
P				
∴ R	22	**69**	7	**87**
3. P & Q, or R & S				
Not-P				
∴ Q	13	**75**	12	**77**
4. P & Q, or R & S				
Not-P				
∴ R	**78**	15	**83**	10

There was no reliable difference between the five semantic conditions in response accuracy or in the time that it took to read the first premise. But, a significant difference in response times occurred across conditions when all responses were considered (Friedman Test, chi-squared = 20.08, df = 1, $p = .0005$), and when we included only the responses predicted by the mental model theory (Friedman Test, chi-squared = 10.66, df = 1, $p = .03$). All further analyses are based only on the responses predicted by the mental model theory, because it is difficult to know what the participants were doing when they got the answer right to the illusory problems and wrong to the control problems.

There were two principal results:

1. Responses were faster when the first premise referred to fewer individuals (1-person condition, mean 6.8 secs, 2-person conditions, mean = 8.6 secs, and 4-person condition, mean = 8.3 secs; Kruskall Wallis Test, chi-squared = 10.42, df = 2, $p < .003$).

2. The difference was significant in the different-model condition (1-person condition, mean 7.4 secs, 2-person conditions, mean = 9.9 secs, and 4-person condition, mean = 10.5 secs; Kruskall Wallis Test, chi-squared = 12.2, df = 2, $p < .002$) but not in the same-model condition (1-person condition, mean 6.3 secs, 2-person conditions, mean = 7.4 secs, and 4-person condition, mean = 6.6 secs; Kruskall Wallis Test, chi-squared = 1.89, df = 2, $p < .20$).

The results corroborated the occurrence of illusory inferences, and reasoners seem likely to construct just two models of disjunctions of the form:

Either P and Q or otherwise R and S.

They overlook the different ways in which the conjuncts could be false in the case of the six model problems, i.e., those with a content that does not eliminate any of the possibilities. The latencies of the responses bear out our conjecture that inferences are easier when the premises concern fewer individuals. Reasoners can construct more concise models in this case and are less open to confusion about who did what. Faster responses occurred both when the co-referential relation was within one model and when it was between items in different models. However, response times were faster only when reasoners had to consider an alternative model to the one referred to in the categorical premise, probably because that condition places an extra load on working memory.

General Discussion

The mental model theory predicts that when people represent a premise, they do so in accordance with the principle of truth. They construct a representation that makes only some information explicit. Experiment 1 corroborated the principle. It showed that reasoners draw different conclusions from given information, depending on whether it is expressed as a biconditional or an exclusive disjunction. Likewise, Experiment 2 showed that the failure to represent falsity can lead reasoners to make illusory inferences.

A second factor influences mental models: the occurrence of co-reference within the premises. Experiment 1 showed that co-reference within an exclusive disjunction speeded up the process of inference. Experiment 2 showed the same effect, but only when reasoners had to consider an alternative model to the one referred to in the categorical premise. The inferential task in such cases places a bigger load on working memory, and co-reference evidently ameliorates matters. The same factor may explain why there was no facilitation for conditionals in our first experiment. Reasoners can construct a more concise representation of premises containing co-referents. This parsimony reduces the load on working memory and the latencies of more difficult inferences.

The Appearance of Unity: A Higher-Order Interpretation of the Unity of Consciousness

Josh Weisberg (jwsleep@aol.com)

New York, NY 10016 USA

Abstract

Recent developments in neuroscience and psychology have put pressure on the traditional philosophical idea of the unity of consciousness. Some have argued that split-brain cases and multiple personality disorder demand a rejection and elimination of the very notion of a unified consciousness. In this poster, I argue that David Rosenthal's higher-order-thought theory of consciousness allows for an explication of unity that provides for the subjective appearance of unity, but respects the actual and potential disunity of the brain processes that underwrite consciousness.

Introduction

Researchers often have several distinct phenomena in mind when they discuss the unity of consciousness. One issue, which occupies a large part of the neuroscientific focus on unity, is the "binding problem." How are features processed in disparate anatomical and functional locations in the brain brought together into one coherent experience? Closely related is the problem of accounting for the apparent "spatial" relations that hold between our sensations, relations that allow us to view one feature as next to another in the same experience. A third phenomenon associated with unity is the apparent clear and seamless nature of our conscious experience. Finally, there are issues of ownership and the self. Why is it that my conscious perceptions belong, as it were, to me? What is the nature of this "I" that the perceptions belong to?

In this poster, I propose to address the issue of unity by first introducing a theoretical model of the conscious mind, David Rosenthal's higher-order-thought hypothesis, and then seeing which aspects of unity can be explained in terms of nonconscious neuroscientific or psychological processes. Then I will attempt to show how the remaining elements of unity can be adequately dealt with by the theory. I will close by briefly considering some worries about eliminativism that often accompany discussions of unity and consciousness.[1]

The HOT Theory

To begin, I will outline Rosenthal's higher-order-thought hypothesis. The view distinguishes between a transitive and an intransitive use of the term "conscious." The transitive use occurs when we talk about being conscious of something. The intransitive use applies to mental states, which can be described as conscious or nonconscious. The theory holds that for a mental state to be intransitively conscious, we must be *transitively conscious of it* in a suitable manner. Arguably, this process is best explained by the presence of a "higher-order thought" (HOT) to the effect that we are in that mental state. HOTs are intentional states that represent the subject as being in mental states. Being the target of a HOT is what makes a state conscious.

Furthermore, the HOT must arise in the appropriate way. To account for the seeming immediacy of conscious experience, we must be unaware of any inference or observation that causes the tokening of the HOT. Mental states not targeted by HOTs are not conscious states. so the HOTs themselves are generally not conscious states, unless targeted by an additional HOT. To summarize, the theory holds that mental states are conscious when we represent ourselves as being in those states, and this representation is achieved by higher-order thought.[2] .

---

[1] It is important to note that my work on this topic is strongly influenced by David Rosenthal's writings and instruction. Rosenthal has recently completed several articles concerning Unity (Rosenthal, forthcoming a, forthcoming b), and my work herein is meant to compliment that treatment.

[2] Obviously, much more can be said concerning the theory. I hope that this brief outline will suffice for the purposes at hand, and I will fill in details as they become relevant. For a full description and defense of the HOT theory, see Rosenthal

Lower-level Unity

Neuroanatomy tells us that the brain processes that underwrite perception are widely distributed. This raises the question of how the disparate elements of perception are combined into a single coherent experience. How does the brain bring it all together? This is the famous binding problem. The layered explanatory model of the HOT theory allows for this issue to be dealt with largely at the level of nonconscious processes. Promising work has been done in laying out a *temporal* solution to the binding problem (see, e.g., Crick and Koch, 1990; Llinás and Ribary, 1993; Edelman and Tononi, 2000). Very roughly, it is hypothesized that when groups of neurons oscillate at the appropriate rate, they bind by firing in synchrony. Arguably, this solution does not involve consciousness mental states at all.

Unconscious perceptions, like those registered in priming or subliminal perception, influence behavior in virtue of their perceptible properties, and these properties need to be bound, just as in conscious perception. In order for a priming image to have an appropriate semantic effect (for example, in influencing the disambiguation of a sentence), we must perceive the image's features as unified, in order to make the proper identifications. Perceptions are bound whether they are conscious or not. The processes that bind the percepts occur independently from consciousness, so this aspect of unity is not one that a theory of consciousness has to explicate.

Another aspect of unity, our awareness of experienced objects as located in this or that portion of a sensory field, can also be dealt with at the level of nonconscious processing. In vision, for example, various functional locations in the visual cortex nonconsciously extract and organize information concerning spatial orientation. However, this feature of unity can be more fully explicated in terms of sensory qualities. In any event, the explanation can proceed independently of consciousness.[3]

Sensory qualities are properties of mental states grouped in families that exhibit a structural relationship with families of perceptual properties in the world. Our commonsense taxonomy of perceptible color properties, for example, includes similarity and difference relations. Red is more similar to orange then it is to green. The sensory states employed in color vision must maintain these relationships. They must be in families with similarities and differences homomorphic to the similarities and differences that hold among perceptible properties. The spatial properties of sensory states can be dealt with in the same way. Sensory states that underwrite visual spatial perception must possess similarities and differences homomorphic to those possessed by perceptible spatial properties.[4]

In this fashion, sensory qualities can be explained independently of consciousness. What it is for a sensation to be located next to, or above, or below, another sensation in conscious awareness can be explicated by referring to the sensory qualities already possessed by those states. States have the features that locate them in mental space independently of their being conscious. So this feature of unity can be explained without invoking a theory of consciousness.

Thus, these elements of unity, binding and location in a sensory field, can be dealt with without reference to conscious mental states. Our perceptions have these features independently of consciousness. When we do become conscious of perceptual states, our HOTs represent them in terms of these antecedently present features. The act of becoming conscious of these features does not bring them into being. Our mental states are bound and organized in sensory fields independently of consciousness. Our HOTs simply represent these states as they are: bound, unified percepts, occupying this or that portion of the relevant sensory field. In this way, we become conscious of a bound, unified experience.

Conscious Unity

However, even though nonconscious perceptual processes bind and organize our perceptual sensations, it is clear that in some respects our conscious awareness of the world outstrips what is delivered by our perceptual mechanisms. This is exemplified by Daniel Dennett's discussion of a conscious perception of wallpaper made up of many repeated images of Marilyn Monroe (Dennett, 1991, pg. 354-355). When standing in front of such an array, we seem instantly to see that the wallpaper is all Marilyns, and what's more, we see this with an apparent clarity and depth that seems to take in the whole scene with equal acuity. But appearances may be deceiving here. Outside of the small area of foveal vision, we do not actually process visual stimuli with the fine-grainedness that we are aware of in consciousness. But in conscious experience, we seem to be aware of a full, rich, clear, unified expanse. How are we to account for this?

Here, we can refer to the clarifying effect of HOT to explain the appearance of unity. According to the HOT theory, what our HOTs represent us as

---

1986, 1991, 1993, 1997, 1999b. For critical views, see Byrne, 1997; Dretske, 1995; Stubenberg, 1998.

[3] Rosenthal, 1991.

[4] See Rosenthal, 1991, 1999a, 1999b; Sellars, 1956; Shoemaker, 1975; Clark, 1993.

experiencing is what we consciously experience. Our nonconscious perceptual processes deliver a range of information about the visual scene, which grades off sharply as we move away from foveal vision. But in the absence of any alarming discontinuity detectable outside of the foveal area, our HOTs can simply represent the scene in a "more of the same" manner. HOT can represent to the effect that we are in a perceptual state with such-and-such sensory qualities, and those features repeat in a clear and unbroken pattern to the edge of the visual field.

It might be argued that if this is the case, then the homogenizing affect of the HOTs should be readily noticeable in consciousness. However, we will not ordinarily notice the smoothing over imposed by HOT because whenever we look more closely at a scene to see if it really is unbroken and repeating, we refocus our attention, and token a more detailed, though less broad, HOT. Then we become conscious of that particular detail, but are no longer conscious of the whole scene. So we won't be aware of the cleaning-up effect of the HOT when we try to attend to it. But given the *apparent* clarity and depth of the original perception of the Marilyns, and the absence of clear perception away from foveal vision, the smoothing-over effect of the HOT is the best explanation of our unified conscious experience.

Ownership and the Self

Finally, I will turn to the sorts of issues that most often arise in philosophical discussions of unity, the apparent fact that our perceptions are in a sense "owned" by us, and that this ownership points to the presence of a "self" to do the owning. Interesting evidence from neuroscience and psychology over the last several decades (split-brain cases, hemineglect, and multiple-personality disorder [MPD], for example) have put pressure on the idea that there really is a unified self in the brain which experiences all of our perceptions and thoughts. But it sure seems to us that we are unified individuals as we undergo conscious experience. How can we account for this, on the HOT model?[5]

First, we need a little more detail concerning the content of a HOT. A HOT represents to the effect that "I, myself, am in a state with such-and-such properties." By representing in this manner, employing the concept "I," the HOT ascribes the mental state to "I," the self. In doing so, the HOT serves to tag the conscious state to this self, and so the state is represented as being mine. In this way, I "own" the state.

[5] What follows is closely related to Rosenthal's recent treatment in (Rosenthal, forthcoming a, forthcoming b).

It is important to note the indexical features of the concept "I." "I" serves a function much like that of the term "here," which automatically refers to the location of the utterance, and gets its more specific content on the particular occasion its use from the location that it occurs in. "I" works in a similar way. When "I" occurs in a HOT, it refers back to the thinker that tokens the thought. It is the function of a HOT to pick out various states that the organism is in, and by employing the indexical "I" there is a thin sort of immunity to error present in the self-ascription by the HOT, reminiscent of the way that uses of "here" are immune to error by automatically referring to the location of utterance. Our conscious states are owned by us because in becoming conscious of them, we represent the states in conjunction with "I," which automatically refers back to the producer of the thought (cf. Shoemaker, 1968).

So, when we become conscious of a mental state, we token a HOT to the effect that we are in that state. This provides us with a sense of self. We are, so to speak, a creature that ascribes states as being present in that very creature, and ascribes them by employing the concept "I." In this way we become conscious of *our* states, belonging to us.

But more must be said about this "thinker" that "I" refers back to. The concept "I" is best seen as a theoretical term in the folk-psychological theory that enables us to ascribe mental states to ourselves and others. Folk psychology posits the self as the referent of "I," and it posits a variety of features of the self. The self takes in perceptions and initiates action. It has direct, infallible access to thoughts and sensations. It accounts for the continuity we have as individuals, and makes us who we are. But this notion of self has come under strong pressure from philosophy, psychology, and neuroscience. Is there anything left that can serve as the referent of the concept "I"?

I believe that several components of the folk-psychological notion of self can be preserved. First, there are the "biological" or "ecological" elements of the self. These are the features that allow us to navigate through the world, and to distinguish the boundaries of our bodies from the external environment. They are relatively low-level features of an organism's psychology. Primitive creatures like lobsters can respond differentially to their bodies and the environment, and so avoid eating their own legs. The processes that underwrite this ability can serve as the reference of "I." (See Dennett, 1996; Bermúdez, 1998.)

In more developed creatures like us, "I" also picks out those features that account for our psychological continuity. "I" refers to a collection of moods, memories, and abilities present in the individual. We possess a core group of states that define us as a subject. We have memories about who we are, various labels,

like a name, an address, a social security number, we have abilities, like the ability to play the guitar, or to drive, and we have deep seated moods and personality traits, like being lazy, mellow, or high strung.

This group of states shifts over time, and the boundaries between core states and more peripheral states is not a firm one. Furthermore, we may not be able to bring these states to consciousness with any clarity. We may in fact confabulate the content of the states as we become conscious of them, possibly altering their content as we do so. The self is like a novel that is constantly edited and revised as it is read. So the "I" present in HOT refers to those elements of an organism that allow it to negotiate through the environment and distinguish its body from the world, and it refers to the core psychological states that define us as an individual. (See Damasio, 1994, Chp. 10; Ramachandran and Blakeslee, 1998, Chp. 12.)

But what of the remaining elements of the folk-psychological notion of self? Why does it seem to us that we are free agents with direct, infallible access to the content of our own thought? Here, once again, the HOT that makes us aware of our states misleads. The concept of self that we employ in HOT is the unrevised folk-psychological one. It goes beyond what is really there in our minds. It seems to us that we are this sort of being because our folk-psychological concept posits such features, and our HOTs employ this concept in making us conscious of our thoughts and experiences. But on this score, we are in error.

So, some aspects of the folk-psychological conception of self which informs our intuitions about unity are mistaken. The self is not what it seemed to be. Does this entail that we don't really have selves, and that the unity of consciousness is a fiction, an illusion? I would argue that this worry rests on an overly-strong criteria of what marks a concept for elimination. In this case, we do maintain some aspects of our folk-psychological conception of self, namely its connection with autobiographical continuity and ability. We also can see how other aspects unity, like the presence of bound, spatially located perceptions "owned" by a subject, are maintained by our theory. I suggest that the self is still there, and that consciousness is indeed unified, but things are not exactly as they appeared prior to our investigations.

Acknowledgments

A version of this poster was presented as a paper at the ASSC 4 conference in Brussels, July, 2000. My thanks to the audience there for helpful comments. Thanks also to Roblin Meeks, Doug Meehan, and especially David Rosenthal.

How to Solve the Problem of Compositionality by Oscillatory Networks

Markus Werning (markus.werning@uni-erfurt.de)
Department of Philosophy, P.O. Box 900221
D-99105 Erfurt, Germany

Abstract

Cognitive systems are regarded to be compositional: The semantic values of complex representations are determined by, and dependent on, the semantic values of primitive representations. Both classical and connectionist networks fail to model compositionality in a plausible way. The paper introduces oscillatory networks as a third alternative. It provides neurobiological evidence for the adequacy of those networks and argues that they are compositional. Oscillatory networks combine the virtues and avoid the shortcomings of classical and connectionist architectures.

Compositionality and Systematicity

Minds have the capacity to compose contents. Otherwise, they would not show a systematic correlation between representational capacities: If a mind is capable of certain intentional states in a certain intentional mode (perception, thought, imagination, preference, etc.), it most probably is also capable of other intentional states with related contents in the same mode. The capacity to see a red square in a green circle, e.g., is statistically highly correlated with the capacity to see a red circle in a green square. To explain this empirical phenomenon, which is closely related to the well-known binding problem, compositional operations are postulated. They enable the system to build complex representations from primitive ones so that the semantic value of the complex representation is determined by, and dependent on, the semantic values of the primitives. Several theories have been developed to meet the requirement of compositionality. Both classical and connectionist attempts suffer from severe deficits, though.

Fodor and Pylyshyn (1988) for one take recourse to a language of thought, which they link to the claim that the brain can be modeled by a Turing-style computer. A subject's having a mental representation, they believe, consists in the subject's bearing a computational relation to a mental sentence; it is a relation analogous to the relation a Turing machine's control head bears to the tape. Accordingly, the mind composes complex representations from primitive ones just the way a computer composes phrases from words: by concatenation. The trouble with classical computer models is well known and reaches from the frame problem, the problem of graceful degradation, and the problem of learning from examples (Horgan & Tienson, 1996) to problems that arise from the content sensitivity of logical reasoning (Gigerenzer & Hug, 1992).

To avoid the pitfalls of classicism, connectionist models have been developed. Some of them attempt to meet the compositionality constraint. Smolensky (1995) maps the terms and the syntax of a language homomorphically onto an algebra of vectors and tensor operations. Each primitive term of the language is assigned to a vector. Every vector renders a certain distribution of activity within the connectionist network. The syntactic operations of the language have tensor operations as counterparts. Barnden (1991) pursues a related approach. As far as syntax is concerned, some connectionist networks can completely implement compositional languages.

The kind of compositionality that is necessary for systematicity, however, focuses not on syntactic, but on semantic features. The capacity to think that a child with a red coat is distracted by an old herring is not correlated with the capacity to think that a child with an old coat is distracted by a red herring. The thoughts ought to be correlated, though, if syntactic composition was sufficient for systematicity. Although both thoughts are syntactically composed from exactly the same primitives by exactly the same operations, they are not correlated because red herring is idiomatic, i.e. because the mapping (red, herring) $\rightarrow$ red herring is syntactically, but not semantically compositional. One may well have the capacity to think of red coats and old herrings even though one lacks the capacity to think of red herrings. We may infer, thus, that semantic compositionality is necessary for systematicity and that syntactic compositionality is not sufficient. The strategy to map the syntax of a systematic language homomorphically onto a connectionist network does not suffice to establish that the network itself is systematic.

To put the dilemma in a nutshell, connectionist models seem to be too weak to explain systematicity, whereas classical models are apparently too strong to be implemented by real brains. The rest of the paper will explore the option of something "in between" classical and connectionist architectures. The presented solution differs significantly from other approaches to the dilemma (Lange & Dyer, 1989; Shastri & Ajjanagadde, 1993; Hummel & Holyoak, 1997; Sougné 1999). Especially with respect to the representation of relations, the

presented model might have more plausible implications.

Constituency

A further argument provides us with a deeper insight into what's wrong with traditional connectionist networks and gives us a key how to match this deficit. Most semantic theories explain the semantic properties of internal representations either in terms of covariance, in terms of inferential relations, or in terms of associations. One may, e.g., hold that a certain internal state is a representation of redness because the state covaries with nearby instances of redness. This covariance relation is, of course, backed by the intrinsic and extrinsic causal properties of the redness representation. One may also hold that bachelor representations characteristically are such that the subject is disposed to infer unmarried-man representations from it. Those dispositions, again, are grounded in the causal properties of bachelor and unmarried-man representations. One may, thirdly, hold that the semantic value of the cow representation is determined by the fact that it is associated with representations like milk, leather, mammal, grass etc. The mechanism of association, too, supervenes on the causal properties of the representations in question. All of these theories have one principle in common: An internal representation has its semantic value because it has a certain causal role within the system (and – perhaps – the rest of the world). The question of how the semantic values of primitive representations determine the semantic value of complex representations, hence, leads to the question of how causal properties can be inherited from primitive to complex states. From chemistry we know that atoms determine the causal properties of molecules because atoms are constituents of molecules. Physics gives similar answers with regard to atoms and elementary particles. One can even make it a hard metaphysical point: If the causal properties of a state B are determined by, and dependent on, the causal properties of the states A_1, ..., A_n and their relations to each other, then A_1, ..., A_n are constituents of B. Here, constituents are conceived of as necessary parts: A is a constituent of B if and only if the following is necessary and generally true: If B occurs at a certain region of space at a certain time, then A occurs at the same region at the same time.

The failure of connectionist attempts, therefore, is that the homomorphism between language and network structure does not preserve the constituent relations within the language. The network counterparts of brown and cow aren't constituents of the network counterpart of brown cow. Since the homomorphism does not preserve constituent relations, it fails to transfer semantic compositionality: Although the operation (brown, cow) → brown cow is semantically compositional, the network operation (h(brown),h(cow)) → h(brown cow) may not be semantically compositional (h being the homomorphism). If h(brown) and h(cow) aren't constituents of h(brown cow) you cannot say: h(brown cow) co-varies with brown cows because h(brown) co-varies with brown things and h(cow) covaries with cows. If the constituent relations were preserved, you could say this. For the same reason, you are deprived of the possibility to explain the inferential and the associative properties of the complex representation on the basis of the inferential and the associative properties of the primitive representations.

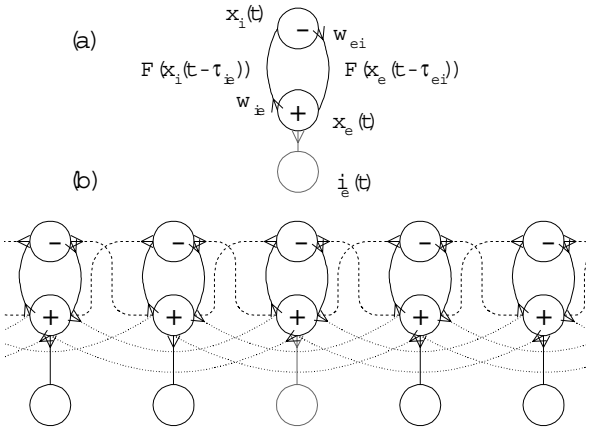

Figure 1: (a) Elementary oscillator consisting of a coupled pair of an excitatory (+) and an inhibitory unit (–) together with an input unit. t, time; x(t), unit activity; F(x) sigmoidal output function; w, coupling weight; τ, delay time; $i_e(t)$, external input. Subscripts: e, excitatory unit; i, inhibitory unit. (b) Oscillatory elements coupled by short-range synchronizing connections (dashed) and long-range desynchronizing connections (dotted), without interaction at crossings. The figure is meant to show the principle of coupled oscillators, rather than a particular connectivity pattern.

Synchrony

Constituency is a synchronic relation, while causal connectedness is a diachronic relation. Whole and part co-exist in time, whereas causes and effects succeed in time. The reference to causal connections and the flow of activation within the network will, therefore, not suffice to establish constituent relations. What we, in addition, need is an adequate synchronic relation. Oscillatory networks provide a framework to define such a relation: the relation of synchrony between phases of activity. Synchrony and asynchrony are synchronic relations because the relata, phases of activity, coexist in time. An elementary oscillator is realized by coupling an excitatory unit with an inhibitory unit using delay connections. An additional unit allows for external input (figure 1a). Within the network, oscillatory elements are coupled by either short-range synchronizing connections or long-range desynchronizing connections

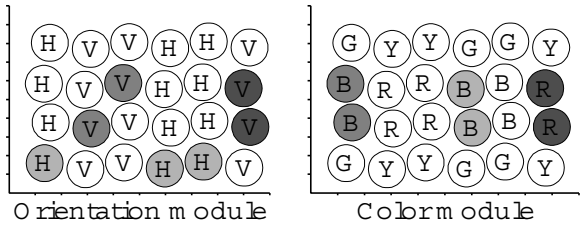

Figure 2: Scheme of a typical neuronal response aroused by a blue vertical, a red vertical, and a blue horizontal object. Circles with letters signify neurons with the property they indicate (V, H: horizontal, vertical; R, G, B, Y: red, green, blue, yellow). Like shadings signify synchronous activity. The phases of some blue-neurons are synchronous with the phases of some vertical-neurons (middle-shading), some phases of vertical-neurons are in synchrony with some phases of red-neurons (dark-shading), and some blue-neurons fire in phase with some horizontal-neurons (light-shading).

(figure 1b). A multitude of oscillators can be arranged in feature modules (e.g., the color module), employing appropriate patterns of connectivity. Given a certain selectivity of the input unit, each oscillator is designed to indicate a certain property (e.g., redness) within the feature domain. Oscillators for like properties are connected synchronizingly; those for unlike properties are connected desynchronizingly. The pattern of connectivity may as well reflect topographical features. The behavior of oscillatory networks have been studied in detail elsewhere (Schillen & König, 1994). Stimulated oscillatory networks, characteristically, show object-specific patterns of synchronized and desynchronized oscillators within and across feature modules. Oscillators that represent properties of the same object synchronize because oscillatory networks implement the Gestalt principles. Oscillators that represent properties of different objects desynchronize. We observe that for each represented object a certain phase of activity spreads through the networks. The phase pertains only to oscillators that represent the properties of the object in question. Assuming that elementary oscillators are models of neurons and that oscillatory networks are models of part of the visual cortex, the results of these studies support two hypotheses:

Indicativity. As part of the visual cortex, there are collections of neurons whose function it is to show activity only when an object in the perceptual field instantiates a certain property.

Synchrony. Neurons that belong to two collections indicative for the properties π_1 and π_2, respectively, have the function to show activity synchronous with each other only if the properties π_1 and π_2 are instantiated by the same object in the perceptual field.

The hypotheses are supported by neurobiological evidence. The indicative function of neurons was discovered by Hubel and Wiesel (1962, 1968). Neurobiologists meanwhile have specified a great variety of feature domains: color, orientation, direction of motion, speed, luminance, etc. Property indicative neuronal collections will, subsequently, be called π-collections, with π standing for the property the neurons of the collection indicate.

A number of experimental data support the hypothesis of synchrony (detailed review: Singer & Gray, 1995).[1] Synchrony of neurons (<200µm apart) within one column was recorded in many different species and cortical regions of awake and lightly anaesthetized animals, and can be observed in the local field potential as well as in the multi-unit and paired single-unit recordings (Gray & Singer, 1989; Kreiter & Singer, 1992). Intercolumnar synchrony of distant neurons (>2mm) was shown by simultaneously recording the activity of neurons in different parts of the cortex (Schwartz & Bolz, 1991). Its occurrence within and between visual areas depends upon whether the neurons are stimulated by single or separate objects. For example, synchrony is strong when two neurons in V1 with non-overlapping but collinear preferred orientations are stimulated by a single long bar moving across their receptive fields (Gray et al., 1989). It is weaker when they are stimulated by two short collinear bars moving in the same direction, and it is absent altogether when the two short bars move in opposite directions. These and other results support the view that the synchrony of distributed activity in the visual system implements the well-established Gestalt principles of perceptual grouping. The issue of object-binding as stated by the principle of synchrony is supported by evidence from the primary visual cortex of the cat (Engel, König, & Singer, 1991) and other animals. These experiments show that when two neurons with different orientation and direction preferences are stimulated by a single moving bar that is sub-optimal for both, then they synchronize, but when they are stimulated by two separate bars, each being optimal for one of the neurons, then they do not. The representational function of synchrony is supported by studies of binocular rivalry with awake strabismatic cats (Fries et al., 1997). There has long been anatomical evidence for long-range horizontal connections in V1 (Rockland & Lund, 1983). Lowel and Singer (1992) observed that these connections play a synchronizing role. Figure 2 provides a schematic overview.

Algebra

Oscillatory networks that implement the two hypotheses can be given an abstract algebraic description:

$$N = \langle N_i, N_p, N_s; \varphi_1, \ldots, \varphi_m; F_1, \ldots, F_n; \approx, \neq, \varepsilon, \wedge \rangle.$$

[1] O'Keefe and Recce (1993), Wehr and Laurent (1996), Gawne, Kjaer and Richmond (1996) assume a more critical attitude with respect to the role of synchrony in object binding.

Below, this algebra will be shown to be isomorphic to a systematic language. The primitive entities of the algebra are (i) the phases of activity picked out by the symbols φ_1, ..., φ_m and (ii) the sets of phases related to each π-collection and referred to by the symbols F_1, ..., F_n. The phases of activity are elements of the set of all neuronally possible phases N_i. The sets of phases are elements of N_p. The operations denoted by the symbols $\approx$, $\not\approx$, ε, and $\wedge$ serve to build complex neuronal states from primitive entities. The set of all complex neuronal states constructible in N is N_s. Superior "N" signifies that symbols or sequences of symbols in square brackets are interpreted in the algebra N. Thus φ_1^N, φ_2^N, ..., φ_m^N are phases of activity; F_1^N, F_2^N, ..., F_n^N are sets that comprise the phases of related π-collections; and $\approx^N$, $\not\approx^N$, ε^N, $\wedge^N$ are operations. Instead of F_1, F_2, ..., we will sometimes use more suggestive capital letters like the H, V, R, G, B, and Y of figure 2.

In N there is only one fundamental operation: being synchronous with. It is referred to by the operation symbol $\approx$ and relates phases of activity to each other:

$[\varphi_i \approx \varphi_j]^N$ is the state $[\varphi_i$ is synchronous with $\varphi_j]^N$.

The remaining N-operations are derivationally defined by means of standard symbols, with "¬" and "&" signifying negation and conjunction, "∃" the existential quantifier, "x" a variable, "(" and ")" prentices, "∈" set membership. We can thus define asynchrony $\not\approx^N$ in a natural way:

$[\varphi_i \not\approx \varphi_j]^N$ is the state $[\neg\, \varphi_i \approx \varphi_j]^N$.

If neurons of a π-collection, to which the set of phases F_j^N is assigned, show a certain phase of activity φ_i^N, we say that the phase φ_i^N or a synchronous equivalent is an element of the set F_j^N. To refer to this neuronal state, we define the relation of pertaining ε^N:

$[\varphi_i \varepsilon F_j]^N$ is the state $[(\exists x)(x \approx \varphi_i \,\&\, x \in F_j)]^N$.

A further operation is co-occurrence $\wedge^N$ of two states p^N and q^N. It is trivially defined:

$[p \wedge q]^N$ is the state $[p \,\&\, q]^N$.

The four operations are motivated by the hypothesis of indicativity and synchrony. They allow us to give an algebraic description of the scheme shown in figure 2. Assuming that the middle-shaded neurons show the phase of activity φ_1^N, the dark-shaded neurons the phase φ_2^N and the light-shaded neurons the phase φ_3^N, figure 2 expresses the cortical state:

$[\varphi_1 \varepsilon V \wedge \varphi_1 \varepsilon B \wedge \varphi_2 \varepsilon V \wedge \varphi_2 \varepsilon R \wedge \varphi_3 \varepsilon H \wedge \varphi_3 \varepsilon B]^N$.

Language

The notation already suggests that the algebra N might be isomorphic to a compositional and systematic language L. Since languages can be treated as algebras, we may define:

$L = \langle L_i, L_p, L_s; \varphi_1, ..., \varphi_m; F_1, ..., F_n; \approx, \not\approx, \varepsilon, \wedge \rangle$.

The entities of L are indexical expressions like this and that (included in the set L_i), predicates like red and vertical (in L_p) and clauses like this is red or this is the same as that (in L_s). The primitive symbols φ_1, ..., φ_m pick out specific indexicals and the primitive symbols F_1, ..., F_n specific predicates. Again we will sometimes use more suggestive capital letters instead of F_1, ..., F_n. The fundamental operation of L is sameness $\approx^L$:

$[\varphi_i \approx \varphi_j]^L$ is the clause $[\varphi_i$ is the same as $\varphi_j]^L$.

The remaining operations can derivationally be defined. Difference $\not\approx^L$:

$[\varphi_i \not\approx \varphi_j]^L$ is the clause $[\neg\, \varphi_i \approx \varphi_j]^L$.

Using $\in$ as the symbol for predication this time, the copula ε^L, which links an indexical expression φ_i^L to a predicate F_j^L, is defined by:

$[\varphi_i \varepsilon F_j]^L$ is the clause $[(\exists x)(x \approx \varphi_i \,\&\, x \in F_j)]^L$.

The copula (English: "is") enables us to paraphrase natural language sentences like this is vertical in L: $[\varphi_1 \varepsilon V]^L$. The conjunction $\wedge^L$ between two clauses p^L and q^L is defined:

$[p \wedge q]^L$ is the clause $[p \,\&\, q]^L$.

The sentence there is a blue vertical, a red vertical, and a blue horizontal object can now be paraphrased:

$[\varphi_1 \varepsilon V \wedge \varphi_1 \varepsilon B \wedge \varphi_2 \varepsilon V \wedge \varphi_2 \varepsilon R \wedge \varphi_3 \varepsilon H \wedge \varphi_3 \varepsilon B]^L$.

Isomorphism and Preserved Constituency

To prove that the algebras N and L are isomorphic, a number of conditions have to be warranted. (i) There are as many phases of activity in N as there are indexical terms in L. (ii) Each π-collection, respectively, each related set of phases in N is assigned to exactly one predicate of L. (iii) L-clauses, by stipulation, are identical if and only if they are logically equivalent. For, cortical states are identical if and only if they are referred to by logically equivalent N-descriptions. To ensure this non-trivial condition, we thus have to accept that order is irrelevant in L. This leads to a non-standard notion of language: Concatenation, no longer, is the fundamental operation of concept composition. (iv) The two fundamental operations synchrony and sameness are isomorphic. If so, this isomorphism then conveys to all operations that have recursively been defined. Since sameness is a reflexive, symmetric, and transitive relation, we have to define synchrony between phases as a reflexive, symmetric, and transitive relation, too. This is consistent with recent neurobiological data (cf. Eckhorn, 2000) and the computer simulations of oscillatory networks mentioned above.

In previous sections we argued that an architecture might not be compositional even if it is syntactically homomorphic to a compositional language. To preserve semantic compositionality, the isomorphism between L and N must, in addition, preserve the constituent structure of the language. If a primitive term is a constituent of a complex term, the isomorphic counterpart of the primitive term must be a constituent of the isomorphic counterpart of the complex term. The primitives of L are the indexicals φ_1^L, ..., φ_m^L and the predicates F_1^L, ..., F_n^L. Every L-operation will lead to targets with those primitives as constituents. The clause $[\varphi_1 \approx$

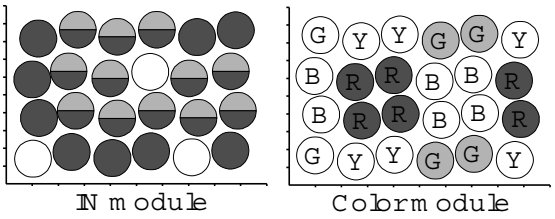

Figure 3: Predicted neuronal representation of relations. The state $[\varphi_1 \varepsilon G \wedge \varphi_2 \varepsilon R \wedge \langle \varphi_1, \varphi_2 \rangle \varepsilon' IN]^N$ is shown. The phases φ_1 of the G-neurons (light shading) occurs on the IN-module only in superposition with the phase φ_2 of the R-neurons (dark-shading) forming the duplex phase $\{\varphi_1, \varphi_2\}$ (hybrid shading). Since φ_2 also occurs as simplex on the IN-module, the situation on the IN-module is rendered by $[\{\{\varphi_1, \varphi_2\}, \{\varphi_2\}\} \varepsilon' IN]^N$. By definition, this is equivalent to $[\langle \varphi_1, \varphi_2 \rangle \varepsilon' IN]^N$.

$\varphi_2]^L$ can impossibly be tokened without tokening the indexicals φ_1^L and φ_2^L. With respect to constituency, what is true for L is also true for N: The state $[\varphi_1 \approx \varphi_2]^N$ is tokened just in case the phases φ_1^N and φ_2^N are tokened. Two phases are synchronous only if both of them actually occur within the cortex. The same is true mutatis mutandis for asynchrony. In L, the indexical φ^L and the predicate F^L are constituents of the clause $[\varphi \varepsilon F]^L$. Therefore, the phase φ^N and the π-collection to which the set F^N relates must be tokened, whenever the cortex is in $[\varphi \varepsilon F]^N$. This is obviously true because φ^N cannot pertain to the π-collection unless both the phase and the π-collection occur in the cortex. Figure 2 illustrates that the isomorphism preserves constituent relations for every operation: The complex state shown can only be tokened if, indeed, certain bursts of activity and certain collections of neurons are tokened. We may infer that oscillatory networks are not only syntactically, but also semantically compositional.

Relations

The representation of relations poses a binding problem of second order. The sentence this red vertical object is in that green horizontal object not only binds four property representations into two object representations, it moreover binds the two object representations by the relation in. The constituency preserving isomorphism between L and N straightforwardly generates a prediction of how to realize relational representation by oscillatory networks: After L has been extended by the tools for representing relations known from logic, N has to be extended in a way that perpetuates the isomorphism and the congruence with respect to constituency structure. The tools needed in the extensions of L and N are the operation of pairing, a higher-order copula and relation constants, or, respectively, their neuronal counterparts. Following Kuratowski (1967), ordered pairs are by common standards defined as asymmetric sets of second order:

$$[\langle \varphi_i, \varphi_j \rangle]^{L/N} =_{def} [\{\{\varphi_i, \varphi_j\}, \{\varphi_j\}\}]^{L/N}.$$

With the relations R_1^L, ..., R_k^L being sets of pairs, the higher-order copula links pairs to relations in the manner of set membership. On the neuronal level, the R_1^N, ..., R_k^N can be interpreted as relational modules:

$$[\langle \varphi_i, \varphi_j \rangle \varepsilon' R_1]^{L/N} =_{def} [\langle \varphi_i, \varphi_j \rangle \in R_1]^{L/N}.$$

The sentence this green object is in that red object can now be paraphrased in the extension of L:

$$[\varphi_1 \varepsilon G \wedge \varphi_2 \varepsilon R \wedge \langle \varphi_1, \varphi_2 \rangle \varepsilon' IN]^L.$$

Its neuronal counterpart – superior "L" is replaced by superior "N" – is shown in figure 3. To achieve a distribution of phases thus complex, some neurons are required to show a superposition of two phases. The presented model, therefore, predicts multiplex activity as a means of representing relations. Gasser and Colunga's (1998) simulation, which also uses superposed phases in relational representations, supports the prediction.

Neither Connectionism nor Classicism

Cognitive architectures can be distinguished along three features:

Syntactic Trees. There are mappings from ordered sets of argument representations onto target representations.

Constituency (presupposes trees). For every syntactic tree, its argument representations are constituents of its target representation.

Order (presupposes constituency). For every target representation, there is a determinate order among its constituents.

These features are each realized by every standard language: There is a syntax, words are constituents of phrases, and the words follow a determinate word order. We can now ask which of these features a certain cognitive model implements. Turing-style computers typically implement all three features because they build complex representations from primitive representation by concatenation following certain syntactic rules. Integrated connectionist/symbolic architectures only implement syntactic trees. They do not implement the principle of constituency and the principle of order. Oscillatory networks, however, implement both syntactic trees and the principle of constituency. They do not implement an order among representations.

Oscillatory networks lie in some sense in between classical and connectionist architectures. They resemble connectionist networks in many respects: They may serve as associative, content addressable memories. They process information in parallel. They are able to learn from examples. They degrade gracefully. Etc. Still, oscillatory networks are stronger than traditional connectionist networks because, in oscillatory networks, primitive representations are constituents of complex representations. The primitive representations

inherit their causal properties to complex representations and, thereby, determine their semantic properties. Oscillatory networks unite the virtues and avoid the vices of classical and connectionist networks. They are semantically compositional and systematic.

Acknowledgments

Research for this paper was sponsored by the National German Scholarship Foundation. It was enabled by a one-year research scholarship at Rutgers University and the Rutgers Center of Cognitive Science. I owe many of the presented insights to seminars and discussions with Andreas Engel, Thomas Metzinger, Wolf Singer, Jerry Fodor, Ernie LePore, Brian McLaughlin, Bruce Tesar and Gerhard Schurz. I am grateful, also, to the Berlin Colloquium "Philosophy Meets Cognitive Science".

A Model of Perceptual Change by Domain Integration

Gert Westermann (**gert@csl.sony.fr**)
Sony Computer Science Laboratory
6 rue Amyot
75005 Paris, France

Abstract

A neural network model is presented that shows how the perception of stimuli can be changed due to their integration between different domains. The model develops representations based on the correlational structure between the stimuli of the domains. It shows how prototypicality, categorical perception, and interference effects between the domains can arise without the explicit labeling of categories. The model is extended to learn the sensori-motor integration between articulatory parameters and speech sounds and it is shown how it can, in accordance with the ideomotor principle, imitate sounds based on the developed mappings in a "babbling phase".

Introduction

The ability to categorize is one of the most fundamental cognitive processes. Nevertheless, uncovering the mechanisms that underlie this ability has challenged experimenters and modelers alike. The reason for this difficulty might be that categories can be formed in many different ways: in some cases, perhaps mainly in experimental situations, explicit information about the category of a stimulus is given. In other cases, no feedback might be available about the categorization choice, and in even others, no explicit categorization choice might be made at all.

At the same time, recent research has suggested that categorization itself can exert an influence on perception (Goldstone, 1995; Schyns *et al.*, 1998). While these effects have mainly been studied in a supervised paradigm, perceptual changes also occur prominently in categorization without supervision and without explicit labeling, for example, in being exposed to the phonemes of one's native language (Kuhl *et al.*, 1992).

Finally, there is clear evidence that in categorizing the world, we make use of all available information and integrate the information from different modalities, making categorization more robust and easier. For example, visual and auditory information are integrated in speech perception, leading to enhanced activity in the cortical areas responsible for both domains (e.g. Calvert *et al.*, 1999).

In this paper a neural network model is described that aims to integrate several aspects of categorization, namely, the combination of modalities and the perceptual changes that go hand in hand with categorization. The model suggests that some of the phenomena that are usually explained as the consequence of explicit categorization, e.g., prototype formation and categorical perception, can arise without such explicit categorization based on the correlational structure of the stimuli from different modalities, and that they can facilitate subsequent explicit categorization when it occurs.

The integration between modalities has previously been modeled by de Sa and Ballard (1998). Their neural network model consisted of one layer for each modality, and each layer made an explicit category decision. In a process of self-supervised learning both modalities learned to agree on their decision. While the model performed comparably to supervised models, it was necessary to determine the number of categories *a priori*, and due to absolute category boundaries in each modality, perceptual phenomena such as gradedness and varying sensitivities to differences between stimuli could not be modeled. The present model aims to give an account of how such perceptual phenomena that are usually linked with explicit categorization can occur without an explicit category decision and without labeling, and how such a model can be extended to also account for sensori-motor integration. The model is loosely inspired by neurobiological considerations.

The rest of the paper is organized as follows: first, the model is described in detail. Then, experiments with a simple data set are described that lead to perceptual change as the result of the integration between modalities. Finally, the application of the model to sensori-motor integration and the imitation of sounds is described.

The Domain-Integration Model

The model described here integrates the stimuli from two domains (modalities) into a unified percept. The architecture of the model is shown in fig. 1. Each domain is represented by a neural map, and Hebbian connections between the maps allow for the coordination between them. Usually, an input pair (one input per map) is presented to the maps simultaneously, and in the following the activation and weight update mechanisms are described.

Each neural map consists of a number n of units that are randomly positioned in the input space (in this paper, the input spaces for both domains are two-dimensional

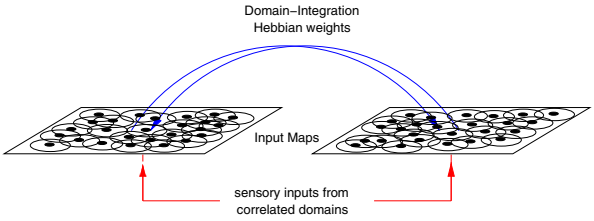

Figure 1: The architecture of the model.

to facilitate visualization). In the current model, the positions of these units remain fixed throughout learning. Each unit acts as a receptive field with a Gaussian activation function of a fixed width. Such receptive fields exist in many areas of the cortex. When an external input x is presented to the map, the Gaussian activation of the units is computed as

$$act_{i_{ext}} = e^{\frac{pos_i - x}{\sigma^2}} \tag{1}$$

where pos_i is the position of unit i, x is the input signal, and σ is the standard deviation (width) of the Gaussian. Each unit is connected with unidirectional Hebbian weights to all units on the map for the other domain. The Hebbian activation of a unit is the dot product of the weight value vector and the activation vector of the units on the other map:

$$act_{i_{hebb}} = \sum_k act_k w_{ik} \tag{2}$$

where the units on the other map are designated by the index k and w_{ik} is the weight from a unit k on the other map to the current unit i on this map.

The total activation of a unit is computed by summing the activations from the external stimulus and those from the Hebbian connections with the other map:

$$act_i = \gamma_e act_{i_{ext}} \quad \gamma_h act_{i_{hebb}} \tag{3}$$

where γ_e and γ_h are weighting parameters to control how much each partial activation contributes to the total activation of the unit.

The activation update after presentation of a pattern is synchronous for all units, and the activation values are scaled to a maximum of 1.0.

One input to a map will typically activate several units, and the response r_i to an input x, that is, how the neural map "perceives" that input, is computed by a population code: the response is the vector sum of all units i, weighted by their activation values:

$$\mathbf{r}_x = \frac{\sum_i act_i \mathbf{pos}_i}{\sum_i act_i} \tag{4}$$

Such population codes have been found to play a role for example in the encoding of motor commands in the monkey cortex (Georgopoulos *et al.*, 1988) where the direction of arm reaching is predicted accurately by adding the direction vectors of direction sensitive neurons, weighted by their firing rate. In computational models, population codes have been successfully used to show the emergence of a perceptual magnet effect for phonemes (Guenther and Gjaja, 1996).

The Hebbian connections between the maps are updated with the covariance learning rule (Sejnowski, 1977):

$$\Delta w_{ik} = \alpha(act_i - \bar{act}_i)(act_k - \bar{act}_k) \tag{5}$$

where $\bar{act}_i$ and $\bar{act}_k$ are the average activation values of units i and k over a certain time interval. This rule strengthens the connections between units when their activation values are positively correlated, weakens them when the activations are negatively correlated, and does not change the weights when the activations are decorrelated.

This correlation-based weight update has the consequence that units that respond to stimuli that consistently co-vary across the domains develop higher activations due to the growing Hebbian weights: co-varying inputs in the two domains result in the same units on both maps to have co-varying activation values, and thus to develop strong Hebbian connections. This results in such units not only receiving external, but also strong Hebbian activation and becoming more active than other units that do not reliably co-vary with units from the other domain map. Given that the population code response is weighted by unit activations, this means that such units "pull" the response towards them and induce a perceptual change (fig. 2). Therefore, an input-pair with normal (previously observed) correlational structure will become more prototypical so that other, nearby inputs will be displaced towards it.

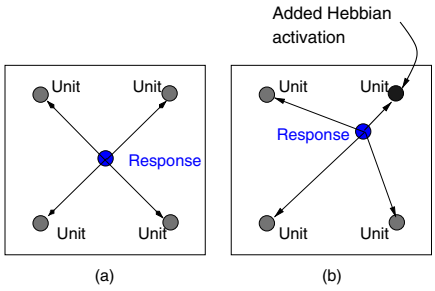

Figure 2: The response to an input is influenced by external Hebbian activation. (a): Without Hebbian activation, the response lies in the middle between four equally activated units. (b): When one unit is activated more due to Hebbian activation, the response is displaced towards that unit.

In the following section, experiments with this model are described that investigate the nature of the induced perceptual changes based on the integration between the two input domains.

Experiments

The domain-integration model was tested with a simple data set (fig. 3) to investigate the nature of the developed perceptual changes and the role of correlations between data from the two domains in this process.

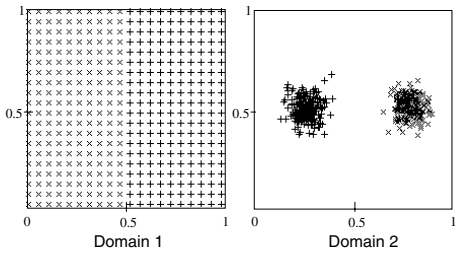

Figure 3: The data used to evaluate the model. The correlational structure between data items splits each domain into two classes, denoted by x and +, respectively.

Domain 1 consists of 400 evenly distributed two-dimensional data in the range from 0 to 1. Domain 2 consists of two clusters of 200 data each with Gaussian distributions around the centers $(0.25, 0.5)$ and $(0.75, 0.5)$. In training, the "left half" of the data in domain 1 (i.e., between 0.0 and 0.5) co-occurred with data from the "right" cluster of domain 2, and the "right half" in domain 1 (0.5 to 1.0) with data from the "left" cluster in domain 2.

Although this data set is artificial, it could be interpreted as, for example, a continuous variation of width and height of an object (domain 1) and associated sounds at certain frequencies and volumes (domain 2) in a modality-integration experiment.

The neural maps for each domain consisted of 200 randomly placed units. All data pairs were presented to the model a single time in randomized order. The Hebbian connections between the maps had initial values of 0 and were updated after presentation of each data pair. The parameter settings were $\alpha = 0.01$, and for each map, $\sigma = 0.05$, $\gamma_e = 1.0$, and $\gamma_h = 0.02$.

Development of Prototypes

Fig. 4 shows the initial and final responses to the data set. Each data input creates a response on its neural map (eq. (4)). Fig. 4A shows the initial response of the neural maps to the data from each domain. With all Hebbian connections being zero, the response is only determined by the actual input signal to the map and gives a rather faithful representation of the original data set in fig. 3. Due to the random location of units the original data is slightly distorted in the response.

During the training of the model, the Hebbian connections between units responding to co-varying data in both domains are strengthened and those responding to non-co-varying data are weakened or remain unchanged (eq. (5)). This process results in strong connections between units that respond to the centers of their categories because they will be active for both central and more

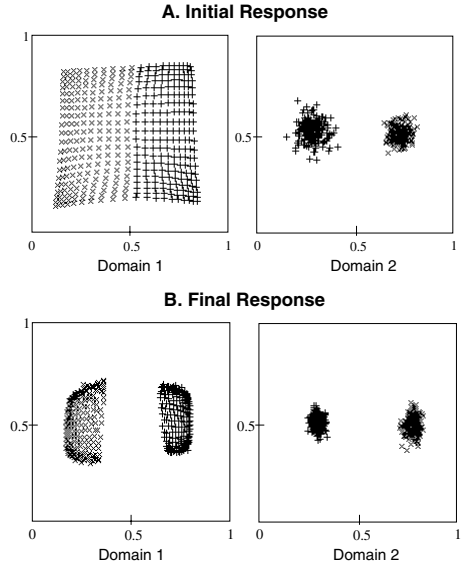

Figure 4: The initial (A.) and final (B.) response of the model to the data set in fig. 3.

peripheral inputs from a certain category. As a consequence, such central units will become more active than others when correlated inputs are presented. Their activation is a sum of the external activation caused by the inputs themselves, together with the activation mediated through the strengthened Hebbian weights from the other map (eq. (3)). Therefore, the response to peripheral stimuli will be pulled towards the center of each category. Fig. 4B shows the responses of the maps to the data after presentation of each data item and corresponding updating of the Hebbian connections. The continuous data in domain 1 has split into two clusters that correspond to the co-variance relations with the clusters in domain 2. Each cluster is based around a prototype determined by the central data item of each set. Similarly, the clusters in domain 2 have become very dense around their respective centers. Prototypes thus develop simultaneously in both domains, based on the interactions between the domain maps.

Categorical Perception

Categorical Perception (CP) is a phenomenon that occurs both innately and in learned categorization (see Harnad, 1987, for an overview): different stimuli within one category are perceived as more similar than stimuli with the same "distance" that straddle category boundaries. One example for innate CP is the perception of color, e.g. in a rainbow: although the light frequency changes continuously, we perceive separate bands of color. For example, within the red band we do not perceive differences between changing light frequencies, but an equally small change at the border of that band leads to the abrupt perception of orange.

It has been shown that CP also develops in learned categories such as phonemes of one's native language

(e.g. Kuhl *et al.*, 1992). More recently, CP has also been shown to arise for visual stimuli in categorization task experiments (Goldstone *et al.*, 1996). In these experiments, subjects had to group a set of continuously varied shapes into categories in a supervised learning task. After having learned the categories, they were better able to distinguish between two stimuli that were near a category boundary than between those that were within a category. Therefore, CP can be said to constitute a warping of similarity space in which the sensitivity to differences of (relevant) stimuli is enhanced near category boundaries and is decreased within categories.

Guenther and Gjaja (1996) modeled categorical perception for phonemes in an unsupervised model. They argued that the firing preferences of neurons in the auditory map reflect the distribution of sounds in the language, and due to the non-uniform distribution of these sounds CP arose in the model in a self-organizing process. While this model accounts well for CP in phoneme perception, it relies on a non-uniform distribution of the data. CP that arises for uniform stimuli as a result of explicit categorization has been modeled in supervised radial basis (Goldstone *et al.*, 1996) or backpropagation (Tijsseling and S.Harnad, 1997) networks. It therefore seems that CP can arise from different causes (data distribution or explicit teaching), and in the model presented here a third route is taken: it is studied how CP can arise in a homogeneously distributed data set that is correlated with non-uniform data in another domain, without the explicit teaching of category labels. Instead, categories form in an unsupervised way based on the correlational structures between the two domains.

In the present experiments, the x-coordinate of the data is the relevant dimension for determining category membership (with the categories defined by the correlations across domains). To establish whether CP did occur in the model, after training the map of domain 1 was presented with a sequence of data points from (0.0, 0.5) to (1.0, 0.5) in steps of 0.01, i.e., a walk from the left to the right side of the map. The difference between the responses of the model to every pair of adjacent data points is shown in fig. 5. There is a marked peak of sensitivity at the category boundary (0.5) where a difference of 0.01 in the input data is perceived as a difference of 0.08 in the responses. By contrast, at a distance from the category boundary, the sensitivity of the model to differences between stimuli is decreased.

This result models the basic characteristics of CP: an increased sensitivity to differences at the category boundary, and a diminished sensitivity within the categories.

Domain Integration: The McGurk Effect

Many experiments have shown that visual information can enhance the understanding of speech, suggesting an integration of the visual with the auditory signal in this task (see Massaro, 1998, for an overview). Striking evidence for the strength of this integration comes from the

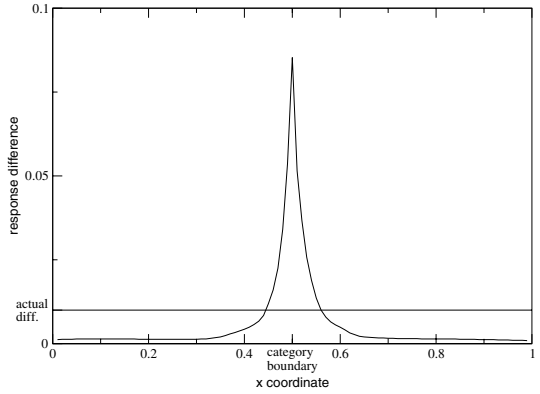

Figure 5: CP in the model: sensitivity to differences is increased around the category boundary.

McGurk effect (McGurk and MacDonald, 1976): when subjects are presented with conflicting visual and auditory data, their perception of what is said can be different from both the visual and the auditory signal. For example, when a face articulating /ga/ is dubbed with the auditory /da/, subjects perceive /ba/. This effect is highly pervasive and not subject to volitional control. It is not restricted to vision and auditory integration, but has also been found for touch and audition (Fowler and Dekle, 1991).

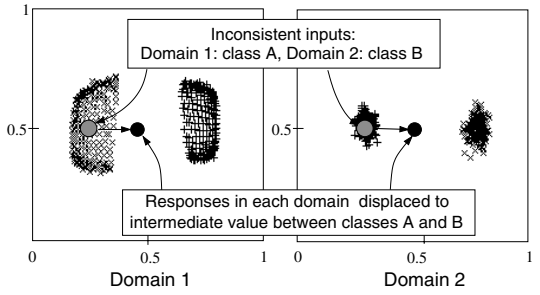

Figure 6: Exemplary response of the model to a data pair that does not correspond to the learned correlational structure. The previously learned responses are denoted by x and +, the data pair that does not correspond to the learned correlational structure by grey circles, and the response of the model to this data pair by black circles.

To test whether the model displayed a response similar to the McGurk effect in humans, data pairs were presented that did not correspond to the previously learned correlation structure. While during training the "left" half of the data set for domain 1 co-occurred with the "right" cluster in domain 2, now data from the "left" half in domain 1 was presented together with that from the "left" cluster of domain 2. Conceptually this corresponds to presenting e.g., an auditory /da/ together with a visual /ga/. The model integrated these conflicting inputs to a

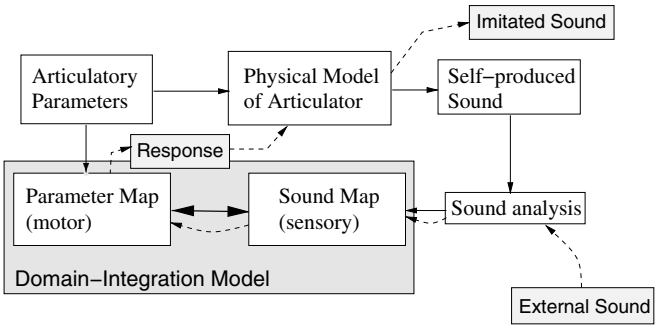

Figure 7: The model for sensori-motor integration and the imitation of sounds. Solid arrows indicate the "babbling phase" where the mapping from motor to sensory parameters is learned. The dashed arrows show the pathway for the subsequent imitation of sounds.

response that was a blend between the responses to each individual input (fig. 6).

While the McGurk effect has been studied in great detail and has revealed many results that are much more subtle than a simple blend between the auditory and visual information, the present model can give a principled account of how the domain integration that lies at the basis of this effect can arise. The details of the McGurk effect cannot be modeled with the artificial data set used here to investigate the general functionality of the model, but experiments are planned to use a more realistic set of auditory and visual signals that will give more detailed results.

In summary, the domain integration model displays, without the explicit teaching and labeling of categories, several of the effects that are generally supposed to rely on such labeling, namely, the formation of prototypes as attractors in the stimulus space, categorical perception in an evenly distributed set of stimuli, and an integration of stimuli from different domains to form a unified percept that forms a "compromise" when conflicting data is presented in the domains simultaneously.

The Model in Sensori-Motor Integration

In the previous sections it was described how the domain integration model integrates between two sensory domains, leading to psychologically observed phenomena such as prototype formation, categorical perception, and the McGurk effect. In this section, an extension to this model is proposed to account for sensori-motor integration (fig. 7). This extension works by presenting in one domain a representation of an action (e.g., motor parameters), and in the other, a representation of the sensory consequences of that action. The model then learns the associations between the motor commands and their sensory consequences, developing simultaneously in both domains prototypes of actions and consequences of these actions, based on a reliable correlation between them.

The sensori-motor variant of the model was tested on sound production. For this purpose, a physical model of a speech synthesizer (Boersma and Weenink, 1996) was used. In initial experiments, two parameters, jaw opening and the position of the styloglossus muscle (a muscle that controls the position of the back of the tongue) were varied continuously at 18 steps each, and the resulting sounds were analyzed with respect to their firsts two formant values. The model was trained on the resulting two-domain data set with 324 items. Fig. 8 shows the initial and final responses of the model. While the motor parameters are evenly distributed prior to training, after training prototypical parameter-sound pairs have formed in both domains due to their correlational structure.

The sensori-motor integration model corresponds to the ideomotor principle which postulates a tight coupling between perception and action. As such it can give an account of the imitation of sounds (fig. 7, fig. 8B): an external sound that is presented to the model evokes a response on the auditory map. This response is propagated through the developed Hebbian connections to the motor map where a motor response is evoked which can be used to articulate, i.e., imitate, the corresponding sound. However, the imitation of the heard sound is displaced towards a prototype that the model has developed during training (indicated by an arrow in the auditory map in fig. 8B). In this way, imitation is not merely a reproduction of an external stimulus, but a re-interpretation of that stimulus based on the developed structure of the model.

Discussion

The model described in this paper presents an algorithm to integrate sensory information between two domains to form a unified percept, thereby displaying phenomena also observed in human categorization. The model can be extended to also account for sensori-motor integration and the imitation of low level percepts. While the simple data sets used in this paper were used to demonstrate the principled functionality of the model, more realistic and

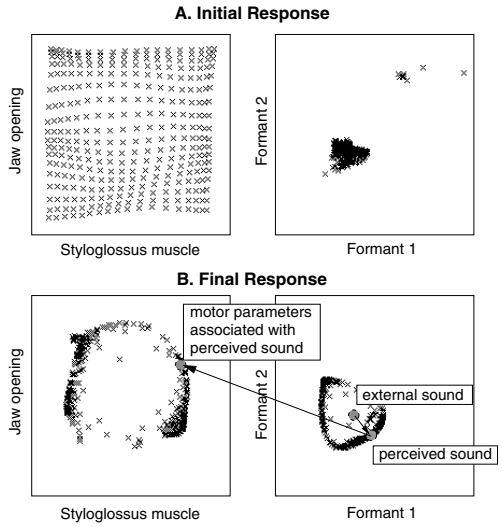

Figure 8: A. Initial and B. final responses of the sensori-motor integration model.

extensive experiments are necessary to establish whether it can account for more detailed results in these domains. We have now started to use higher-dimensional data for the learning of the articulation–perception mapping in sound production and imitation, and preliminary results look promising.

An important property of the model is that it shows a unified account of sensori-sensor and sensori-motor integration in a neurobiologically inspired framework.

An alternative view of this model could be as a variant of supervised category learning: when one map receives the inputs (i.e., object representations) and the other the targets (i.e., category labels), the model learns the mapping from the category members to their labels if there is a sufficient number of different categories. The domain integration model, however, adds an important aspect that is often neglected in supervised category learning models: not only category members, but also the concept of "category" has a topology and is changed by its members. For example, the "concepts" of the dog and cat categories will move closer together on the target map if their members share properties. In this way it becomes possible to measure the similarity between concepts by investigating the developed topology on the target map.

In its present form the model is simple, though it allows insights into how perception can change due to categorization. However, more realistic training data, as well as an extension of the model to be able to handle sequential and more complex data, are necessary. These will be the next steps in the described research.

Acknowledgments I would like to thank Eduardo Miranda for providing the data set for the sound imitation experiments.

Abstract

A constraint-based theory of abstractness was investigated according to which abstractness of entities is a function of (i) perceptual observability and (ii) characteristics of contextual constraints. Participants performed ratings of context availability, imagery, and abstractness for 36 nouns that varied in abstractness and familiarity. The ratings were used to compare the predictions of abstractness ratings by context availability, dual coding theory and the constraint-based approach outlined in this paper. We found that only constraints explain variation of perceived abstractness for abstract concepts, whereas context availability and imagery are good predictors of the dichotomous distinction of concrete-abstract, and of variations of concreteness for concrete concepts only. A second study shows that introspection-based constraints are most critical for abstractness ratings. Implications are discussed.

Abstractness

Every-day communication is pervaded by references to abstract entities, such as *explanation*, *regret*, and *intention*. Typically, we think of an entity as abstract when it cannot be perceived. However, there are no clear-cut criteria for what makes entities abstract or concrete. Several theoretical approaches exist to predicting perceived abstractness. This paper compares three theories: dual-coding theory, context-availability theory, and our approach, called the *contextual constraint theory*.

We propose that perceived abstractness depends on two factors. First, entities are abstract or concrete, depending on whether they are physical in nature (i.e., perceivable through vision, touch, etc.). Second, within these groups, abstractness varies according to more specific types of information. Together, we call this the *two-factor model of abstractness*. We will start by reviewing the plausibility of the dichotomy of abstract and concrete, as proposed by the first factor. The remainder of this paper will address the factors underlying abstractness variation within the groups of abstract versus concrete entities.

Abstract and Concrete: Dichotomy or Continuum?

Concrete and abstract nouns are commonly defined by reference to perceivability: Concrete entities are considered to be physical entities with characteristic shapes, parts, materials, etc., whereas abstract entities lack physical attributes (e.g., Crystal, 1995). The first proposed factor follows this broad distinction.

Some entities challenge the notion of a dichotomy of abstract and concrete entities. Examples for entities that cannot clearly be classified as abstract or concrete are *government*, *officer*, or *anger*. A *government* is abstract in that we cannot really point to who or what it is, but it is also concrete in that it involves a number of specific, concrete entities, such as people, buildings, and particular locations. *Officer* is a social agent term, referring to concrete individuals with characteristics defined by a particular social role or profession. Their roles are not obvious characteristics, but are inferred from more complex information, such as behavior patterns in specific situations.

Finally, emotion terms such as *anger* are a special group of entities. Emotions can be perceived within individuals who experience them. Outwardly, we can perceive emotion through nonverbal and verbal behavior. Still, emotions are qualitatively different from concrete entities such as cups and office chairs. In fact, they have been proposed to constitute a distinct group from both concrete and abstract entities (Altarriba, Bauer, & Benvenuto, 1999). The alternative view suggested by these challenges is a contiuum view, according to which all entities vary in concreteness, and the distinction of abstract versus concrete is an oversimplification.

A simple way to test both views is to ask people to rate the concreteness of a large sample of entities, including abstract and concrete ones. If concreteness is one dimension and all entities vary along this dimension, then ratings should be distributed pretty evenly across the entire scale. In contrast, if abstract and concrete entities were two distinct classes of entities, ratings should fall into two clusters. There would be a lot of entities rated as abstract, versus a lot of entities rated as concrete. That is, the distribution of

concreteness ratings would assume the shape of a bimodal distribution.

What is found is, in fact, that the ratings form two fairly distinct clusters with a different mode each. One mode is centered over the abstract half of the scale, the other mode is located over the middle of the concrete half. This finding has first been reported for 2172 words by Nelson and Schreiber (1992), and has been replicated here for an independently sampled set of 1660 nouns (see Figure 1).

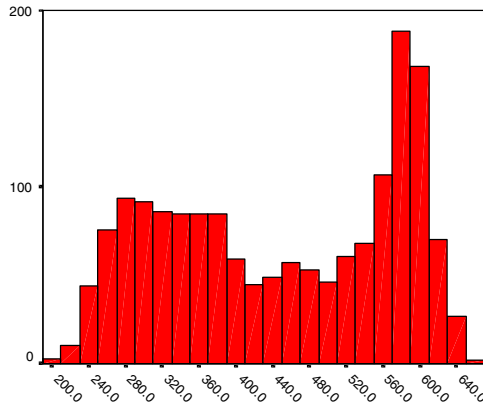

Figure 1
Distribution of concreteness ratings for 1660 nouns

The bimodal distribution is consistent with the view that abstract and concrete entities fall into two big clusters according to particular characteristics (e.g., tangibility or visibility). It is also obvious that, within these two clusters, entities vary in concreteness. What factors are causing this variance? The remainder of this paper addresses this question.

Variation in Abstractness

What information underlies the variance of abstractness in abstract entities? If an entity cannot be perceived, it is abstract. The lack of concreteness can account for it being abstract, but the same information cannot explain why some abstract entities are more abstract than others. For example, lack of perceptual information cannot explain why *principle* is rated more abstract than *idea*.

Our research aims to specify what factor(s) cause concrete entities to vary in perceived concreteness, and what factor(s) cause variance in the perceived abstractness of abstract concepts. Our studies are motivated by two lines of reasoning. The first directly follows from the *two-factor model of abstractness.* We do not think that perceivability accounts for the entire variation in concreteness. Instead, we assume a second factor. This intends to replace the commonsense notion that abstract concepts get more abstract to the degree that they get less perceivable (concrete). Second, it is quite likely that the difference between abstract and concrete is not so much a quantitative distinction, but a qualitative one. That is, it is conceivable that the factor or factors that make abstract entities more or less abstract are distinct from the factors that make concrete entities differ in concreteness. To identify possible factors, we next review theories that have been proposed to understand abstractness.

Theories of Abstractness

Theories pertinent to explaining abstractness include dual coding theory, context-availability theory, and contextual constraint theory. The predictions of each are discussed in turn.

Dual-Coding Theory / Imagery

The dual-coding model (Paivio, 1986) is one of the oldest theories about differences of abstract and concrete concepts. It proposes that the fundamental difference between abstract and concrete concepts is that only the concrete ones they are associated with imagery (henceforth IM) information, whereas both abstract and concrete concepts can be processed in a language-like code. The availability of two codes for the representation and processing of concrete concepts results in their processing advantage in many tasks, such as comprehension, word recognition and recall.

Applying the dual-coding theory to the prediction of perceived abstractness is fairly straightforward. The model is essentially dichotomous in its division of abstract and concrete, but one could derive the prediction from it that more concrete entities have higher imageability. If the dual-coding theory can be applied to variation of abstractness within the group of abstract entities, then one should find that abstract entities rated as most abstract are the entities that elicit the least imagery.

Context Availability Theory

The context availability theory (henceforth CA; Schwanenflugel & Shoben, 1983) argues that it is easier to think of a context for concrete objects than for abstract ones. The issue here is not whether a context can come to mind at all, but how long it takes to retrieve or construct it based on information in memory. Typical studies instruct participants to rate CA based on the time it takes to think of a context. If it takes a long time, then the rating should be low. If they can think of a context immediately, they should give a high rating.

Research has shown that CA ratings can account for a lot of effects labeled as concreteness effects, often even better than concreteness ratings themselves. If abstract words are more difficult to process because of less available context, then the prediction for abstractness ratings is that a word will be rated the more abstract, the less context is available for it.

Evidence Related to Context Availability

Rated CA has been shown to correlate highly with rated abstractness. Thus, it may offer a theoretical basis for predicting abstractness. However, Altarriba et al. (1999) found that the correlation of CA with concreteness differed for abstract, concrete, and emotion terms. Interestingly, the correlation was highest for concrete words (r = 0.68), second for emotion terms (r = 0.41), and lowest for abstract terms (r = 0.25). All three correlations were significant, but it is clear that the concreteness ratings for abstract words were only weakly related to CA, in comparison with the other groups.

The results cannot be applied directly to this work, because the sample used by Altarriba et al. was not limited to nouns. Another goal of the present study was to compare the correlations of ratings separately for abstract versus concrete entities, to examine whether the findings of Altarriba et al. hold up for a sample of nouns exclusively.

Contextual Constraint Theory

Abstract entities are associated with contexts (Schwanenflugel, 1991; Wiemer-Hastings & Graesser, 1998). They "apply" to, or are manifested in, situations. This application is contingent on particular events and circumstances in the situation. For example, an idea is contingent on an agent with a mental event, which will be expressed verbally or in some kind of behavior, and can be evaluated. An idea is thought of in one moment, expressed in another, maybe rejected in a third. As such, many abstract entities have characteristics akin to verbs: they are related to observable events in a situation, which are defined temporally.

Depending on the situation aspects that an abstract entity is contingent on, it can occur in many or few kinds of context. Roughly, the more particular situation elements are necessarily involved in its manifestations, the more constrained its occurrence is. An entity that is contingent only on few, and rather abstract situation characteristics (such as the presence of some entity) can occur in all kinds of situations.

Do contextual constraints affect the abstractness of abstract entities? Conceivably, an entity that is not strongly constrained is more abstract than an entity that is contingent on a fairly extensive set of constraints. Additionally, entities that only occur when concrete situation aspects are present may be less abstract than entities that are contingent on abstract, unobservable, or complex temporal elements of situations, or of information that is only accessible to introspection (such as a mental process). To test this contextual constraint theory, the materials for the study were coded for contextual constraints.

Constraints Naturally, situations vary. For example, *ideas* occur in various settings, through different agents, related to different problems, and varying in quality. However, the underlying constraints, such as the presence of an agent, remain largely unvaried. To examine the influence of such constraints, a list of contextual constraints was derived from a simplistic situation model, as exhaustive as possible. The list consists of agents, objects, "issues", mental states, relations, and temporal information. The constraints were selected to be relevant to abstract concepts (see Table 1). These constraints are not intended to describe situations with all the richness of information they contain, but to identify abstract building blocks of situations, without regard to their specific contents.

Table 1: Contextual constraints on abstract entities

Concrete elements	**Introspective elements**
Agent	Goal
Agent 2	Knowledge / memory
Group (people)	Belief / attitude
Object	Feeling
Location	Mental event / thought
Utterance	**Relations**
Action	Agent-agent
Object attribute	Agent-other people
Nonverbal behavior	Agent-object
Situation elements	Agent-thematic subject
Issue / topic	Relation between two entities
Obstacle	Utterance-issue relation
Temporal aspects	
Relevance of past	
Relevance of future	
Changes between time slices (Event)	
Continuity of change between time slices (Process)	
Continuity of state between time slices (State)	
Time-adjacency of events (causality)	

Such constraints can play a powerful role in the processing of abstract concepts. Assuming that context information must be accessed to comprehend the concept (e.g., Schwanenflugel, 1991; Schwanenflugel & Shoben, 1983), constraints can be used to guide the

mental construction of a context example. As such, they functionally resemble schemata and scripts (Schank & Abelson, 1977). Constraints fall into several groups, including concrete situation elements, object attributes, agent characteristics, situation elements, relations, and information about temporal characteristics and sequences.

Study 1: Comparing Accounts for Abstractness

The experiment systematically compared to what extent different theories can predict abstractness ratings. Participants were asked to make ratings of the predictor variables for a set of 36 words.

Materials

Words were randomly sampled from about 2000 nouns collected from the MRC2 database (Coltheart, 1981). An exhaustive search was made for nouns for which frequency estimates (Kucera & Francis, 1967), familiarity, and abstractness ratings (Gilhooly & Logie, 1980; Paivio, Yuille, & Madigan, 1968; Toglia & Battig, 1978) were available.

The sample was divided into 6 sets of different levels of abstractness, based on the abstractness ratings from the MRC2 database. The range was divided into six equal-sized parts, regardless of the number of words falling into each section. Words were matched in familiarity across groups to control for familiarity effects (see Kacinik, Shears, & Chiarello, 2000). From each of the groups, six words were randomly selected to be included in the study. The words were the concrete words *bass, beehive, blossom, hairpin, insect, labyrinth, lace, mackerel, morass, nectar, owl, pest, prize, sedative, tree, venom, vine,* and *zone* and the abstract words *aspect, day, daybreak, desperation, emancipation, exception, formation, happiness, hope, inaction, ingratitude, jeopardy, mischief, pity, possession, removal, saga,* and *story*.

Instructions

Instructions varied to elicit different kinds of information associated with the words presented. Participants performed abstractness ratings, imageability ratings, and CA ratings of all 36 words. The words were presented in random order in each task. All the ratings were made on a 7-point scale.

The predictions of the dual-coding theory were tested by having participants rate the imageability of each entity. For CA, we used instructions used in previous research. We asked participants to rate how difficult it would be to mentally generate a context for the entity. For all tasks, participants were encouraged to make ratings according to their personal understanding of the words.

Results

Manipulation Check

The word sample was constructed based on the MRC2 abstractness ratings. We checked whether the perception of our participants agreed with these abstractness ratings. Abstractness ratings performed by the participants were highly correlated with the MRC2 abstractness ratings (r = 0.94, p < 0.001). This indicates that participants in our study in fact perceived entities selected as most abstract as most abstract, and the most concrete entities as most concrete.

Predicting Abstractness of Overall Sample

Multiple regression analyses for the three predictors found that CA (r = 0.66) and IM (r = 0.77) both predicted concreteness ratings for the entire sample (p < 0.01), and for the *concrete* sub-sample. Ratings for these two variables were also significantly different for abstract versus concrete words in t-tests (t (34) = 4.41, p < 0.01 for CA and t (34) = 6.33, p < 0.01 for IM.) The number of contextual constraints was not a significant predictor; however, the percentage of abstract constraints was a good predictor (r = 0.47, p < 0.05).

Some of the predictor variables, especially ratings for CA and IM, were highly correlated. Therefore, a stepwise regression with all predictors was performed to examine their relative contribution towards explaining the variance in abstractness ratings. Only 23 cases were valid for this analysis because for some entities, none of the contextual constraints applied.

Predictors in this analysis included (i) CA ratings, (ii) IM ratings, (iii) the number of contextual constraints (CC), and the percentage of abstract constraints (ACC). The two highest predictors, which both contributed significantly to the regression, were IM and ACC. Together, these variables explained more than half of the variance (R^2 = 0.56). The change in the amount of variance explained by IM was 0.36 (F (1, 21) = 11.99, p < 0.01); the change due to ACC was 0.2 (F (1, 20) = 8.89, p < 0.01). The other variables did not add any significant changes in the amount of variance explained.

Predicting Abstractness of Abstract Sample

The only substantial predictor for ratings on the abstract nouns was the percentage of abstract contextual constraints (marginally significant; r = -0.47, p = 0.52). This measure was computed as the percentage of constraints for an entity that are not directly observable, such as mental / introspective constraints and relations.

This suggests that constraints play an important role for abstract entities over and beyond CA and IM. However, the number of words in this study was very limited. A second study was conducted to examine whether this finding holds up for a large set of abstract entities. Further, the second study involved entities of relatively high abstractness only, with less variance than in Study 1. Abstractness ranged from 2.2 to 3.6 on a 7-point scale, with a mean of 2.88 (SD=0.35). The result is a critical test of whether contextual constraints are discriminating enough to predict variation at such a fine level.

Study 2: Constraints and Abstractness

A total of 121 abstract nouns were coded for the contextual constraints described above. The coding indicated whether each constraint was *by necessity* part of a context in which the entity could occur. For example, *determination* requires an agent (who is determined), an agent goal, a certain attitude, and a stretch of time during which the attitude and goal do not vary (a state). Coding reliability on a 25% subset of the words, measured as correlation and Cohen's kappa, was significant (p<0.01) for three independent coders.

Based on the codes, we computed the number of constraints and the percentage of abstract constraints for each noun. Additionally, the codes were summarized across types of constraints to test whether particular kinds of constraints would yield particularly strong or weak predictions. The constraint groups were (1) concrete entities, (2) temporal constraints, (3) relational constraints, and (4) introspection-related constraints.

Results

All measures were submitted to a correlation with abstractness ratings from the MRC2 database. The astonishing result was that only the group of introspection-based constraints was significantly correlated (r=-0.21, p<0.05). This group includes mental constraints (goals, feelings, attitudes and beliefs, knowledge, and thoughts) and relational constraints between agents and other agents, objects, or issues. The percentage of abstract constraints yielded the second highest correlation (r=-0.14), but it was not significant. The finding for introspective constraints is interesting because it supports the recent proposal by Barsalou (1999) that introspection plays a central role in the processing of abstract concepts.

Overall, the result is consistent with the finding in study 1 that constraints play a role in our perception of abstractness. Importantly, the second study shows that constraints -- at least some of them – are good predictors even when fine discrimination is required.

Discussion

The results show that IM and CA are limited in explaining abstractness variations. Whereas ratings for both can account for the differences between abstract and concrete in general, they do not explain the variance in abstractness for different abstract concepts. This replicated the finding by Altarriba et al. (1999). The number of contextual constraints did not significantly predict abstractness ratings, but the abstractness of the constraints was a relatively strong predictor.

The findings are consistent with the two-factor model of abstractness, according to which abstractness and concreteness are determined by two different kinds of information. For concrete entities, both CA and IM were good predictors of the variation of ratings. For abstract concepts, the most critical type of information was the type of contextual constraint involved.

Research focusing on abstract concepts, rather than mere differences between concrete and abstract concepts, should presumably not be conducted on the basis of the assumptions made by CA and IM alone, since apparently these theories account mostly for the differences of the dichotomous classes of abstract and concrete entities. Research aiming to reveal characteristics of abstract entities should additionally take into account information that is specifically relevant to them, such as a system of context constraints that may guide our identification of these entities in context. The present results suggest that introspective processes and information, and to some extent abstract constraints in general, may be a good candidate for this abstract concept-specific information.

A system of constraints such as the one presented in Table 1 may further be useful in investigations of context effects, as they have been reported in previous research on abstract concepts. For example, some studies on CA effects produced the inconsistent result that abstract concepts were not processed faster when presented in context. A principled way to predict *what* context information is relevant to an abstract entity may account for such findings: Perhaps, the abstract words were presented in contexts that did not instantiate the relevant constraints.

Concrete versus Abstract

Maybe one of the most interesting implications of the findings is that constraints put the relevant information *outside of* the rated entity. That is, it is not an aspect of the entity itself that makes it abstract, but it is the abstractness of the constraints on situations in which it is used. This point offers a nice bridge to the CA theory, which argues that abstract concepts are abstract

because less context for their processing is available in memory.

The constraints may offer an explanation for this phenomenon. The more abstract the constraints are, the less guidance we have in constructing a mental context (or a simulation, see Barsalou, 1999). The constraints are there but they leave open most aspects of the concrete context. For example, the concept *comparison* requires (among other abstract constraints) the presence of two entities to be compared. The constraint does not dictate these entities to be of any particular nature, thus, they could be people, essays, houses, laws, feelings, etc.

In the case of a less abstract entity, such as *arrival*, the constraints involved are of a more concrete nature, and thus more effectively constrain the number of contexts we could construct to process the concept. An arrival involves an agent, an action (movement), and a particular location that the agent moves towards. These constraints can readily be used to simulate a fairly concrete situation in which an arrival takes place.

Features and Constraints

An interesting thought to pursue in future research is that features may fulfill the same function for concrete entities as abstract contextual constraints do for abstract entities. Thus, it is possible that the number of features / concreteness of features decrease from the concrete to the abstract pole, whereas the abstractness of the contextual constraints decreases from the abstract to the concrete end.

Familiarity Effects

This study controlled for familiarity effects through strategic sampling. Future research could examine an interesting question in connection to CA: It is likely that highly familiar concepts are represented with default contexts, which can easily be accessed, whereas contexts for other concepts have to be constructed.

Acknowledgments

Many thanks to Xu Xu, Jan Krug, and Priscilla Fernandez for assistance with material construction, data collection, and constraint coding, and to Larry Barsalou for productive discussions of some of the ideas reported here.

Abstract

Latent Semantic Analysis (LSA) has been shown to perform many linguistic tasks as well as humans do, and has been put forward as a model of human linguistic competence. But LSA pays no attention to word order, much less sentence structure. Researchers in Natural Language Processing have made significant progress in quickly and accurately deriving the syntactic structure of texts. But there is little agreement on how best to represent meaning, and the representations are brittle and difficult to build. This paper evaluates a model of language understanding that combines information from rule-based syntactic processing with a vector-based semantic representation which is learned from a corpus. The model is evaluated as a cognitive model, and as a potential technique for natural language understanding.

Motivations

Latent Semantic Analysis (LSA) was originally developed for the task of information retrieval, selecting a text which matches a query from a large database (Deerwester, Dumais, Furnas, Landauer, & Harshman, 1990)[1]. More recently, LSA has been evaluated by psychologists as a model for human lexical acquisition (Landauer & Dumais, 1997). It has been applied to other textual tasks and found to generally perform at levels matching human performance. All this despite the fact that LSA pays no attention to word order, let alone syntax. This led Landauer to claim that syntax apparently has no contribution to the meaning of a sentence, and may only serve as a working memory crutch for sentence processing, or in a stylistic role (Landauer, Laham, Rehder, & Schreiner, 1997).

The tasks that LSA has been shown to perform well on can be separated into two groups: those that deal with single words and those that deal with longer texts. For example, on the synonym selection part of the TOEFL (Test of English as a Foreign Language), LSA was as accurate at choosing the correct synonym (out of 4 choices) as were successful foreign applicants to US universities (Landauer et al., 1997). For longer texts, Rehder et al (1998) showed that for evaluating author knowledge, LSA does steadily worse for texts shorter than 200 words. More specifically, for 200-word essay segments, LSA accounted for 60% of the variance in human scores. For 60-word essay segments, LSA scores accounted for only 10% of the variance.

In work on judging the quality of single-sentence student answers in an intelligent tutoring context, we have shown in previous work that although LSA nears the performance of intermediate-knowledge human raters, it lags far behind expert performance (Wiemer-Hastings, Wiemer-Hastings, & Graesser, 1999b). Furthermore, when we compared LSA to a keyword-based approach, LSA performed only marginally better (Wiemer-Hastings, Wiemer-Hastings, & Graesser, 1999a). This accords with unpublished results on short answer sentences from Walter Kintsch, personal communication, January 1999.

In the field of Natural Language Processing, the eras of excessive optimism and ensuing disappointment have been followed by study increases in the systems' ability to process the syntactic structure of texts with rule-based mechanisms. The biggest recent developments have been due to the augmentation of the rules with corpus-derived probabilities for when they should be applied (Charniak, 1997; Collins, 1996, 1998, for example).

Unfortunately, progress in the area of computing the semantic content of texts has not been so successful. Two basic variants of semantic theories have been developed. One is based on some form of logic. The other is represented by connections within semantic networks. In fact, the latter can be simply converted into a logic-based representation.

Such theories are brittle in two ways. First, they require every concept and every connection between concepts to be defined by a human knowledge engineer. Multi-purpose representations are not feasible because of the many technical senses of words in every different domain. Second, such representations can not naturally make the graded judgements that humans do. Humans can compare any two things (even apples and oranges!), but aside from counting feature overlap, logic-based representations have difficulty with relationships other than subsumption and "has-as-part".

Due to these various motivations, we are pursuing a two-pronged research project. First, we want to evaluate the combination of a syntactic processing mechanism with an LSA-based semantic representation as a cognitive model of human sentence similarity judgements. Second, we are

[1] We do not describe the functioning of the LSA mechanism here. For a complete description, see (Deerwester et al., 1990; Landauer & Dumais, 1997)

implementing a computational system to automate the processing of texts with this technique. This paper describes the human data we collected for the cognitive modeling aspect, the evaluation of our approach with respect to that data, and our initial attempts to implement the computational system.

Data collection

In (Wiemer-Hastings, 2000), we reported our initial attempts in this direction. In that evaluation, we compared our technique (described more fully below) to human ratings that were previously collected as part of the AutoTutor project (Wiemer-Hastings, Graesser, Harter, & the Tutoring Research Group, 1998). To our surprise, we found that adding syntactic information actually hurt the performance of an LSA-based approach. This could have been due to some problem with the approach, or due to some difficulty with the human data. The previous ratings had been based on complete multi-sentence student answers and ideal good answers. The raters were asked to indicate what percentage of the content of the student answer matched some part of the ideal answer. In the current work, we are looking at similarity ratings for specific sentences. Thus the previous data was not appropriate for our current goals.

To get more relevant human data, we started with text from the AutoTutor Computer Literacy tutoring domain so that we could more directly compare the results with our previous results, and because we had already trained an LSA space for it. AutoTutor "understands" student answers by comparing them to a set of target good answers with LSA. For this evaluation, we randomly paired 300 student answer sentences with 300 target good answers from the relevant questions. We split these into four booklets of 75 pairs, and gave each booklet to four human raters. Because we are also interested in the effect of knowledge on the reliability of ratings, we had previously asked the raters if they were proficient or not with computers. We gave each booklet to two proficient and two non-proficient raters.

We told the raters that the sentence pairs were from the domain of computer literacy, and asked them to indicate how similar the items were on a 6-point scale, from completely dissimilar to completely similar. Here is an example item:

> Sentence 1: ROM only reads information from the disk.
> Sentence 2: The central processing unit, CPU, can read from RAM.

We did not specify how the raters were to decide what similarity means.

The averaged correlations between the human raters were:

> Non-Proficient: $r = 0.35$, $P < 0.001$
> Skilled: $r = 0.45$, $P < 0.001$
> Mean Non-Proficient with Mean Proficient: $r = 0.53$, $P < 0.001$

Although these numbers are relatively low for inter-rater reliability on similarity tasks in general (Tversky, 1977; Goldstone, Medin, & Halberstadt, 1997; Resnik & Diab, 2000, for example), we have found this level of agreement in our other studies of sentence similarity. This task is obviously a difficult one for humans. In future work, we will study the effects of varying the level of context that is available for making these decisions.

Experiment 1: Part-of-speech tags

One way of deriving structural knowledge from text is by performing part of speech tagging. This is one area in which NLP systems have been fairly successful. Brill's tagger (Brill, 1994) is trained on a marked corpus and uses rules to assign a unique tag to each word. It first assigns the most common tag for each word, then applies a set of automatically-derived context-based rules to modify the original tagging.

When LSA is trained, it does not distinguish between words which are used in multiple parts of speech. This may have significant semantic ramifications. The word "plane", for example, has very different senses as a verb and as a noun. One way to add structural information to LSA would be to allow it to distinguish the part of speech for each word when training and comparing sentences.

Approach

Our approach to this task was to use the Brill tagger to assign a part-of-speech tag to every word in the training corpus and every word in the test set (which had been given to the human raters). The tag for each word was attached to it with an underscore so that LSA would view each word/tag combination as a single term. For example:

```
ROM_NNP is_VBZ information_NN the_DT
computer_NN was_VBD programmed_VBN with_IN
when_WRB it_PRP was_VBD built_VBN ._.
```

The original training corpus was 2.3 MB of text taken from textbooks and articles on computer literacy. We trained LSA on the tagged corpus at 100, 200, 300, and 400 dimensions because these dimensions had shown reasonable levels of performance in previous evaluations. Then we evaluated this approach by using the new LSA space to calculate the cosines between the tagged versions of the test sentences that had been given to the human raters. We calculated the correlations between the cosines and the human ratings.

Results

Figure 1 shows the correlations between the different LSA models and the human ratings. The first bar depicts the correlation using the standard LSA space (at 200 dimensions) as applied to the untagged versions of the sentences.

Discussion

It is clear that the performance of the tagged models do not match human judgements as closely as the standard

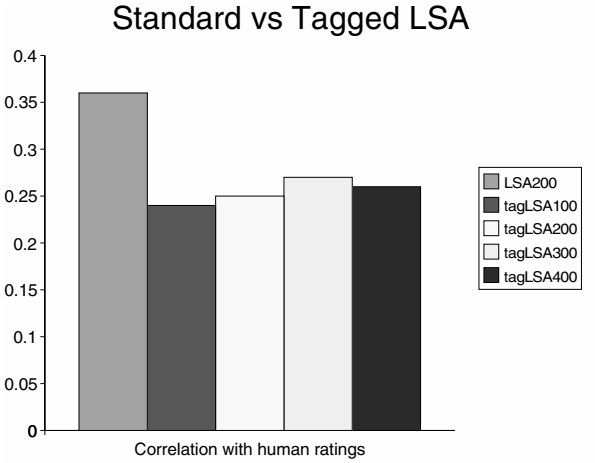

Figure 1: The performance of tagged LSA

LSA approach does. It is not clear why this is. This could support Landauer's claim with respect to the irrelevance of structural information for determining meaning. Perhaps LSA somehow does manage to account for different senses and uses of a word even though it does not have explicit knowledge of the syntactic context of the word's use.

Alternatively, the relatively poor performance could be due to some inadequacies of this particular approach. For example, although the number of dimensions was in the correct relative range with respect to non-tagged LSA processing, perhaps tagged LSA works better with more (or fewer?) dimensions. It could also be that the performance was hampered by mistagging of key words in the sentence. Because the Brill tagger is trained on the Wall Street Journal corpus, its tagging rules often lead it astray when processing the colloquial and domain-specific student answers in our tutoring domain. For example, one student answered a question about a computer's memory like this, "RAM stores things being worked with." The Brill tagger mistagged the word "stores" as a plural noun, thus greatly altering the overall meaning of the sentence.

Experiment 2: Surface parsing

Another obvious potential contribution of sentence structure to meaning is by providing information about the relationships and actions of the participants: the "who did what to whom" information. Although some might claim that LSA is able to derive this information from its training corpus (because men rarely bite dogs, for example), this can not always be the case. And with the exception of case-marked pronouns like "I" and constructions like "there is . . . ", it is difficult to think of any entity references that can not appear as both subject and object of a sentence. Thus, if we can separately determine the subject, object, and verb parts of a sentence, we should be able to provide information that, in addition to that which we get from LSA, will improve sentence similarity judgements.

The approach: Structured LSA

In standard LSA, the input to the procedure is an entire text, represented as a string. The string is then tokenized into words, and the vector for each word is accessed from the trained vector space. LSA ignores words that it can not find, i.e. those that did not appear in more than one document in the training corpus, or those that appear on the stop-word list, a list of 440 very common words, including most function words. The vector for a text is constructed by simply adding together the relevant word vectors. Two texts are compared by calculating the cosine between their vectors.

In our approach which we call Structured LSA (SLSA), we preprocess input sentences to derive aspects of their structure. More specifically, for each sentence, we:

- resolve pronominal anaphora, replacing pronouns with their antecedents,
- break down complex sentences into simple sentences,
- segment the simple sentences into subject, verb, and object substrings.[2]

.

For example, we transform the student answer: "RAM stores things being worked with, and it is volatile" into:

("stores" "RAM" "things being worked with")
("volatile" "RAM")

This yields a verb string, subject string, and (optional) object string for each sentence. Note that for copular sentences as in the second simple sentence above, the "verb string" is the description following the verb. Also note that our human data was collected not on the original sentences, but on sentences on which the first two steps above were already completed.

SLSA similarity rating

To calculate a similarity score between two sentences with the SLSA approach, the preprocessing is performed on the sentences. Then we separately pass the verb strings, subject strings, and object strings to LSA which computes the cosines between them. Then we average the three together to get an overall similarity rating between the sentences.[3]

Note that this approach provides more information than the standard LSA approach. For each pair of sentences, there are four separate similarity ratings instead of just one.

[2]Passive sentences were normalized, putting the syntactic object as the subject, and vice versa.

[3]In (Wiemer-Hastings, 2000), we evaluated three different methods for aggregating the segment cosines, including a subject-predicate approach and given-new approach. In the current evaluation, the simple average provided the best performance, so we do not present the others here.

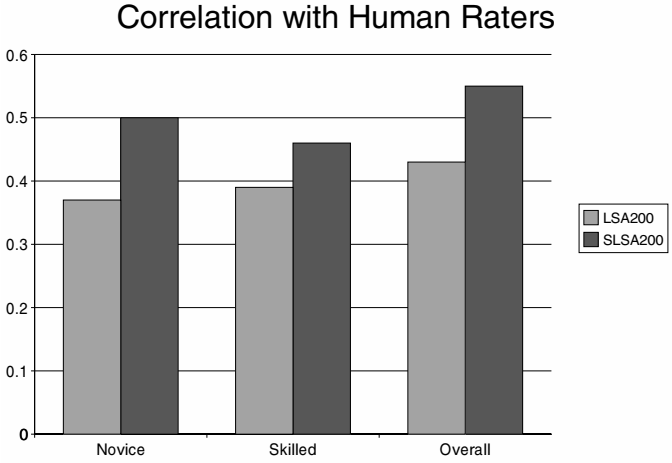

Figure 2: The correlation between SLSA scores and human ratings

In addition to the overall similarity score, SLSA produces separate measures of the similarity of the segments of the sentences. This additional information could be very useful for dialog processing systems.

Results

Because we were interested in evaluating this approach in principle, and not with respect to any particular implementation of the preprocessing technique, we preprocessed the entire test set by hand as described above. Then, the SLSA similarity scores were calculated and correlated with the human ratings. Figure 2 compares the LSA and SLSA approaches with respect to the correlations to human ratings for the non-proficient, proficient, and averaged ratings.

SLSA performed better with respect to each subset of human ratings than did the standard LSA approach. The correlation with the mean of all four human raters was slightly better than the highest level of agreement among the human raters.

Discussion

These results are not consistent with Landauer's claim that syntax does not convey additional semantic content beyond the meanings of individual words. Human sentence similarity judgements are better modelled by an approach that takes structural information into acccount. Although the standard LSA approach does perform as well as humans on longer texts, this may be because the information about who does what to whom in individual sentences is lost in the noise, or is constrained by the larger context.

Toward a hybrid natural language understander

Now that we have validated the benefits of this approach, we have begun to develop a system that will use shallow parsing techniques to automatically perform the preprocessing of input sentences for SLSA. This section describes different approaches that we are evaluating.

Surface parsing

Shallow parsing is currently an area of intense interest in the corpus-based natural language processing community. In fact, the 2001 Computational Natural Language Learning workshop at the Association for Computational Linguistics conference will include a shared task which is to evaluate different techniques for clause splitting. Clause splitting is defined as separating a sentence into subject and predicate parts.

We are currently evaluating the feasibility of using several publicly available surface parsing tools: LTChunk, the SCOL parser, and the Memory-Based Shallow Parser (MBSP). LTChunk was developed by the Language Technology Group at the University of Edinburgh (described at `http://www.ltg.ed.ac.uk/software/chunk/`). It identifies noun phrases and verb groups (combinations of adverbs, auxiliaries, and verbs) in text. The SCOL parser was developed by Abney (1996), and parses text using a set of cascaded rules which delay "difficult" decisions like where to attach prepositional phrases. MBSP (Daelemans, Buchholz, & Veenstra, 1999) is part of the Tilburg Memory Based Learner project (Daelemans, Zavrel, van der Sloot, & van den Bosch, 2000). It is also trained on Penn Treebank Wall Street Journal corpus, performs part-of-speech tagging, and segments texts into subject, verbs, and objects.

Current work

Each of these different methods has drawbacks. The corpus trained approaches have the same difficulty as that noted above: the student answer texts differ sufficiently from the Wall Street Journal to lead to many mistaggings, and therefore, misparses.

Our current efforts are focussing on using the Brill Tagger (adjusting its tags to be more appropriate for our domain), and then the SCOL parser to identify sentence segments. We are developing a postprocessor to transform the output of the parser into the subject, verb, object segmentation that we need as input to SLSA. The postprocessor handles active, passive, and imperative constructions. We are also working on a simple coreference resolution mechanism to allow substitution of antecedents. Our set of hand-processed sentences gives us a useful gold standard against which to evaluate our approach.

The process of matching the segments of the two sentences can be viewed as structure mapping of the type that Gentner et al developed for processing analogies (Gentner, 1983; Forbus, Ferguson, & Gentner, 1994, for example). Ramscar and colleagues have developed a two-stage model for processing analogy which first performs structure-mapping between two scenarios, and then uses LSA to determine the similarity of the slot fillers between the two structures (Yarlett & Ramscar, 2000). For SLSA, the proper treatment of syntactic structures like passives is

quite important. Even more difficult are alternations like "give" and "take" which can have the same syntactic structure, but completely different semantic role structures. Resolving such cases seems to require semantic information, resulting in a chicken-and-egg situation. How can we use SLSA to interpret the meaning of a sentence if we must know the meaning in order to use SLSA? Our current research involves treating the verbal and nominal parts of the input sentences differently.

Conclusions

Our findings do not support the claim that syntax provides a negligible contribution to sentence meaning. Instead, a sentence comparison metric that combines structure-derived information with vector-based semantics models human similarity judgements better than LSA alone. As previously mentioned, this approach provides a number of advantages. Its overall fit to human data is not only better than standard LSA, but it provides additional information about the similarity of the different parts of sentences. This could be used in a dialogue-based tutoring system to focus the student's attention on some particular aspect of the target good answer.

With respect to traditional parsing techniques, SLSA has three obvious advantages. First, it is fast, because it does not deal with the combinatorial explosions from ambiguity that most parsers face. Second, it does not require a hand-built semantic concept representation which is tedious to build and brittle. Third, LSA is (in a sense) grounded. Although it does not have direct experience of the world, LSA does have indirect experience via its training corpus. The corpus provides a rich set of interconnections between terms which allows LSA to successfully model many aspects of human linguistic competence.

The limitation of SLSA as a natural language understanding mechanism is that it is only appropriate for tasks where understanding can be cast as computing the similarity of an item to an expected utterance. For tutoring, the approach is feasible because the tutor (whether computer or human) normally determines the topic of conversation, and has some idea of what the student should say. For other tasks where the input utterance is less constrained, this approach might not be the best. On the other hand, if a natural language generation system could be used to generate a set of expected utterances in a particular domain, expectation-based understanding might be feasible and effective.

Although we have presented the syntactic analysis of this work as being derived from symbolic, rule-based mechanisms, our analyses of SLSA as a cognitive model do not depend on this. They would be equally applicable with a connectionist surface parsing technique.

These findings raise quite a few interesting questions for future research. For example:

- What exactly are humans measuring when they rate sentence similarity? Perhaps varying the instructions for human raters will get them to focus on different aspects of meaning.
- What is the best level of granularity to use in segmenting sentences? We have evaluated the use of subject, verb, and object segments, but a coarser or finer segmentation may perform better.
- How much semantic information can be derived from a sentence without knowing its meaning? Inducing additional relationships between the parts of a sentence might improve the SLSA approach, but may require already knowing what the sentence is about.

Addressing these questions will be the focus of our future research.

Did Language Give Us Numbers?
Symbolic Thinking and the Emergence of Systematic Numerical Cognition

Heike Wiese (heike.wiese@rz.hu-berlin.de)
Humboldt-University Berlin, Department of German Language and Linguistics, Unter den Linden 6
10099 Berlin, Germany

Abstract

What role does language play in the development of numerical cognition? In the present paper I argue that the evolution of symbolic thinking (as a basis for language) laid the grounds for the emergence of a systematic concept of number. This concept is grounded in the notion of an infinite sequence and encompasses number assignments that can focus on cardinal aspects ('three pencils'), ordinal aspects ('the third runner'), and even nominal aspects ('bus #3'). I show that these number assignments are based on a specific association of relational structures, and that it is the human language faculty that provides a cognitive paradigm for such an association, suggesting that language played a pivotal role in the evolution of systematic numerical cognition.

Introduction

Over the last decades, results from several disciplines relating to cognitive science (in particular from psycholinguistics, developmental psychology, cognitive ethology, and cognitive neuroscience) have shed new light on the relationship between language and numerical cognition.

On the one hand, the acquisition of some aspects of mathematical knowledge seems to be linked to the number words of a language. Psychological and neurological studies suggest that the representation of memorised mathematical knowledge such as multiplication tables and its application in mental calculation is closely linked to the language it was originally learned in (cf. Dehaene, 1997).

In addition, cross-linguistic studies on the acquisition of number words have shown that the structure of a number word sequence can have an impact on children's mathematical performance:[1] a highly regular and transparent number word sequence makes it easier for children to grasp multiplicative and additive relationships between numbers and to correlate them with Arabic numerals, than a sequence that contains opaque elements.

For instance in the Chinese number word sequence, as opposed to the one in English, the underlying decimal structure is always transparent in complex number words (for instance, the Chinese counterparts for English 'ten – eleven – twelve – thirteen – fourteen – ... – twenty' have the form 'ten – ten-one – ten-two – ten-three – ten-four – ... – two-ten'). In accordance with this linguistic difference, Chinese children were shown to have a better grasp of the base ten structure of their number system and performed initially better in arithmetic tasks than their American counterparts.

On the other hand, converging evidence from developmental psychology and cognitive ethology has revealed numerical capacities that seem to be independent of language. Preverbal infants as well as higher animals were shown to be able to grasp small numerosities (the cardinality of small sets) and perform simple arithmetic operations on them.[2] Evidence from lesion and brain-imaging studies indicates that a specific brain region, the inferior parietal cortex, might be associated with this ability.[3]

This suggests that, while some later aspects of mathematical cognition might be influenced by linguistic factors, we also possess a biologically determined concept of cardinality: a concept of numerical quantities and their inter-relations that is independent of the acquisition of a specific language, and independent of the human language faculty in general.

Does this mean that our concept of *number* is independent of language? In this paper, I will argue that it is not. I will argue that language contributed to numerical cognition in a fundamental way: in the history of our species the emergence of language as a mental faculty opened the way for systematic numerical cognition. Symbolic thinking as the basis of language provided a cognitive pattern that enabled humans to make the step from primitive quantitative reasoning to a generalised concept of number, a concept that is not restricted to cardinality, but allows us to employ numbers to identify cardinal as well as ordinal and even nominal relationships between empirical objects.

To develop this claim, I will first spell out the relationship between numbers and cardinality and show that it is crucial for our understanding of the cognitive

[1] Cf., for instance, Miura et al. (1993) and Ho & Fuson (1998) for Asian (Chinese, Korean and Japanese) versus US-American (English-speaking) and European (British, French and Swedish) first-graders and kindergarteners.

[2] Cf. Wynn (1998) for a detailed discussion of the evidence from infants and new-borns; Butterworth (1999) and Dehaene (1997) for overviews of numerosity concepts in human infants and animals.

[3] Cf. Dehaene, Dehaene-Lambertz & Cohen (1998).

number domain not to focus on cardinality alone. I will then introduce a unified notion of number assignments that brings together cardinal, ordinal and nominal aspects. On this basis, I analyse structural parallels between number assignments and symbolic reference that suggest that language provides a cognitive pattern for systematic number assignments.

Numbers and Cardinality

One of the aspects that make numbers so interesting is their enormous flexibility. A quality like colour, for instance, can only be conceived for visual objects, so that we have the notion of a red flower, but not the notion of a red thought. In contrast to that, there seem to be no restrictions on the objects numbers can apply to. In his 'Essay Concerning Human Understanding', John Locke put it this way: "[...] number applies itself to men, angels, actions, thoughts; everything that either doth exist, or can be imagined." (Locke 1690, Book II, Ch.XVI, §1).

This refers to contexts where numbers identify the cardinality of a set: they tell us how many men or actions etc. there are in the set. This number assignment works for any sets of objects, imagined or existent, no matter what qualities they might have otherwise; the only criterion is here that the objects must be distinct in order to be quantified.[4]

Frege (1884) regarded this flexibility as an indication for the intimate relationship between numbers and thought: "The truths of arithmetic govern all that is numerable. This is the widest domain of all; for to it belongs not only the existent, not only the intuitable, but everything thinkable. Should not the laws of number, then, be connected very intimately with the laws of thought?" (Frege 1884, §14).

However, this is only one respect in which numbers are flexible. Not only can we assign them to objects of all kinds, we can also assign them to objects in ways that are so diverse that on first sight, they seem not to be related at all. Of these number assignments, the one that relates to the cardinality of sets is probably the first that comes to mind, but it is by no means the only way we can assign numbers to objects.

The same number, say 3, can be used to give the cardinality of pencils on my desk ('three pencils'); to indicate, together with a measure unit, the amount of wine needed for a dinner with friends ('three litres of wine'); it can tell us the rank of a runner in a Marathon race ('the third runner'); or identify the bus that goes to the opera ('bus #3' / 'the #3 bus').[5]

[4] This criterion on objects can be reflected in language by the distinction of count nouns versus mass nouns, as their designations (cf. also Wiese & Piñango, this volume).

[5] As the examples in brackets illustrate, these different usages of numbers establish different contexts for number words that have to be mastered in first language acquisition. Cf. Fuson & Hall (1983) for a study of the acquisition process.

We can subsume our different usages of numbers under three kinds of number assignments: cardinal, ordinal, and nominal assignments (cf. Wiese, 1997).

Cardinal number assignments are denoted by expressions like 'three pencils' or 'three litres of wine', where 'three' is an answer to 'How many?'. In cardinal assignments, the number identifies the cardinality of a set, e.g. a set of pencils or a set of measure units that identify a certain volume (in our example, litres).

In *ordinal number assignments*, the number applies to an element of a sequence. For instance in the Marathon example, 3 indicates the rank of a particular person within the sequence of runners (the third runner).

We encounter *nominal number assignments* in the form of house numbers, in subway and bus systems, in the numbering of football players, or in telephone numbers. What these cases have in common is the fact that the numbers identify objects within a set: in nominal assignments, numbers are used as readily available (and inexhaustable) proper names. So rather than thinking of names like 'Mike' or 'Lucy' for buses, we assign them numbers when we want to identify them (for instance, 'bus #3'), and similarly, we assign numbers to houses in a street or to the members of a football team.

Hence, numbers are flexible tools that can be used in a wide variety of contexts, where they identify different properties of objects. Of these properties, cardinality is only one instance – it is *a* property that we can identify with numbers, but it is not necessarily more closely connected to numbers than other properties that can also be identified in number assignments (that is, the rank of an object in a sequence, or the identity of an object within a set). Figure 1 illustrates this view:

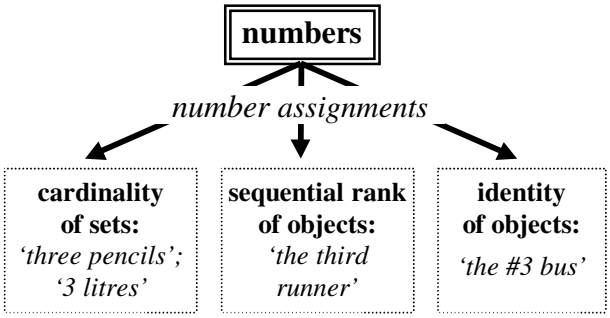

Figure 1: Numbers as flexible tools –
Integration of cardinality into the number domain

This approach, then, integrates cardinality into a broader view of the number domain. It distinguishes numbers and cardinality by characterising numbers as elementary tools that are not necessarily linked up with cardinality, but can equally bear on cardinal aspects, ordinal aspects, or nominal aspects in application, when employed in the different kinds of number assignments.

A Unified Approach to Number Assignments

What is it that makes numbers so flexible, how are their different usages related to each other? To answer this question, let us have a closer look at the different ways numbers apply to objects, that is cardinal, ordinal and nominal number assignments.

A theory that gives us a handle on these different types of number assignments is the Representational Theory of Measurement (henceforth, RTM).[6] This theory, which has been highly influential within philosophy and experimental psychology, is concerned with the features that make a number assignment[7] significant; it aims to establish the criteria that make sure that the number we assign to an object does in fact tell us something about the property we want to identify.

In the present section I will employ the machinery of this theory to a somewhat different purpose, interpreting the RTM as a unified framework for number assignments. This framework allows us to lay down the constitutive features of meaningful number assignments, the features that underly a systematic concept of numbers and of the relations which they identify between empirical objects.

In a preliminary approach, we can identify an assignment of numbers to objects as meaningful when certain relations between the numbers represent relations between the objects. Figure 2 gives an example:

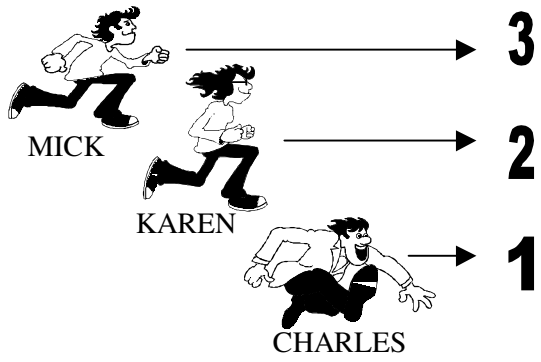

Figure 2: A meaningful number assignment: Numerical ranking of runners in a race

In this instance of number assignments, numbers have been assigned to participants in a race, such that the '<' relation between the numbers represents the ordering of the runners by the relation 'is faster than': Charles, as the fastest runner, received the smallest number, 1; Mick, who is slowest, received the largest number, 3, and Karen, who is faster than Mick and slower than Charles, got a number that is smaller than Mick's and larger than Charles's, namely 2. This way the ordering of the runners as 'Charles is faster than Karen who is faster than Mick' is reflected by the ordering of the numbers that they received: '1 < 2 < 3'.

The general features that make a number assignment meaningful can be captured by two requirements. The first requirement is that we regard the objects and the numbers only insofar as they form *relational structures*, that is, sets of elements that stand in specific relationships to each other. The two relational structures are distinguished as *numerical relational structure* (the relational structure constituted by the numbers) and *empirical relational structure* (the one established by the objects).

Accordingly, in the runner example we regarded the runners not as unrelated individuals, but treated them as elements of a particular sequence. The empirical relational structure is here constituted by the relation 'is faster than'. The relation between the numbers that we focused on was '<' ('lesser than'). All other relations that might hold between the objects (for example, the relative age of the runners) or between the numbers (for example, odd numbers versus even numbers), are ignored for the purposes of number assignment.

The second requirement for the number assignment is that the correlation between numbers and objects constitutes a *homomorphic* mapping, one that not only correlates the elements of the two relational structures, but also preserves the relevant relations between them.

In our example, the homomorphism associates the relation 'runs faster than' from the empirical relational structure (the sequence of runners) with the '<' relation in our numerical relational structure (the numbers). So for instance from the fact that one runner received the number 2 and another one got the number 3, one can deduce that the first runner was faster than the second one, because 2 < 3.

The interesting aspect for our discussion is now that this implies that number assignments are essentially links between relations: it is not so much the correlation between individual objects and individual numbers that counts, but the association of relations that hold between the empirical objects with relations that hold between the numbers.

As a result, ew can now analyse the different kinds of number assignments as instances of a unified pattern: they are constituted by a homomorphic mapping between two relational structures; a mapping that associates, in each case, a particular numerical relation with a relation between empirical objects:[8]

---

[6] Cf. Krantz et al. (1971), Narens (1985), Roberts (1979).

[7] The RTM uses the term 'measurement' (instead of 'number assignments') here. This terminology is slightly at odds with our pre-theoretical usage, where 'measurement' refers only to a particular class of cardinal number assignments (those identifying empirical properties like weight, volume or temperature), but excludes ordinal and nominal number assignments, which are included under the RTM notion of 'measurement'. In the present paper, I therefore use the more intuitive term '(meaningful) number assignments'.

[8] For a detailed discussion and formalisation of the different kinds of number assignments cf. Wiese (2001).

In *cardinal number assignments*, the empirical objects are sets. A number *n* identifies the cardinality of a set *s* (*n* tells us how many elements *s* has). The mapping associates the numerical relation '>' with the empirical relation 'has more elements than'. The number assignment is meaningful if and only if a one-to-one-correlation between the numbers from 1 to *n* and the elements of *s* is possible. For instance, when we assign the number 3 to a set of pencils, this number assignment can be regarded as a meaningful cardinal number assignment when it is possible to link up each pencil with a different number from 1 to 3. (We employ this verification procedure in counting routines.)

In *ordinal number assignments* (like the one in Figure 2), the empirical objects are not sets, but individual elements of a sequence. A number *n* identifies the rank of an object within a sequence *s*. For this task, we focus on the sequential order of numbers. The homomorphism that constitutes our number assignment associates the numerical relation '<' (or '>', respectively) with the relative ranks of the objects within *s* (for instance, the relative ranks of runners as established by the relation 'is faster than' in Figure 2). The number assignment is meaningful if and only if objects receive higher and lower numbers with respect to their higher and lower positions within *s*.

In *nominal number assignments*, the empirical objects are elements of a set (for example the bus lines in a city), and the numbers are used as labels: a number *n* identifies an object within a set *s*. The mapping associates the numerical relation '=' (or '≠') with the empirical relation 'is (non-)identical with'. The numerical statement is meaningful if and only if distinct objects always receive distinct numbers.

What these different number assignments have in common is the translation of relational structures. In cardinal, ordinal, and nominal number assignments alike, a relation between empirical objects is associated with a relation that holds between the numbers. It is this translation of relational structures that constitutes number assignments, and by doing so, lays the ground for systematic numerical cognition.

How did this principle evolve? In the following section I argue that the translation of relational structures as a cognitive pattern might have its origins in the emergence of symbolic thinking. I will argue that it is symbolic thinking, as a basis for the human language faculty, that made this pattern available to the human mind, and this way enabled us to develop a systematic number concept.

The Contribution of Language to the Emergence of a Systematic Number Concept

According to an account of language evolution as developed in Deacon (1997), the main step in the emergence of human language (as opposed to animal communication systems) is the development of a symbolic system; in a process of co-evolution of language and the brain, the adaptation of our brain to symbolic thinking gave rise to the emergence of the linguistic faculty we have today. To understand the significance of this view for our investigation into numbers and language, it is crucial to understand what Deacon means by *symbolic reference* here.

Following a semiotic taxonomy as introduced by Charles Peirce, Deacon distinguishes three kinds of signs: icons, indices and symbols. In *iconic* reference the sign shares some features with its referent, it is similar to the object it refers to (such as the icon ♿ that refers to a wheel-chair user). In *indexical* reference the sign is related to the object by a physical or temporal relation; it occurs together with its referent (for instance, tears could be interpreted as an index for grief).

In *symbolic* reference, the link between sign and object is established by convention, as in the case of human languages. The critical similarity, the similarity between symbols and their referents, emerges on a higher level, namely on that of the system. Symbols are always part of a system, and they refer to objects not as individual tokens, but with respect to their position in that system. In the case of symbols, reference shifts from individual signs and individual objects to relations between signs and relations between objects; it shifts from the token to the system.

Under this account, symbolic reference as the basis of human languages is crucially a link between relations (sign-sign and object-object), not between individuals (signs and objects). It is the relations between words that reference is based on.

These can be linear relations like the order of words in a sentence, or hierarchical relations like 'object of' or 'subject of', which mark the relations between a verb and its complements. For instance in the sentence "The dog bites the rat." one can identify the dog as the attacker and the rat as the victim, because the noun phrase 'the dog' comes before the verb, which is the position for the subject in English, and 'the rat' comes after the verb, in object position, and the noun phrases in these positions denote the Agent (attacker) and the Patient (victim) of the 'biting'-action, respectively.

So the connection one makes is between (a) symbolic relations like 'The words *the dog* come before the word *bites*' (linear) or 'The noun phrase *the dog* is subject of the verb *bite*' (hierarchical) and (b) relations between referents, namely 'The dog is the Agent in the biting-event'; and similarly for the rat:

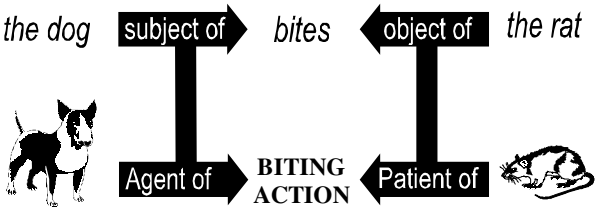

Figure 3: Symbolic reference as an association of relations

According to Jackendoff (1999), in the course of language evolution direct relationships between the linear order of words and their referents are replaced by links that are mediated by complex hierarchical syntax. Here, this would mean that the focus of symbolic relationships shifts from linear to hierarchical relations: on an early stage in the evolution of language, *linear relations* between symbols as evident in speech ('comes before / after') would directly be associated with hierarchical relations between referents ('Agent of / 'Patient of'), whereas on a later stage we would have (syntactic) *hierarchical relations* between symbols, like 'subject of / object of', which can be linked up with hierarchical relations between referents.

In both cases, it is the relationships that are associated, rather than individual symbols and individual referents. Unlike in iconic and indexical reference, in symbolic reference we pick out an object indirectly, relying on links that connect relationships between symbols (such as 'comes before / comes after', or 'subject of` / object of') with relationships between objects (such as 'Agent of / Patient of'). This is what symbolic reference is ultimately about: it is a connection between signs and referents that focuses on relationships.

This means that symbolic reference is constituted by a mapping between *relational structures*: we regard the symbols and their referents only insofar as they are part of a system whose elements stand in specific relations to each other; the association of symbols and their referents is determined by the respective relations that hold between them.

This is a phenomenon very similar to the one we encountered in the case of number assignments. As Figure 4 illustrates (for two of the runners from Figure 2 above), number assignments are based on links between relations, too: in number assignments we associate numerical relations with relations between empirical objects, just as in language we associate *symbolic* relations with relations between objects.

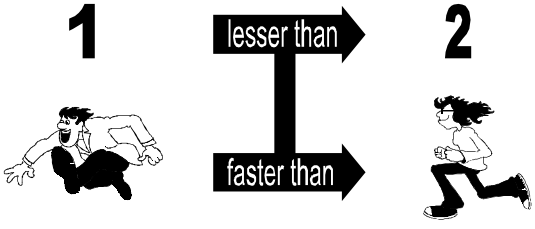

Figure 4: Number assignment as an association of relations

When we assign numbers to empirical objects, the links we establish are not between individual numbers and individual objects, but between a numerical relational structure and an empirical relational structure. And when we assign symbols to their referents, the links we establish are not between individual signs and individual objects, but between a relational structure of signs and a relational structure of the objects that they refer to.

This means that we can identify the same pattern in number assignments and in symbolic reference: in number assignments a numerical relational structure is correlated with an empirical relational structure; in symbolic reference a 'symbolic relational structure' is correlated with an empirical relational structure.

In both cases, the links between individual tokens (a number and an object, or a symbol and its referent) are based on their respective positions in the system, they are constituted by links between relations (numerical relations and empirical relations, or symbolic relations and relations between referents). Figure 5 illustrates these parallels:

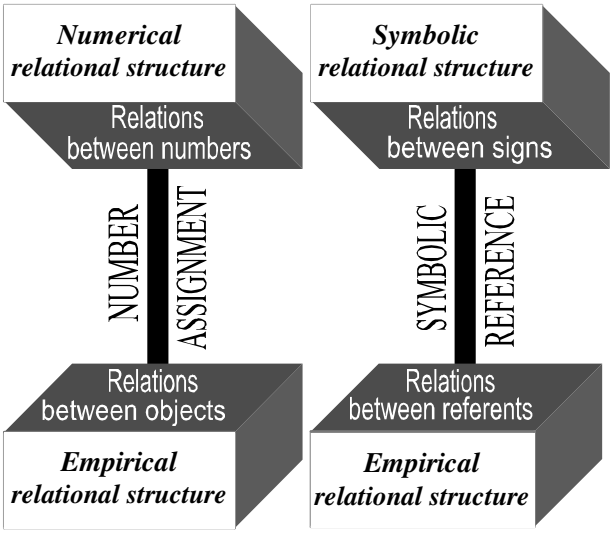

Figure 5: Translation of relational structures in number assignments and symbolic reference

This puts number assignments in a close association with the symbolic reference that lies at the core of our linguistic capacity, and shows us a way how systematic numerical cognition could have evolved in the human mind: in the development of our species the evolution of symbolic thinking in the emergence of language might have enabled us to grasp the logic of number assignments.

Once we passed the symbolic threshold, a paradigm was set for the systematic correlation of relational structures, and could be applied in the number assignments that underlie our numerical concepts. This way symbolic thinking prepared the way for systematic numerical cognition.

Under this approach, we can account for the capacity to systematically assign numbers to objects by a relatively small evolutionary step. According to this account, the use of numerical relational structures did not develop from scratch, but could build on already existing cognitive patterns that had evolved as part of sym-

bolic cognition – a re-usage that makes a lot of sense in terms of evolutionary economy.

At the same time, language gave us a handle on infinity. The phrases we can potentially generate in a language represent a discrete infinity: from a set of primitive elements – the lexical items of our language – we can generate an infinite number of complex constructions by means of combinatorial rules. In the words of Steven Pinker: "In a discrete combinatorial system like language, there can be an unlimited number of completely distinct combinations with an inifinite range of properties." (Pinker 1994, 84).

It is these combinatorial rules that constitute the infiniteness of number word sequences. The sequences of words we employ for counting ('one, two, three, …') are open-ended because of the generative rules governing the construction of complex elements. Through number words, language provides us with the notion of an infinite sequence.[9]

Note that it is the possesion of the *language faculty*, the emergence of language as a mental faculty in the history of our species, that is crucial here, not the successful and complete acquisition of a particular language in individual development. This also means that acquired or innate impairments of the language capacity do not necessarily affect our ability to grasp number assignments, as long as the basic linguistic capacity is still intact (including the association of relational structures by homomorphic mappings).

And let me emphasise again that this does not mean that without language, we would have no concept of properties like cardinality or rank that we identify with numbers. As the above-mentioned evidence from animal studies and studies with human infants shows, the emergence of our number concept could draw on prelinguistic capacities we share with other species, for instance our grasp of cardinality as a property of sets.

Language has been crucial in integrating these early concepts into a systematic number concept, one that is based on an infinite sequence of numerical tools that can be used to identify empirical properties via a correlation of relational structures.

Under this notion, numerical cognition as well as language can be regarded as genuinely human; as mental faculties that are not merely of greater complexity (than, say, animal communication systems and numerosity concepts) and grounded in a higher general-purpose intelligence, but qualitatively different and specific to the human mind.

---

[9] Cf. Hurford (1987) for a detailed analysis of number words; Wiese (1997; 2001) for the status of number word sequences within language and numerical cognition. In Wiese (2001, ch.4) I show that linguistic generativity (and therefore infinity) could be passed on to numerical cognition via counting sequences, and that this transfer could take place not only in individual cognitive development – as for instance assumed by Bloom (1994) –, but also in hominid evolution.

Abstract

Evolutionary algorithms are playing an increasingly important role as search methods in cognitive science domains. In this study, methodological issues in the use of evolutionary algorithms were investigated via simulations in which procedures were systematically varied to modify the selection pressures on populations of evolving agents. Traditional roulette wheel, tournament, and variations of these selection algorithms were compared on the "needle-in-a-haystack" problem developed by Hinton and Nowlan in their 1987 study of the Baldwin effect. The task is an important one for cognitive science, as it demonstrates the power of learning as a local search technique in smoothing a fitness landscape that lacks gradient information. One aspect that has continued to foster interest in the problem is the observation of residual learning ability in simulated populations even after long periods of time.

Effective evolutionary algorithms balance their search effort between broad exploration of the search space and in-depth exploitation of promising solutions already found. Issues discussed include the differential effects of rank and proportional selection, the tradeoff between migration of populations towards good solutions and maintenance of diversity, and the development of measures that illustrate how each selection algorithm affects the search process over generations. We show that both roulette wheel and tournament algorithms can be modified to appropriately balance search between exploration and exploitation, and effectively eliminate residual learning in this problem.

Introduction: EC and Cognitive Science

Evolutionary computation (EC) is increasingly used in cognitive science, both for evolving cognitive models and for modeling evolutionary processes.

Many algorithms use evolutionary search in one form or another. No single search algorithm will be optimal for all tasks (a thesis colloquially known as "no free lunch", Wolpert & Macready, 1996). In any simulation study, characteristics of the task need to be taken into account in the selection of algorithms. However, to many cognitive science researchers it is not clear which aspects of tasks are important in the design of a search process, and what properties of evolutionary search algorithms need to be taken into account to select an appropriate design.

This study is part of a wider program of research whose goal is to enhance the effective use of evolutionary computation techniques in cognitive science domains. This program involves assessing the performance of popular evolutionary algorithms on tasks of interest to cognitive scientists.

Current areas in cognitive science that are utilizing EC methods include the direct modeling of evolutionary processes, such as the role of learning in evolution, learning as a local search technique in a genetic algorithm, the evolution of modularity, the evolution of cooperation, and the evolution and learnability of language (e.g., see the biennial "Evolution of Language" conferences, or the Evolutionary Computation "Special Issue on EC and Cognitive Science", Wiles & Hallinan, 2001).

Other domains use evolutionary algorithms for optimization, for example, testing theories of infant development; modeling populations of individuals engaged in cognitive tasks; testing outcomes following damage in neural network models; and exploring the range of behaviors in a dynamic model of an artificial language learning task.

In all of the cognitive science domains mentioned, evolutionary algorithms have been tested on specific problems, but little work has been done at a methodological level to characterize the nature of the tasks per se, and the way in which they interact with the evolutionary algorithms chosen. Many factors affect the performance of evolutionary algorithms, including the choice of fitness function, representation of the genome, population size, selection technique, and genetic operators.

Learning and EC

For this study, the area of interest is the interaction of learning and evolution known as the Baldwin effect, first formalized as a computational problem by Hinton and Nowlan (1987). Hinton and Nowlan's simulation of the Baldwin effect provided insight into how learning can guide evolution within a Darwinian, rather than a Lamarkian evolutionary framework.

In Hinton and Nowlan's model, each individual consisted of a bit string representing a simple neural network with twenty connections, which must be set correctly via either learning or evolution. A network that achieves the correct settings has a fitness dependant upon the time required to achieve the correct settings, while all incorrect networks have equal, minimal fitness. This task has a single fitness peak, which is surrounded by a perfectly flat fitness landscape, making it a classic needle-in-a-haystack problem (henceforth referred to as the *haystack* problem). The task is analogous to finding the components of a module in which no partial credit is given for partial solutions. Issues of modular design were popularized by Dawkins in the Blind Watchmaker (Dawkins, 1986), and are particularly relevant to understanding the evolution of complex cognitive systems.

The haystack task requires exhaustive search if genetic operators alone are used (crossover and mutation). However, if each agent modeled in the search population is allowed to perform some local searching, then the task can be solved by a much smaller population.

Hinton and Nowlan used a population size set to approximately the square root of the size of the search space, with each agent able to search on average a portion of the search space also equal to the square root of the size of the space. The choice of population size and local search space balanced the need for a population to have sufficient diversity to cover the space, and sufficient flexibility to find the "needle" (maximum fitness) in almost every trial.

Computationally, each individual is implemented as a string of twenty "genes", each of which may be either 1, 0, or ? (question mark). The ? represents a learnable gene. The individual learns by guessing 0 or 1 with a probability of 0.5. The target pattern is a string of twenty 1s. The number of guesses required to achieve this target is recorded and used to calculate the individual's fitness. The next generation is created by repeatedly selecting two parents, to produce pairs of new individuals. Parents are probabilistically selected proportional to the individual's fitness relative to the total population fitness.

Hinton and Nowlan (1987) demonstrated that under these conditions, the ability to learn, represented by ?s, was replaced by appropriate instincts, represented by 1s. The number of 1s rose from an initial 25% of alleles in the population to 50-80% after 50 generations, with the remainder of the alleles ?s. Non-target alleles, represented by 0s, disappeared from the population.

An interesting feature of Hinton and Nowlan's simulation is the persistence of learnable genes in the population once it has stabilized. Hinton and Nowlan suggested that there is very little selective pressure in favor of genetically specifying the last few connections, since learning can occur in very few guesses. Several researchers have studied the phenomena of the residual question marks in the haystack problem and identified a variety of factors, including selection pressure and drift as significant factors in the results (Belew, 1989, Harvey, 1993).

In a previous study, we analyzed multiple simulations of the haystack problem to identify the characteristics of two classic selection algorithms (one fitness proportional and the other rank based) with respect to exploitation and exploration of the fitness landscape (Wiles et al., in press). These simulations demonstrated that fitness proportional selection finds good solutions and the average fitness of a population rises quickly, but at high fitness levels the population drifts gradually to homogeneity (all the alleles in one position on the chromosome are identical for all individuals in a population). Residual learning is frequently a result of an interaction between a pseudo-founder effect (dominance by one early successful solution) and drift to homogeneity at one or more of the genes. Selection by rank has the opposite effect, with populations drifting initially, until a critical mass find good solutions (or until an allele becomes homogeneous in 0s, resulting in an unsuccessful trial). Of the successful trials, at high fitness levels, populations converge to homogeneity based on fitness, rather than drift. By comparing fitness level and number of homogeneous genes to generation number, the relative effects of drift and selection pressure can be monitored during evolution.

The analyses in our previous study provide tools to understand how selection pressures are working during trials. The two techniques produce very different characteristic performance. Fitness proportional selection has initially fast fitness increases followed by slow convergence, whereas rank-based selection has initially slow and erratic fitness increases followed by fast convergence.

For the haystack problem, neither of these selection methods can be considered optimal in balancing the exploration of possible solutions with the exploitation of good solutions. Fitness proportional selection has too strong an exploitation of early successful solutions, leading to a pseudo-founder effect, and insufficient pressure to optimize when most of the population have good solutions. In contrast, rank-based selection has insufficient exploitation of its good early solutions, allowing drift to reduce the diversity of alleles available before fitness pressures shape the search space.

Method

In this study, we report three sets of simulations. The first set replicates our previous work on the classic fitness proportional (roulette wheel) and stochastic

rank-based (tournament) methods and is reproduced here for comparison.

The second set of simulations was designed to investigate other selection algorithms on the haystack task, and also to test whether the analysis would be useful for their evaluation. For this set, we designed two additional algorithms to combine the search characteristics of fitness proportional and rank-based selection. The first operator was designed to exhibit fast fitness rises and fast convergence, and the second to exhibit slow fitness rises and slow convergence.

The third set of simulations directly addressed the problems inherent in fitness proportional and rank-based selection using modifications suggested in the literature. To modify fitness proportional selection, the expected number of offspring for any one individual was scaled in proportion to its deviation from the mean fitnesses of other individuals, which balances the selection pressure over a trial. To modify rank-based selection, the two fittest individuals (replacing the offspring of one pair of parents) were copied to the next generation, thus preserving good solutions once found. In the next section, the algorithms are described, and then the results summarized and presented together for ease of comparison.

Simulation details for the haystack problem

Hinton and Nowlan (1987) modelled the Baldwin Effect using a simple genetic algorithm, with no mutation and a crossover value of 1.0; each pair of parents undergoes crossover once during each reproduction event. The next generation is created by repeatedly selecting two parents for each pair of new individuals. The probability of selecting an individual as a parent is proportional to its fitness divided by the total population fitness. The fitness, *f*, of an individual is calculated using the recorded number of guesses, *g*, taken to find the target:

$$f = 1 + \frac{(L-1)(G-g)}{G} \qquad (1)$$

where G is the maximum number of guesses allowed and L is the length of the chromosome. In Hinton and Nowlan's model, $G = 1000$, $L = 20$, and the population size, $N = 1000$.

We implemented Hinton and Nowlan's model, and as in our previous work, selection of each parent was implemented using a fitness proportional algorithm. After selecting two parents, a crossover point was chosen at random, and two new individuals were then created. Parameters were set similar to Hinton and Nowlan (1987), with initial proportions of 1, 0 and ? alleles set to 0.25, 0.25 and 0.50 respectively. A minor change from their parameters was setting both population size and maximum number of guesses to 1024 instead of 1000. All trials were run until the population converged (homogeneous in all genes).

For each selection method, 100 trials were performed. We report the proportion of trials that successfully eliminated all zeros from the population, the average number of residual question marks at the end of each trial, and the average number of generations to homogeneity (see Table 1). The average fitness pressures in the early and late stages of trials were calculated as the average number of generations until the fitness rose to 50% of the maximum (Stage 1) and from the midpoint to final convergence (Stage 2). By defining these values, the relative selection pressures early and late in a run can be compared. The average fitness of the population when the first gene in each trial became homogeneous was also calculated (see Table 1, column 4). This measure shows the potential exploration available to the algorithm.

Set 1: Original algorithms

Traditional roulette wheel (fitness proportional) selection: The fitness of an individual is determined using equation (1) given above, and the selection procedure for two parents is as described for Hinton and Nowlan's simulations.

Tournament (rank based) selection: In this algorithm two candidates are selected at random from the parent population, and the individual with the higher fitness becomes a parent. The probability of being selected as a parent for the next generation therefore depends on the relative rank of an individual within the population, rather than its proportional fitness. Under tournament selection, the reduced fitness differential later in evolution does not change the ranking of individuals and selection pressure is maintained as long as there are different fitnesses within the population.

Set 2: Modified algorithms

Roulette with ranking: In order to produce a selection strategy that should both begin and end rapidly, ranking was added to roulette wheel selection. This algorithm has also been called stochastic tournament (attributed to Wetzel by Goldberg, 1989). Continued pressure after the initial fast start means that selection will force the population to converge, rather than simply drifting to homogeneity.

To select each parent, two candidates are chosen using roulette wheel selection. The fittest of these two individuals becomes one parent, as in tournament selection. A second parent is selected in the same way. The fitness-proportional selection of candidates enables very successful individuals to have many offspring, in a similar manner to roulette wheel selection. The addition of a tournament between two candidates ensures that as fitness differentials decrease later in trials, the selection

pressures continue. The strategy is identical in all other ways to the others that have been used previously.

Probabilistic tournament: The second variation is a strategy that is designed to start slowly and end slowly. For this strategy, tournament selection was modified to include the proportional elements of roulette wheel strategy.

For each parent, two candidates are chosen randomly from the parent population. The one that will become a parent is chosen using proportional selection based on the fitness of these two individuals. That is, the one that is fitter will be more likely to be chosen than the less fit individual, but both still have a chance of being a parent. The selection of candidates with equal probability means that each individual, even the fittest one, can expect on average to contribute genes to a maximum of four offspring. The second parent is chosen in the same way, and reproduction continues as in the other selection strategies.

Set 3: Optimized algorithms

Sigma Scaled Roulette: Amongst the known problems with roulette wheel selection is the variable selection pressure between early and late stages in a trial and the premature convergence of populations with inadequate exploration of the search space (Mitchell, 1996). A variety of modifications of roulette wheel selection have been proposed. One such mechanism is to balance the selection pressures evenly throughout a trial. Sigma scaled roulette is a renormalized version of roulette wheel. We use the description given by Mitchell (1986, who credits an early unpublished manuscript of Forrest from 1985). The expected number of offspring, *E*, is calculated from the mean and standard deviation of the fitnesses of the population:

$$E = 1 + \frac{f(i) - m}{2\sigma} \qquad if \sigma \neq 0$$

$$= 1 \qquad if \sigma = 0$$

where $f(i)$ is the fitness of individual i, m is the mean fitness of the population and σ is the standard deviation. This means that an individual with a fitness equal to the mean will gain a slice of the roulette wheel proportional to one unit. An individual with fitness one standard deviation above the mean will (on average) gain a slice proportional to 1.5 units, and one with fitness one standard deviation below will gain a slice proportional to 0.5 units. If the expected value for an individual is less than 0.1, then the slice is set to 0.1. The total size of the wheel is the sum of the slices of all individuals in the population. The expected number of offspring is proportional to the size of the slice, with corrections for the very small slices. For each pair of parents selected, two offspring are produced. Using the standard deviation of the fitness maintains a constant selection pressure in the population throughout a trial.

Elite tournament: The slow initial period of all trials during tournament selection is a known problem. Even when a good solution is found, recombination of parents results in disruption of the solution and drift (rather than selection) can lead to homogeneity in one or more of the genes. Many researchers use elitism to preserve good solutions (first introduced in the 1970s by de Jong, according to Mitchell, 1996). In this strategy, one or more individuals with the highest fitnesses are copied to the next generation unchanged. In our implementation, elite tournament is identical to tournament selection, except that the individuals with the two highest fitnesses are copied to the next generation.

Results and Discussion

The results from all three sets of simulations have been collated in Table 1, which shows the performance of each selection technique, the average number of residual question marks, and the number of generations to convergence (i.e., all genes become homogeneous) over 100 trials. Figures 1-3 show the selection pressures during early and late stages over 10 trials. Stage 1 is the average number of generations taken to reach a fitness value of 10 (i.e., 50% of the maximum fitness), the point at which fitness increases most rapidly in this task. Low values (few generations) indicate high initial selection pressure and high values indicate low selection pressure. Stage 2 is the average number of generations from this level of fitness to convergence of the population and indicates the selection pressure after the initial increase in fitness. The mean population fitness when the first allele becomes homogeneous generally indicates how good the solution will be. If an allele is homogeneous before the population is very fit, the solution tends to be poor.

The simulations in Set 1 (roulette wheel and tournament) provide a benchmark for the later studies. Performance in these simulations was consistent with our previous results (Wiles et al. in press). Using roulette wheel selection, all trials eliminated zeros from the population, and at convergence, individuals had an average of 1.4 residual question marks (stdev. 0.9). The change in selection pressure is revealed by the average number of generations spent in Stage 1 (10) versus Stage 2 (1437). See Table 1 for the means and standard deviations of all results.

Using tournament selection, 85/100 trials eliminated all zeros. In the successful trials, individuals retained an average of 1.2 residual question marks, with a much higher variance (stdev. 2.2). The average time spent in Stages 1 and 2 is reversed in this case, with 185 generations in Stage 1 and 23 generations in Stage 2.

The interaction between Stages 1 and 2 for roulette wheel and tournament selection is clear in Figure 1.

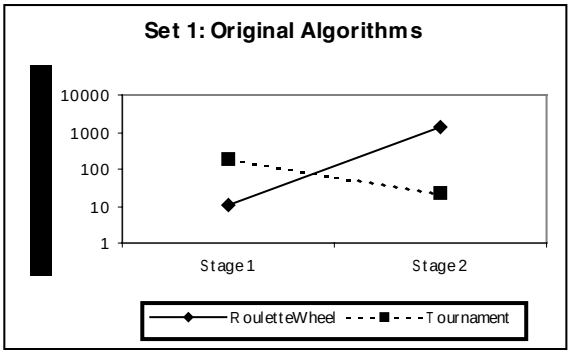

Figure 1. Time to convergence in Set 1, the original roulette wheel and tournament selection algorithms. Note that the y-axis is logarithmic. The algorithms show clear differences in behaviour, with roulette wheel faster in Stage 1, and tournament faster in Stage 2.

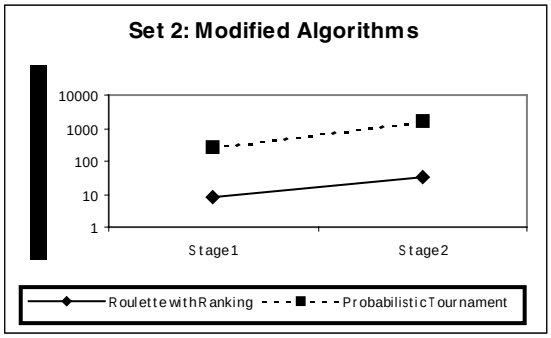

Figure 2. Time to convergence in Set 2, the modified algorithms. The Stages 1 and 2 components from Set 1 (see Fig 1), have been recombined as intended, to produce one algorithm in which both Stages 1 and 2 are fast (roulette with ranking), and the other algorithm in which both Stages 1 and 2 are slow (probabilistic tournament). Note that neither of these algorithms eliminate residual question marks.

In Set 2, the number of successful trials and residual question marks are similar to those from Set 1, but the time spent in Stages 1 and 2 differed markedly, as expected. Roulette wheel with ranking was fast in both stages (averages 7.6 and 33 generations respectively), and stochastic tournament was slow in both stages (average 249 and 1624 generations respectively, see Figure 2).

In Set 3, the original roulette and tournament selection procedures were modified to address their major known weaknesses, and both showed considerable improvement in optimization performance (as evidenced by the number of residual question marks). All trials eliminated zeros from the population, the time to convergence was short and very few residual question marks remained (an average of 0.02 in sigma scaled roulette and 0.06 in elite tournament).

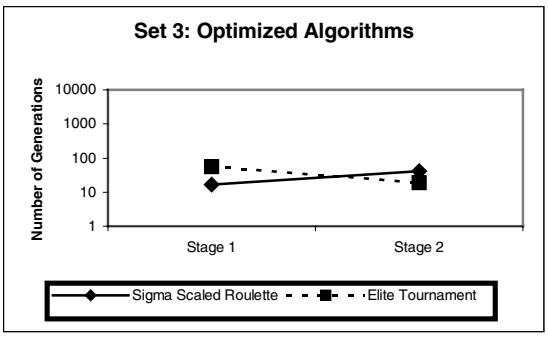

Figure 3. Time to convergence in Set 3, the optimized algorithms. Both sigma scaled roulette and elite tournament eliminate virtually all residual question marks and are much faster than the algorithms in Sets 1 and 2 (cf. Figs 1 and 2).

The average time spent in Stage 1 and Stage 2 was also much more balanced (16 and 42 generations respectively in sigma scaled roulette and 56 and 19 generations respectively in elite tournament, see Figure 3).

Premature convergence is a known problem for these evolutionary algorithms. Tracking progress towards homogeneity can therefore provide valuable information. The average fitness at which the first gene becomes homogeneous provides a quantifiable measure of diversity at a significant point in a simulation. This fitness value was recorded for each selection regime (see Table 1, column 5). Higher values (maximum is 20) indicate that higher levels of diversity are maintained in the population. For problems in which hitchhiking genes (sub-optimal genes that are carried by pseudo-founders in a population) are liable to cause problems such as in the haystack problem, this measure is a good indicator of potential problems with premature convergence. The tournament-based algorithms that have trials that do not eliminate all zeros show the lowest values with average population fitnesses at the first homogeneous alleles of 9.1 and 6.0 for Sets 1 and 2 respectively. Values for the corresponding roulette wheel-based algorithms are higher (16.7 and 13.6 respectively), but are not optimal. The best algorithms, those in Set 3 have the highest values (19.3 for sigma-scaled roulette and 19.9 for elite tournament) indicating that none of the trials suffered from premature convergence.

The combination of relatively balanced fitness pressures in Stages 1 and 2, short times to convergence, and high fitness before diversity is reduced indicate that both selection algorithms in Set 3 are well-adapted to the haystack task.

Conclusions

One specific conclusion from these experiments is that residual learning is not an inherent aspect of the Baldwin effect. Rather, it is a consequence of the way

the fitness landscape is searched, and the application of selection pressures at different stages. The methodological studies presented in this paper are one way to explore such issues. Further work is needed to tie these results to biologically-plausible learning scenarios, but that is beyond the scope of this study.

At a more general level, the simulations show that the haystack task is one for which tailoring of the algorithm makes a qualitative difference to the behaviors observed. Specific issues addressed in this study concern the characteristics of the algorithms and the nature of the landscape.

The simulations of the original algorithms illustrate properties such as premature convergence in roulette wheel and the dangers of early homogeneity in one or more genes due to drift in tournament selection. With appropriate modifications, the optimized algorithms achieve a balance between exploration and exploitation, resulting in convergence to good solutions. Residual learning can be almost eliminated, and performance on the haystack problem can be near optimal.

These results illustrate the need for a characterization of task types in cognitive science, and a characterization of evolutionary algorithms and their performance on these tasks. Such a classification would facilitate the tailoring of algorithms to particular problems, and has the potential to significantly reduce artifacts due to implementation details.

Abstract

This paper addresses the problem of how and when learning is an aid to evolutionary search in hierarchical modular tasks. It brings together two major areas of research in evolutionary computation, the performance of evolutionary algorithms on hierarchical modular tasks, and the role of learning in evolutionary search, known as the Baldwin effect. A new task called the jester's cap is proposed, formed by adding learning to Watson, Hornby and Pollack's Hierarchical-If-and-only-If, function, using the simple guessing framework of Hinton and Nowlan's Baldwin effect simulations. Whereas Hinton and Nowlan used a task with a single fitness peak, ideally suited to learning, the jester's cap is a hierarchical task that has two major fitness peaks and multiple sub-peaks. We conducted a series of simulations to explore the effect of different amounts of learning on the jester's cap. The simulations demonstrate that learning aids evolution only in search spaces in which the simplest level of modules are difficult to find. The learning mechanism explores local regions of the search space, while crossover explores neighborhoods in higher-order modular spaces.

Introduction

This paper addresses the problem of how and when learning is an aid to evolutionary search in hierarchical modular tasks. It brings together two major areas of research in evolutionary computation (EC), the performance of evolutionary algorithms (EAs) on hierarchical modular tasks, and computational models of the role of learning in evolutionary search, known as the Baldwin effect.

We begin with a brief review of modular tasks that have been proposed to explore the performance of evolutionary algorithms, and then briefly describe the Baldwin effect. We then describe a specific task, the *jester's cap*, that incorporates learning into a hierarchical modular task. In many simulation tasks, learning is costly and does not improve the performance of an evolutionary algorithm (French and Messinger, 1994; Mayley, 1996; Pereira et al., 2000). This study is as much an investigation of things that don't learn, as of ones that do.

There are many types of EAs, and the field of evolutionary computation is still determining features of problems that are easy or hard for a particular class of EA, and the conditions under which such algorithms will perform better than other search techniques. In evolutionary computation, characterization of an EA's performance concerns not just optimization per se, but the behaviors of populations as a whole, reflecting their original motivations as models (albeit abstract ones) of real evolutionary processes.

Some of the oldest and most popular techniques for evolutionary search are genetic algorithms (GAs), which use crossover as their major search technique. Originally developed by Holland (1992), their efficacy is thought to be based on groups of genes acting together as modules (or *building blocks*, to use Holland's original terminology), and have been studied extensively since (for general introductions see Goldberg, 1989 and Mitchell, 1996).

A variety of modular tasks have been proposed to study the conditions under which GAs outperform comparable search techniques. The most widely known of these are the Royal Road (RR) problems introduced by Mitchell et al. (1992). However, some forms of hill-climbers were found to easily outperform the GA, and a variety of tasks that incorporate deceptive elements have been defined (s.a., RR4 by Mitchell et al., 1994; HDF by Pelikan and Goldberg, 2000; hdf by Holland, 2000).

An alternative approach to incorporating deceptive elements is to define a fitness function with two or more conflicting maxima. Watson et al. (1998) defined Hierarchical-If-and-only-If (*H-IFF*) as such a function. H-IFF is a simple function that is hierarchical, modular, is not searchable by mutation, but is amenable to search by crossover. Its defining characteristics are two fitness peaks at opposing ends of the search space. Combinations of the sub-components that comprise each level of the competing hierarchies cause many sub-optimal peaks and consequently many local minima (see below for the complete definition).

Before proceeding further with the computational aspects, it is worthwhile considering the relevance of module building to many areas of cognitive science. The role of modules in evolution has long been recognized (e.g., Dawkins, 1986). In evolutionary psychology there is a particularly strong interest in modules, in part due to Tooby and Cosmides (1994) claims that humans have behavioral modules analogous to other mental functions. By studying building block problems, we are considering the types of processes that allow species to evolve varieties of modules, and their combination into complex mental organs. For example, echolocation in bats requires both the ability to emit and to receive high fre-

quency sounds. Each of these abilities has utility as a module in its own right, but the combination provides an additional capacity that goes beyond the cumulative benefit of the independent components.

The Baldwin effect: How learning can guide evolution

Under Darwinian inheritance, the things that an animal learns during its life cannot be passed directly to its offspring via the genotype. However, researchers in the late 19th century (Baldwin, 1896; Morgan, 1896), proposed a way in which learned behaviors could be incorporated into a genome over many generations (i.e., become instinctual). The mechanism is purely Darwinian, and relies on gradual changes in the distribution of genes in a population, as the following rationale explains.

Consider a population of agents comprising a variety of search strategies with initially random starting points and a range of search radii. The starting point and search radius of an agent is its "bias". An evolutionary algorithm that selected for speed in finding a point in the search landscape over many generations would evolve a population of individuals that had starting points close to the fitness maximum and small search radii. That is, behaviors that were initially interpreted as general learning abilities would, over time, become innate. No information about the content of learning is passed from parent to offspring, but in the general variation across the population, some individuals would by chance have starting points closer to the fitness maximum and smaller search radii (i.e., slightly stronger biases). These individuals would have more offspring than those with weaker biases, and in environments with fixed fitness functions, innate behaviors would gradually replace learned ones.

This process is often called the Baldwin effect and has two interesting components. The first is the explanation of how learned behaviors can become innate as described above. The other is the power of learning to augment genetic search to build complex modules. Agents that can search their local environment will be able to explore whole regions of search space in their lifetimes, rather than the single point of their own genotype. In this way, learning can enable an evolutionary algorithm to solve problems that are too costly for genetic search alone.

The first computational simulations of the Baldwin effect were by Hinton and Nowlan (1987). They used a needle-in-a-haystack (NIAH) problem, in which the maximum fitness of an agent corresponded to a genotype comprising all ones. Each gene could be one, zero or question mark. The ones and zeroes were fixed values that did not change during an individual's lifetime. The question marks were learnable genes, which could change during a lifetime. Hinton and Nowlan showed that the zero alleles quickly dropped out of the population and the number of question marks reduced over time. Hinton and Nowlan's study is a landmark in EC because it was the first computational demonstration showing how learning can guide evolution.

Hinton and Nowlan's original simulations have stimulated a considerable body of literature, which is only briefly mentioned here: Belew (1990) replicated and extended the original study, adding changing environments and cultural advantage; Harvey (1993) showed how remnants of residual learning are due to genetic drift; French and Messinger (1994) investigated under what conditions learning supplements genetic search; Mayley (1996) demonstrated how learning is first selected for, then against as evolution progresses; and Mitchell and Belew (1996) discuss issues arising from the original study. A useful reference is the edited volume of papers relating to learning and evolution by Mitchell and Belew (1996), which includes reprints of the original papers by Baldwin (1896), Morgan (1896), and Hinton and Nowlan (1987) as well as many other related studies.

Learning in hierarchical modular spaces

The issues in this study follows from French and Messinger's (1994): Consideration of the circumstances under which is it reasonable to expect that learned behaviors will firstly enhance evolutionary search, and secondly be gradually replaced by genetically specified traits. However, we take an alternative approach and investigate whether learning aids evolution in search spaces that contain competing modules. One way of thinking about this issue is in terms of the difficulty of the search task compared to the operators that are available. In Hinton and Nowlan's NIAH task, the set of twenty ones can be considered as one module, with no intermediate fitness levels for partial results. The search task for the genome is too large to find by populations of size substantially smaller than that of the search space. In this case, learning performs the function of a local search through points close together in Hamming distance. The local search supplements the genetic search, effectively smoothing the search landscape (see top, Figure 1).

The NIAH task is a particularly pathological as it contains no partial information to guide a search process. The majority of tasks of interest in EC and cognitive science have some internal structure, or distinct modules. The most tractable problems that have modular structure are those in which the genes that comprise modules can be selected independently of the settings or global structure of other genes.

As described above, a variety of such tasks have been proposed to explore the functionality of GAs, including the Royal Road problems (Forrest and Mitchell, 1993; Mitchell et al., 1994). The Royal Road problems had only one fitness peak, and hence hill climbing strategies worked well (see Mitchell, 1996 for a summary of the reasons).

The H-IFF problem has the interesting property of symmetry around diametrically opposed fitness peaks with many sub-optimal peaks and consequently many local minima (see bottom, Figure 1).

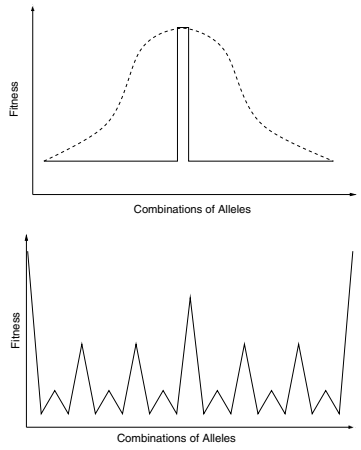

Figure 1: Fitness landscapes in different search tasks. (top) The needle-in-a-haystack task has a single fitness peak, and learning smoothes the search landscape around the peak (adapted from Hinton and Nowlan, 1987, Figure 1). (bottom) A slice through the fitness landscape of H-IFF, showing the multiple fitness peaks and the two maxima at all ones and all zeros (adapted from Watson and Pollack, 1999, Figure 1).

Tasks: H-IFF and the Jester's Cap

H-IFF (Watson and Pollack, 1999) is a function defined on bit-strings of length 2^n. The fitness value of a particular string is defined in terms of hierarchical 'building blocks' which are sub-strings of the main bit-string. The building block at the highest level of the hierarchy is the entire bit-string (i.e., all 2^n bits). Each building block is recursively divided into two equally-sized blocks, except for blocks of size one, which cannot be divided. For a building block to be correctly set, it must consist of either all 1s or all 0s. The value of a correctly set building block of size n is 2^n *plus* the sum of the values of its two sub-blocks (whose values depend on the sub-sub-blocks). Thus, the overall value of a bit-string of length 2^n is the sum of values for the building blocks of sizes $1, 2, 4, \ldots, 2^n$. The optimum bit-strings consist of either all 0s or all 1s so that they are rewarded for building blocks of every size. In the simulations in this paper, we use $2^n = 32$. The evaluation of the H-IFF function is more easily understood by way of example, shown for an 8-bit string in Figure 2.

As described above, the major difference between H-IFF and the more well known Royal Road (RR) function is that RR has a single optimal bit-string (all 1s) and significantly, *no local optima* other than the global optimum (although there are local plateaus). By comparison, H-IFF has two optimal bit-strings and, for bit-strings of length $l = 2^n$, there are $2^{l/2}$ local optima.

In this paper, we apply the learning-based approach of Hinton and Nowlan's simulations to the H-IFF function. We call this modified version the jester's cap. Specifically, we consider a genome of 32 genes, each of which may be a 0, 1 or ?. During its lifetime, an individual tries to 'learn' the best setting of the ? genes. Each of the ? genes can be set to either 0 or 1, and the resulting bit-string, comprising all 1s and 0s is evaluated with the H-IFF fitness function, described above. We take a very simplistic view of learning (as in Hinton and Nowlan's original simulations), and give the agent N attempts at guessing the best setting. The agent tests N replacements of all of the question marks with random choices of 1s and 0s. After N guesses, the best guess (i.e., that which maximizes fitness) is taken and the fitness of the agent is the H-IFF fitness of that guess. (Unlike Hinton and Nowlan's simulations, there is no scaling of the fitness based on the number of guesses required.) For example, an agent with the genome 0??1 may generate the guesses 0101, 0111 and 0011 which evaluate to 4, 6 and 8 respectively. The highest scoring guess (0011) is taken as the 'learned' setting. However, this 'learned' setting is not passed on during reproduction, it is the initial genome, 0??1 that is used in reproduction.

0	**0**	**1**	**0**	**1**	**1**	**1**	**1**	Value
1	1	1	1	1	1	1	1	8
2		—		2		2		6
—				4				4
—								0

Figure 2: Evaluation of H-IFF for the bit-string 00101111 showing hierarchical decomposition. For this bit-string, H-IFF evaluates to $8+6+4+0 = 18$. Note that the maximum obtainable value for each level of the hierarchy is 8, so the maximum value for H-IFF on bit-strings of length 8 is 32. In general, there will be $n+1$ levels of building blocks. Within these levels there will be $2^n/k$ building blocks of size k, each of which has value k. The optimal bit-strings of length 2^n therefore have value $(n+1).2^k$. The minimum value for H-IFF on bit-strings of length $l = 2^n$ is l. Such a bit-string contains all building blocks of size 1 but no higher-level blocks.

Simulation 1: The Jester's Cap

We consider the jester's cap task with three variations of the amount of learning time available to the agents: no learning (replicating the H-IFF task), a small amount of learning ($N = 10$) and a moderate amount of learning ($N = 100$). A population comprising 500 individuals is embedded within a genetic algorithm. In this initial population, 50% of the genes are ?s, 25% are 1s and 25% are 0s, except in the case without learning, where there are no ?s and equal proportions of 1s and 0s. In each generation, the fitness of each of the agents is determined, after learning when appropriate. These fitness values are used to determine the parents for the next generation, those agents with higher fitness being (probabilistically) more likely to be selected as parents than those with lower fit-

nesses. (We used a sigma-scaled roulette algorithm for choosing the parents, see Wiles et al. for further details.) Each pair of parents is used to generate two new offspring using single point crossover (zero mutation). In this recombination technique a 'cut-point' is selected at a random position on the genome. One offspring is generated by joining the genes to the left of the cut-point in parent 1 to the genes to the right of the cut-point in parent 2. The second offspring is formed by the reverse combination.

The idea behind this evolutionary approach is that in the initial population some agents will, by chance, happen to have lower-level modules (or the ability to learn them). These agents will have a slightly higher fitness than the rest of the population, and will be selected as parents more often. When two such agents are paired together for reproduction, it is quite likely that one of the offspring will have two modules, one from each parent. These modules may also combine to form a higher-level module. In later generations, even larger modules can form, so that after a sufficient number of generations the low-level modules that were initially scattered randomly throughout the population have combined in single individuals. The genes of these individuals then begin to dominate the population due to an enhanced fitness, so that every individual has the high-level modules.

These simulations were repeated 100 times for each condition, varying the initial random seed. During the course of a simulation, the mean fitness of the population is monitored. Simulations were run for a maximum of 2000 generations, or until the population converged.

Results

In all three conditions, a sizeable proportion of the 100 populations converged on genotypes of maximum fitness. On average, trials in which agents were allowed either no learning or a moderate amount of learning outperformed those where less learning was allowed, as shown in Figure 3.

Discussion

The genetic operators of crossover are maximally suited to the hierarchical structure of the H-IFF problem. Unsurprisingly, crossover works well on this problem. Learning, which one might expect to perform as well or better, does not match the performance of the genetic operators alone. This result can be explained by considering the way that learning searches the space. Learning in the jester's cap is a mechanism for searching the neighborhood as determined by Hamming distance. This search is only effective for the lowest level of building blocks. At subsequent levels, local and global minima are close in recombination space, but not in Hamming space. At these higher levels, learning merely adds distractions to an otherwise successful algorithm, although adding a sufficient amount of learning can negate any detrimental effects.

In conclusion, learning in this type of hierarchical task is no more effective than genetic search because a way is needed to search module space, not Hamming space. As posed, the jester's cap assumes that low level modules are trivial to find. We next consider a sparse version of the task in which they are not so readily revealed.

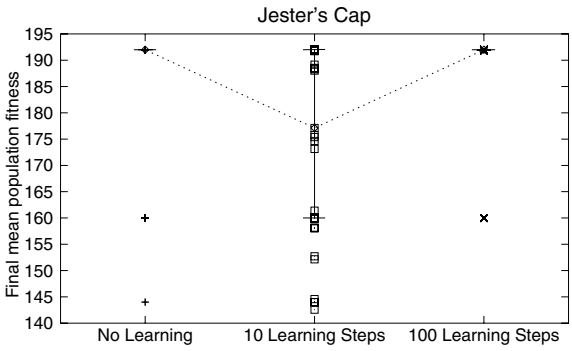

Figure 3: Performance of populations on the jester's cap task under three conditions. Each point represents the final mean fitness of a population. Error bars show first and third quartile and the medians are linked. Note that in the no learning (left) and moderate learning (right) conditions, the error bars are obscured because first, second (median) and third quartiles are all equal. Note also that many populations have identical mean fitness and tend to cluster around a set of discrete values because of the nature of the H-IFF function.

Simulation 2: The Sparse Jester's Cap

In the jester's cap simulations, rewards were given for modules of all levels (i.e, 1, 2, 4, 8, 16 and 32). In the sparse jester's cap, we consider rewarding only a subset of the levels. For example, in Figure 2 the blocks of size 2 may not contribute to the overall fitness of the solution. This modification allows us to vary the nature of the task from the maximally hierarchical H-IFF function (where all levels rewarded) to the NIAH function (where only the highest level rewarded). Varying the rewarded levels of the H-IFF function changes both the ease with which the initial modules can be found, as well as the ease with which the lower-level modules may be combined into the next higher-level of module. In the simulations in this section, only the building blocks of size 1, 16 and 32 are rewarded. With these choices of building-block and population sizes the smallest non-trivial modules (those of size 16) are difficult to find (*cf.* Hinton and Nowlan's simulations where the module is of size 20). It is thus expected that learning will substantially assist for the low-level modules. We repeated the first series of simulations using this alternative fitness function.

Results

Not surprisingly, the populations evolved using the sparse jester's cap fitness function fared substantially worse than those evolved with the (standard) jester's cap,

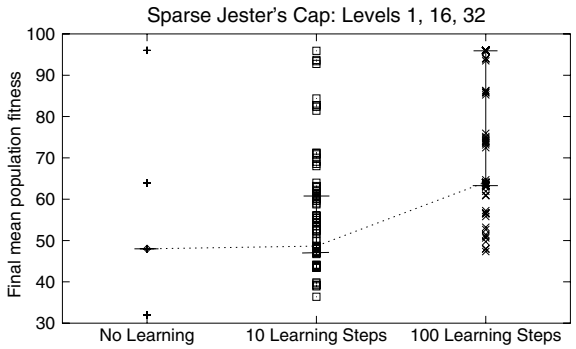

Figure 4: Performance of populations on the sparse jester's cap task under three learning conditions. Each point represents the final mean fitness of one population. Error bars show first and third quartile which are again obscured in some cases. Most populations with no learning (left) converged on a final fitness of 48, corresponding to one module. Populations in the moderate learning case converged on genomes giving a variety of fitness values, indicating some amount of residual learning in the genome (right). With a small amount of learning (center), performance was marginally improved over the no-learning case, although again residual learning remained.

as shown in Figure 4 (note that the y-axes differ between Figure 3 and Figure 4). In the condition of no learning, most populations (83 of 100) found a single module. With a small amount of learning, populations converged on marginally better solutions on average. In this condition, many residual question marks remained in the final populations. As a result, the individuals from these populations could only find modules with some degree of chance, causing the observed scattering of results in Figure 4. With moderate learning, some populations converged on the optimal genomes, others converged on genomes that gave agents the potential of finding the optimal solutions (i.e., there was again residual learning), while others converged on poor genomes. However, the populations with a moderate degree of learning, on average, outperformed the populations in the other learning conditions.

Discussion and Conclusions

This paper addressed the problem of how and when learning is an aid to evolutionary search in the jester's cap, a hierarchical modular task. Simulation 1 showed that evolutionary search could efficiently find the optimal solution with no learning. The addition of a small amount of learning detracted from this performance. A moderate amount of learning had no benefit, but did not detract either. It turns out that H-IFF is not a difficult task for a GA at the levels of complexity studied in this paper.

The main issues in reaching the highest levels of performance on H-IFF relate to maintaining a diversity of modules at intermediate levels. The population size of 500 in these simulations was clearly adequate for maintaining this diversity. Adding learnable alleles increases the search space, without a reciprocal benefit in assisting search.

Simulation 2 showed that the sparse jester's cap (1,16,32), a problem intermediate between H-IFF and NIAH, was not amenable to evolutionary search by the GA. The majority of populations only found a single module (fitness level 48). The smallest module involved 16 bits, and the likelihood of finding two such modules in any one population before convergence was minimal.

In contrast to Simulation 1, in Simulation 2 a small amount of learning (ten steps) marginally improved the success with which populations discovered modules. Ten learning steps is sufficient to effectively search four to five learnable genes, and in this case, learning clearly did provide a reciprocal benefit that more than compensated for the increase in the search space.

Increasing the learning from ten to 100 steps substantially improved the success of populations. All populations found at least one module, 75% found two modules, and at least 25% reached optimal performance. One hundred learning steps is sufficient to search six to seven learnable genes. Although this is only two more than searched by ten learning steps, it had a demonstrable effect on performance.

Simulation 2 demonstrated that in the sparse version of the jester's cap, learning is required to discover the modules, as in NIAH. As in Hinton and Nowlan's simulations, populations are unlikely to find high-level modules by crossover alone. Learning is able to guide the population towards finding the low level modules, and then crossover combines them. However, the performance is still not optimal, and room for improvement remains.

In conclusion, there appears to be a role for learning in situations where crossover is an ineffective search technique. Crossover searches module space whereas learning searches Hamming space. In tasks such as the jester's cap there is very little need for searching Hamming space and the majority of optimization can be effectively performed in module space. In this task, Hamming search is useful only at the lowest-level of module. For higher-level modules crossover searches through combinations of peaks, rather than traversing the troughs between them (Figure 1). Local search provides the wrong operator for preserving and improving fitness because it spends too much time in the troughs of fitness space. In the sparse jester's cap, modules must be discovered before searching module space becomes a viable approach. The difficulty in finding these modules necessitates local search.

NIAH and H-IFF may be viewed as being on alternative ends of a spectrum. In the former, the (single) module is difficult to find as there is no partial feedback to guide search. Learning is required to act as a proxy for this partial feedback. In the latter, modules abound so the important factor is not finding the modules, but discovering how to put them together. Consequently, the

best search process is one that searches through combinations of modules rather than searching for the modules themselves. In this case, learning is merely a hindrance. The sparse jester's cap represents an intermediate point on the spectrum. Modules are sufficiently difficult to find so that learning is required to give partial feedback in the search for the lowest-level modules. Once the modules have been found, recombination can function.

Supporting Understanding through Task and Browser Design

Jennifer Wiley (jwiley@uic.edu)
Department of Psychology, 1007 W. Harrison Street (M/C 285)
Chicago, IL 60607 USA

Abstract

While electronic text offers the potential to explain, illustrate, and scaffold understanding in powerful new ways, few studies on educational use of electronic text resources have shown significant learning gains, or even measured learning outcomes in controlled experiments (Chen & Rada, 1996; Dillon & Gabbard, 1998). In a follow-up to previous studies (Wiley & Voss, 1999), the present experiments study the effects of different tasks and browser designs on navigation and reading patterns, as well as on memory and comprehension measures from electronic text. These studies have revealed that only when both the task and the design support integration (such as in a two-windowed browser) and students are explicitly directed how to use the feature, do students take advantage of the flexibility of the multiple-source environment, integrate across sources, and achieve the best level of understanding.

Introduction

One promise of using electronic text in the classroom is the potential for students to search for, access and read multiple forms of information about a topic. Since the search for and navigation of digital documents is student-initiated, requires student interaction, captures the student's interest, proceeds at the student's own pace, and allows for flexible navigation and juxtaposition of multiple sources, a number of theorists have suggested that the web might be a powerful tool for student instruction (Beeman, et al 1987, Spiro & Jehng, 1990). This optimism is consistent with a number of recent cognitive studies demonstrating that activities that require readers to engage in active, constructive and integrative tasks lead to the best understanding of the subject matter (e.g., Chi, de Leeuw, Chiu & LaVancher, 1994; McNamara, et al., 1996).

However, a review of the literature on educational use of electronic text yields two striking conclusions. First, students generally fail to utilize hypertext links and multiple window capabilities effectively, if at all, as they read (Foss, 1989; Gordon, et al., 1988). This is especially true of novice users (Foltz, 1996; Gray & Shasha, 1989; Tombaugh, Lickorish & White, 1987). And second, few studies on educational use of electronic documents, whether from stand-alone hypermedia or the World Wide Web, have actually shown significant learning gains (Chen & Rada, 1996; Dillon & Gabbard, 1998). What is critically needed is for experiments to determine which specific instructional contexts may allow for effective educational use of electronic text.

Although there has been a great deal of evaluation on effective browser design from a Human-Computer Interaction (HCI) standpoint, effectiveness has been measured largely in terms of efficiency of search or ease in information finding (Dillon & Gabbard, 1998). While such fluency measures may be related to some extent to the amount of information a person is able to recall after reading from computer screens, they may not be correlated with whether a person develops an understanding of the text that is being read. A number of studies have shown that conditions that produce the best surface memory for text are not the best conditions for producing the best understanding of text (e.g. McNamara, et al., 1996; Mayer, 1999; Wiley & Voss, 1999). While surface memory may correlate with the fluency or ease of information processing, understanding may depend to some extent on the need to put effort into developing an underlying representation or situation model of the text (Kintsch, 1998). Thus, previous assessments from an HCI perspective cannot reliably indicate which screen layouts will be most effective for promoting understanding from electronic text. Given this educational goal, browser design must be evaluated specifically using measures of conceptual learning.

In a review of the published studies on hypermedia and learning outcomes between 1990 and 1996, Dillon and Gabbard found only 11 studies that performed controlled experiments on hypermedia and learner performance. Of those 11 studies, there were only four results that actually seemed to suggest an advantage for learning from hypermedia over paper. In the majority of studies there was no clear difference between learning from hypermedia and learning in a control (more traditional) setting. While this may be viewed more optimistically as evidence that learning from electronic resources may sometimes be no worse than traditional classroom methods, there is hardly an overwhelming body of evidence that the web can generally be relied upon to provide an enriching instructional experience.

Of the four studies that netted positive learner performance, only two seem to indicate that hypertext may allow students to engage in learning at a more conceptual level. One of these reported that students learned to recognize aircraft more efficiently and effectively when they were able to view the images

next to each other (and even overlay two images) in a browser during learning (Psotka, Kerst & Westerman, 1993). Clearly the ability to juxtapose and overlay images gave subjects a better concept of the aircraft prototypes, and this allowed them to perform well on later recognition tasks. In a second study, Jacobson and Spiro (1995) found that a hypermedia environment as opposed to a linear electronic presentation of the same materials allowed for the best performance on a problem-solving essay task. Interestingly, the linear presentation of the same material allowed for the best recall of the facts. Unfortunately, no converging evidence of better comprehension in the hypertext vs. linear condition was obtained. However, the differences in essay quality suggest that students in the hypertext conditions benefitted from the flexibility and ability to jump between sources in the hypertext format, allowing for better synthesis of the material that was presented. This result is consistent with perhaps the most consistently cited study on learning in hypertext (Egan et al, 1989) which found that a multi-window environment called Superbook led to better essay writing than a paper control condition.

Based on their review, and these last two studies in particular, Dillon and Gabbard suggest that hypermedia may afford particular advantages for learners on tasks that require comparison across sources. Notably, when students are not given the ability to view two sources at once in a computer environment, they perform less well than with paper on tasks which require integration across two documents (Wang & Liebscher, 1988). Consistent with the intuition provided by these previous studies, Wiley & Voss (1999) reported that students can show better conceptual learning from a web-like environment when they are provided with multiple windows and are given a task that requires them to integrate information across sources.

In one of few empirical studies evaluating conceptual learning from a web-like environment, Wiley and Voss (1999) demonstrated that reading multiple sources presented in a browser can lead to better understanding of subject matter than reading from a textbook. In this study, students read about the Irish Potato Famine either from several on-line documents in a two-window web site or they read the same information in the form of a textbook chapter. When students were asked to write an argument of "What produced the significant changes in Ireland's population" instead of a narrative, and read the on-line sources instead of the textbook chapter, students gained the best understanding of the material. Understanding was assessed by the causal and integrated nature of their essays, as well as their performance on inference verification and analogy identification tasks. Wiley and Voss (1999) concluded that tasks which require students to construct their own representations of a situation will yield the most conceptual learning in web-like environments. The argument writing task promoted understanding because it required students to integrate information from across the multiple sources as they created support for a thesis. And, the multiple source condition may have promoted understanding by supporting the comparison and integration of the individual sources.

This is an important finding, demonstrating empirically that electronic text can be an effective tool for developing student understanding. However, it is important to note the very specific circumstances under which better understanding may be achieved from web-like environments. For one, only students given a task requiring integration of information across sources showed better learning from a browser. Otherwise, learning from a browser was actually poorer than from a textbook. In fact, there were a number of particular features of the Wiley & Voss (1999) environment, any of which may be important in order for the effect to be obtained:

The site had a small set of documents.
The documents were selected for the user.
The documents were largely relevant.
There were no links embedded in the texts.
Each document fit in a single window.
The task was well-defined and specific.
The task required integration across sources.
The browser had two side-by-side windows.
The overview menu was accessible through an icon.
Images were presented in their own window.
Students were instructed to use both windows.
Students were instructed how to use the menu icon.
Conceptual learning was assessed in the post-test.

The present experiments directly test whether the design of the browser with two side-by-side windows might have been critical for the better learning in the web source/argument writing task condition. Although many computerized tutors and interactive environments use multiple windows, there has been little work on how students use multiple windows or the optimal conditions for multiple window use (von Oostendorp, 1996). Interestingly, the three other studies that suggest that students can gain better conceptual understanding from hypermedia environments (Egan, et al., 1989; Pstoka, et al 1993, Jacobson & Spiro, 1993) all used a multi-window display. However, there have been no studies that have manipulated the number of windows and directly measured comprehension. With converging data from essay tasks, comprehension tests and eyetracking protocols, the present studies address whether a multi-window browser supports better understanding in a web-like environment.

Experiment 1

The first experiment investigated the effect of two-window browsers on learning historical subject matter from a web site. This experiment tested the hypothesis that the design of the browser had an impact on students' understanding. Thirty undergraduates were asked to read 10 pages from a web site about the Irish Potato Famine in order to write either a narrative or an argument of what produced the significant changes in Ireland's population. (The pages contained 5 texts (about 1500 words), 4 tables, 1 graph and 1 map.) In addition, students either read the information from a single-window browser, a two-window browser, or from a two-window browser with specific instructions about why they were being given two windows. Further in this third condition the list of documents was split across the two windows, so that in order to read all of the information readers had to use both windows.

Student learning was assessed with a number of learning measures taken from Wiley and Voss (1999). Of most interest are three measures thought to reflect understanding: the proportion of sentences in student essays which represented an integration or "transformation" of the presented information (as opposed to simply copying the presented information), an inference verification task and an analogy task. The inference verification task (IVT) contained 10 inferences that could be generated by integrating information across two sources, such as "As rent costs increased, emigration from Ireland increased." as well as 10 distractors. The analogy task consisted of short descriptions of potentially analogous events. Students were asked to rate the similarity of the causes of each event with the population decline in Ireland. These analogies were intended to vary in surface and deep similarity, and the critical analogy, the institution of a Poll Tax in the U.S. South after the Civil War, was intended to be similar only on a deep level (as it was related to sociopolitical inequities and class power struggles, but there was no large-scale loss of life). Thus, recognition of the Poll Tax as causally similar to the changes in Ireland's population indicates a particularly good understanding of the text. This rating serves as the critical analogy task (CAT).

The means for each condition on each measure are presented in Figure 1. Performance on all measures was better when students wrote arguments as opposed to narratives (TRSENT: $F(1,24)=14.9$, $p<.01$; IVT: $F(1,24)=10.9$, $p<.01$; CAT: $F(1,24)=11.23$, $p<.01$). The main effect for number of windows only reached significance for the inference task, $F(2,24)=5.3$, $p<.01$, as did the interaction, $F(2,24)=7.89$, $p<.01$. However, the interaction approached significance for the proportion of transformed sentences ($p<.15$) as did the main effect for number of windows on the critical analogy task ($p<.13$). Pairwise comparisons based on a priori hypotheses revealed that the two-window/ argument writing condition significantly outperformed

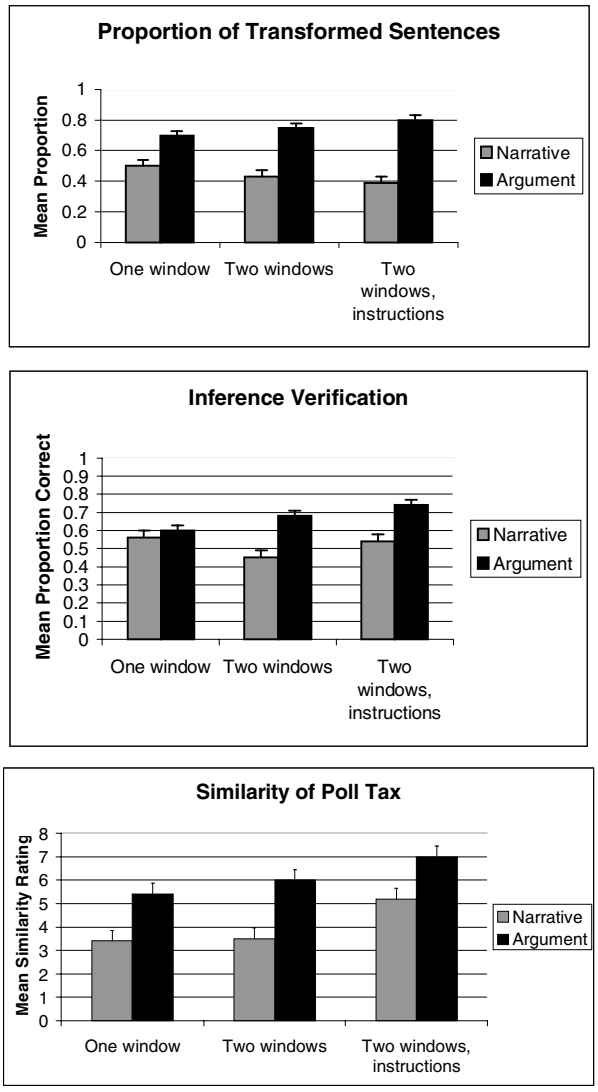

Figure 1: Experiment 1 Results.

the single window/narrative writing conditions on all measures ($ps<.05$), but only when students were given specific instructions.

Two other sources of data may be of interest here. The first is anecdotal evidence from a failed pilot study showing that students are quite reluctant to use a two-window browser. In the first design of the two-window browser, I failed to set the frame so that it could not be removed. The first thing that students did when they were seated in front of a computer with the two-window browser was click and drag that frame off the screen so they had one big window. It is important to note that I designed all my materials so that they would fit in a single side-by-side window. Thus, it was not that students could not see all of the documents that prompted them to want a bigger screen. Their initial preference was for a single window. Further, even once the two-window browser was set so students couldn't remove the frame, many of them still failed to ever use the second window. Instead, many students kept the graph in the right window and read through the sources

on the left. Only when students were given the specific instructions and forced to use both windows did all of the students actually use both windows.

Previous work with multiple window environments is consistent with these findings. Foss (1989) found that about a third of people generally prefer simple screens and only having a single window open. This prevents students from making important connections across sources. Another third of readers did open more than one window at once, but they did not use the multiple windows effectively. Their screens quickly became messy and busy. Only a third of Foss' subjects were able to use multiple windows effectively for a search and decision making task. Tombaugh et al (1987), also found a general preference for and better search in a single window environment, and found that only with practice in a multiple window environment were participants able to use the overlapping multiple windows efficiently. Part of these results may be due to the overlapping window environment that was used, however, as Instone, et al (1996) found that participants were able to use a tiled multiple-window environment more efficiently than an overlapping window display. Unfortunately, all of these previous experiments measured the effects of the windows in terms of speed and accuracy of search for information, and not in terms of comprehension. Only the present study has manipulated the number of windows and investigated how the use of multiple windows can lead to a better conceptual understanding of the subject matter, as it allows for the concurrent presentation of related concepts from different sources.

A second additional source of information about how readers behaved in the different conditions comes from analysis of browsing logs and eyetracking data. These sources indicated that both general instruction about how to use web sources and specific writing instruction yielded different navigation and reading patterns. A pilot eyetracking study on 4 students in the 2-window/2-list condition gives us a better idea of exactly how the students used these windows. Two of these students were told to read with the purpose of writing a narrative, and the other two were told the argument instruction. Like all other students, these readers tended to begin their task by reading through each document, one at a time, in order. Students usually simply went down the documents in the list on the left side of the screen and then down the documents on the right side of the screen. During this initial reading phase, the eyes rarely left the document that was being read. At this point, both readers in the narrative condition stopped reading and declared they were ready to write their essay. On the other hand, both students in the argument condition moved on to a second phase of reading.

One student started over again from the beginning, starting at the top of the left window list and skimmed the documents in order. But, from time to time, she would call up documents in the other window, or skip to another document on the same list and look for particular sentences. The other student in the argument condition began the second phase by calling up pairs of documents and alternated reading between the two. Importantly, the sentences that these students tended to re-read were important for inferences about the causes of the Potato Famine. Eyetracking data revealed that students in argument condition spent more total time on sentences important for inferences. Thus, the selection patterns and eyetracking evidence suggest that under some conditions web sites can promote more active reading patterns, suggesting more active integration of the text at a conceptual level. Further, this second phase of reading, or review of documents, seems to be particularly critical for understanding. It is what students do when they are reading from paper documents, and what Dee-Lucas and Larkin (1995) found when students effectively used structured overviews in electronic text.

Taken together, these sources of data demonstrate that students need to have both a task and an environment that forces them to be more active in order for students to gain the benefits of web resources. Only when both the task and the design support integration, and students are explicitly directed how to use the feature, do students take advantage of the flexibility of the multiple source environment. Only then do students integrate across sources, selectively re-read sources, and achieve the best level of understanding.

The second experiment is an important extension of this work using scientific texts as content. Of particular interest is whether the ability to juxtapose two documents, while performing a task that supports integration, will allow for better understanding of scientific concepts as well.

Experiment 2

Although there may be some differences between reading from history and science-related text, when readers must connect information across documents, in order to make inferences or construct global models of causality, then simultaneous presentation of the sources that need to be linked should help regardless of the subject matter. Thus, the second experiment investigated the effect of two-window browsers on learning from a scientific web site. This experiment tested the hypothesis that the design of the browser has an impact on student's scientific understanding. Forty undergraduates were asked to read 16 pages from a web site about Earthquakes and Volcanoes (based on sources from the USGS web site) in order to write either an essay or an argument of "What caused the explosion of Mt. St. Helens?" (The pages contained 10 texts (about 3000 words), 4 diagrams, 3 maps, and 2 photographs.) In addition, students either read multiple sources in a single-window browser, or multiple sources in a two-window browser with specific

instructions about why they were being given two windows. Further in the two-window condition the list of documents was split across both windows, so that in order to read all of the information readers had to use both windows. This yielded a 2x2 (writing task x presentation format) design with 10 students in each of the conditions.

Student learning was assessed with a number of learning measures similar to those used in Wiley & Voss (1999) and in Experiment 1. The same 3 measures of understanding are reported as in Experiment 1: proportion of transformed sentences (TRSENT), the inference verification and analogy tasks. The inference verification task (IVT) contained 10 inferences that could be generated by integrating information across two sources, such as "Volcanoes are likely to develop where continents collide" as well as 10 distractors. The critical analogy task (CAT) asked students to rate the similarity of the causes of the Kobe earthquake with the causes of the Mt. St. Helens eruption. The Kobe earthquake was intended to be similar only on a deep level (as it was related to disturbance due to subduction of a tectonic plate, but there was no volcanic activity). Thus, recognition of Kobe as causally similar to Mt. St. Helens indicates a particularly good understanding of the text, and the relation between plate tectonics and volcanic activity.

The means for each condition are presented in Figure 2 for the 3 tasks. As in Experiment 1, performance on all tasks was better when students wrote arguments (TRSENT: $F(1,36)=8.96$, $p<.01$; IVT: $F(1,36)=9.06$, $p<..01$; CAT: $F(1,36)=8.81$, $p<.01$). The main effect for number of windows only reached significance for the proportion of transformed sentences, $F(1,36)=6.82$, $p<.01$.

While none of the interactions were significant, based on previous results and a priori hypotheses, pairwise comparisons were performed and revealed that the two-window/argument condition outperformed the essay conditions on all measures ($ps<.08$). However, it is notable that although there was a trend toward a main effect for number of windows on the inference task ($p<.14$), there were no trends in either the windows effect or the interaction on the critical analogy task. This suggests that while the best essay writing may have occurred due to combination of writing task and two-window browser, for the learning measures, the writing task alone was responsible for better understanding.

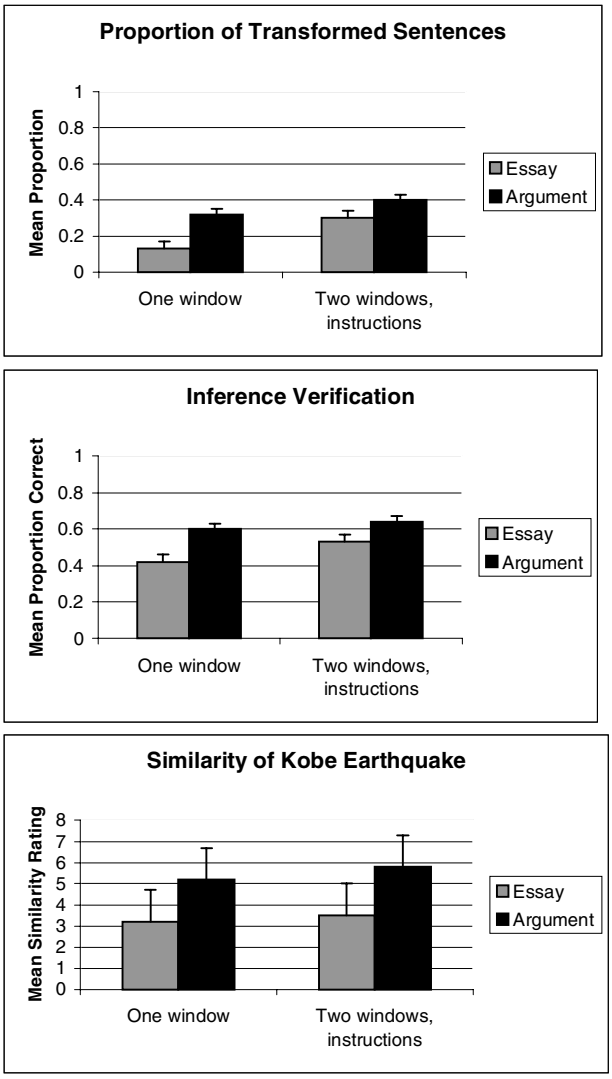

Figure 2: Experiment 2 Results.

Conclusions and Implications

In both experiments, when both the task and the browser design supported integration, and there was explicit instruction how to use the two-window browser, students were able to write more integrated essays in a multiple window environment. This condition also led to the best conceptual learning in both experiments. Although in Experiment 1 it seemed both the writing task and the number of windows contributed to the effect, in Experiment 2, the effect of the two-window browser on the understanding of the subject matter was not as evident. The argument writing task, however, did support better understanding in both history and science.

There are many possible reasons for the differential effects of the browser design in these two studies. The most obvious are the differences in the materials that students were presented with. More information was presented in the scientific site. Further, looking at the single window/narrative essay condition as a baseline, we can see that the scientific tests were more difficult for students. Students accurately recognized 55% of inferences in the history test, whereas they recognized only 40% of inferences correctly in the science site. Further, different kinds of images were used in the history and science sites. These findings have led to several interesting questions that we are currently

pursuing (Wiley, Ash, Brodhead & Sanchez, 2001). Do students simply respond to history and science subject matter differently? Are images processed differently in the two domains? Did the different types of images in the two sites lead to learning differences? Or, is the difficulty of the subject matter driving these processing differences?

Even though we are still looking for the best task/environment combination for conceptual learning from scientific web sites, taken together, the present studies demonstrate that specific conditions are necessary for effective educational use of electronic texts. In order for conceptual learning to occur, readers of electronic text may need a multimedia environment that promotes integration of the presented information and certainly need a task that prompts integration across sources. Only through the specification and demonstration of which computerized learning environments lead to better understanding, may we begin to realize some of the educational potential of electronic text.

Abstract

If a person knows that Fred ate a pizza, then they can answer the following questions: Who ate a pizza?, What did Fred eat?, What did Fred do to the pizza? and even Who ate what? This and related properties we are terming *accessibility properties* for the relational fact that Fred ate a pizza. Accessibility in this sense is a significant property of human cognitive performance. Among neural network models, those employing tensor product networks have this accessibility property. While feedforward networks trained by error backpropagation have been widely studied, we have found no attempt to use them to model accessibility using backpropagation trained networks. This paper discusses an architecture for a backprop net that promises to provide some degree of accessibility. However, while limited forms of accessibility are achievable, the nature of the representation and the nature of backprop learning both entail limitations that prevent full accessibility. Studies of the degradation of accessibility with different sets of training data lead us to a rough metric for learning complexity of such data sets.

Introduction

The purpose of this research is to determine whether a backpropagation net can be developed that processes propositions with the flexibility that is characteristic of certain classes of symbolic neural net models. This has arguably been difficult for backpropagation nets in the past. For example, the model of Rumelhart and Todd (1993) represents propositions such as "canary can fly". Given the input "canary, can" it produces the output "fly". However processing is restricted, so it cannot answer the question "what can fly?" ("canary").

There are, however, at least two types of symbolic nets that readily meet this requirement. One type of net model makes roles and fillers oscillate in synchrony (Hummel & Holyoak, 1997; Shastri & Ajjanagadde, 1993) while another is based on operations such as circular convolution (Plate, 2000) or tensor products (Halford, et al., 1994; 1998; Smolensky, 1990). These models appear to have greater flexibility than models based on backpropagation nets, in that they can be queried for any component of a proposition. We will refer to this property of tensor product nets as omni-directional access (cf. Halford, Wilson & Phillips, 1998). Omni-directional access is the ideal form of accessibility.

Another reason for investigating this lies in the work of Halford, Wilson, and Phillips (e.g. 1998) which seeks in part to define a hierarchy of cognitive processes or systems and to draw parallels between this hierarchy and a second hierarchy of types of artificial neural networks. Levels 0 and 1 of this second hierarchy are 2- and 3-layer feedforward nets, and levels 2-5 are tensor product nets of increasing rank. It thus becomes interesting to consider how well feedforward nets can emulate tensor product networks.

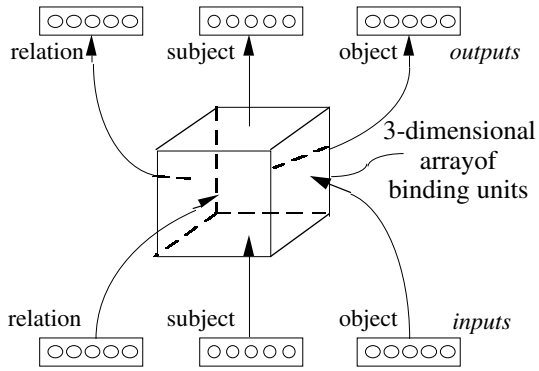

Figure 1 – Tensor product network of rank 3.

As tensor product networks are not as well known as feedforward networks, we shall describe them and their accessibility properties briefly here before proceeding. Tensor product networks are described in more detail, and from our point of view, in Halford et al. (1994). Briefly, a rank k tensor product network consists of a k-dimensional array of "binding units", together with k input/output vectors. For example, a rank 2 tensor product network is a matrix, plus 2 input/output vectors. To teach the network to remember a fact (that is, a k-tuple), the input/output vectors are set to be vectors representing the components of the k-tuple, and a computation is performed that alters the k-dimensional array. Subsequently that fact can be accessed in a variety of ways. It is common to interpret the first

component of the *k*-tuple as a predicate symbol, and the remaining components as argument symbols - e.g. for rank 3, the components might be vectors representing the concepts *likes jane pizza* (Jane likes pizza) (see Figure 1). Once this fact has been taught to a rank 3 tensor product network, the following 7 queries can be formulated and answered by a computation involving the tensor product network.

1) Is *likes(jane,pizza)* true?
2) Who likes pizza? This we often write as *likes(X, pizza)*? The response depends on what else has been taught to the tensor product network. If the tensor product network also knows that *likes(fred,pizza)* and *likes(mary,pizza)* then the response will be the sum of the vectors representing Jane, Fred, and Mary - often written jane + fred + mary.
3) What does Jane like? - *likes(jane,X)*? Similar to 2).
4) What relationships hold between Jane and pizza? - *X(jane,pizza)*? Again, similar to 2).

These four are referred to as limited accessibility.

5) Who likes what? - *likes(X,Y)*? The response in this case would be a rank 2 tensor product network storing the pairs (X,Y) for which *likes(X,Y)* is known to the original rank 3 tensor product network. The tensor product network approach solves this by producing a rank 2 tensor product network, which stores the pairs (X,Y). (This output possibility, and corresponding ones for 6) and 7) below, are not shown in Figure 1).
6) Who does what to pizza? - *X(Y,pizza)*? Like 5).
7) Jane does what to what? - *X(jane,Y)*? Like 5).

The full set of 7 forms of access are referred to as full accessibility, or omni-directional access.

A rank 4 tensor product network would have 15 access modes, a rank 5 tensor product network would have 31 access modes, and so on. Provided that an orthonormal set of vectors is used for the set of vectors representing concepts, retrieval is perfect. Facts are learned by a tensor product network one at a time, and do not interfere with each other (given orthonormal representation vectors).

Tensor product networks using orthonormal sets of representation vectors exhibit what has been called full omni-directional access to the facts that have been taught, as noted above. Humans attempting similar tasks may find some types of access easier than others. For example, children who have recently learned sets of multiplication facts such as 9×7=63 are able to use this knowledge to perform division (9×X= 63, what is X?), but may find this more difficult than multiplication (9×7=X, what is X?). We use the term *accessibility* to refer to imperfect or partial versions of omni-directional access. It turns out that some of the nets discussed in this paper also exhibit accessibility rather than full omni-directional access.

Our specific aim in this paper is to experiment with a feedforward net design that appears to have potential to provide at least limited accessibility in a rank 3 situation. When we move to feedforward networks trained by error backpropagation, we hope to preserve the accessibility property that is characteristic of symbolic nets. The model resembles an auto-encoder but has restricted connectivity.

Architecture of the network

The particular backpropagation network we used to test for accessibility consisted of the following components: 15 input units, 15 hidden units and 15 output units. The 15 input units were used to represent 3 items or patterns, each made up of 5 elements. The hidden and output units also each consisted of three groups of 5 units, connected as shown in Figure 2. The input patterns represented relational instances of the form RELATION(SUBJECT, OBJECT). The target output contained the same information: namely, RELATION, SUBJECT and OBJECT.

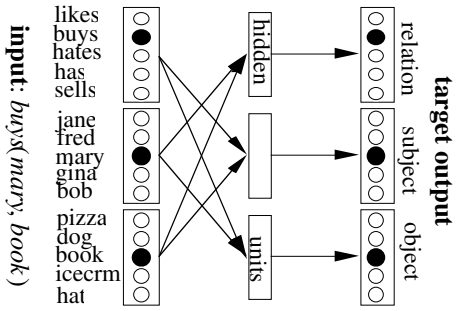

Figure 2 - Connections in our feedforward net architecture.

Notice that this network consists of three functions: one takes as inputs a relation name and a subject, and produces an object as output, the second takes relation name and object and produces subject as output, and the third takes subject and object and produces relation name as output. Thus, while it resembles a traditional auto-association net, note that regular auto-association nets allow connection paths between corresponding input and output neurons, typically allowing total interconnection between input and hidden layers, and between output and hidden layers. In essence, the network architecture can be unraveled into 3 distinct networks that share common inputs. Thus, any weight in the network is influenced by the output errors in only one of the 3 output sets (relation, subject, object). The net makes learning easier by constraining the learning algorithm to look for sets of weights that, for example, ignore predicate input when trying to infer predicate output from argument input. We also conducted some pilot studies with a fully connected network and the network's performance was inferior.

Notice that both the tensor product net architecture and the architecture we are studying here have three groups of input and three groups of output nodes.

Experimental design

The network was given three different sets of relational instances to learn. Each set was made up of five different relational instances. For example, given the relational instance *likes(jane,pizza*), *likes* is the RELATION, *jane* is the SUBJECT and *pizza* is the OBJECT. The training sets varied in terms of the amount of overlap or the degree of interaction between the elements of each of the five relational instances. Training set 1 was set up to contain little or no overlap between the different relational instances. Training set 3 consisted of five relational instances with a large degree of interaction between the different instances. Training set 2 contained an intermediate degree of overlap.

It was hypothesized that relational instances with the least amount of interaction between the different instances would be the easiest to learn. This is because each instance does not have components that overlap with the other instances. These relations are one-to-one mappings. Accordingly, the network is most likely to achieve success in learning such a set of facts. In contrast, the set of relations with the highest level of overlap is expected to be the most difficult for the network to learn. These relations can be classified as many-to-many mappings, and so cannot be completely learned by a feedforward network. Accessibility may be easier to obtain if each relational instance can be represented in isolation, with little or no reference to the other relations. As the overlap and interaction between the relations and their elements increases, so the degree of accessibility that can be obtained is likely to decrease. This is because information from other related instances is more likely to interfere, when the system is presented with queries.

The software used to run the simulations described in this paper is Tlearn v1.01 (Plunkett & Elman, 1997). Other simulators were also used and similar results were obtained. The settings used included a learning rate of 0.1, momentum set to 0 (the default) and an initial weight range of -0.5 to 0.5.

Training set 1

In this simulation, the network was trained on five relations that have no overlap. Each relational instance consisted of a unique OBJECT, SUBJECT and RELATION. Within each relational instance, each field or argument was represented by a 1-out-of-5 localist encoding. The first five relational instances (and their associated patterns) that were given to the network to learn are shown in Table 1. Figure 3 (see training set 1) contains a graphic representation of the relational instances and their relationships (or in this particular case, their lack of relatedness).

The system was trained for 20 000 epochs. At around 4000 epochs the error curve smoothed close to zero. In other words, the difference between the target and the actual output values was negligible.

Table 1 — The instances and patterns in training set 1.

Relational instance	*Action*	*Subject*	*Object*
likes(jane, pizza)	10000	10000	00100
buys(fred, book)	01000	01000	00010
hates(mary, dog)	00100	00100	00001
has(gina, icecrm)	00010	00010	10000
sells(bob, hat)	00001	00001	01000

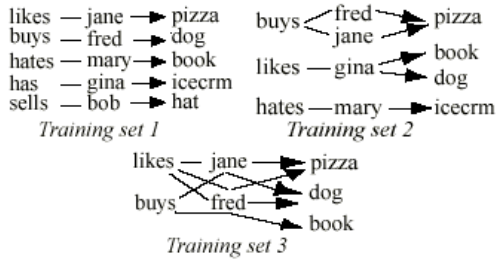

Figure 3 - Graphical representation of 3 training sets.

The system was then presented with a set of test patterns to assess the degree of accessibility that could be obtained (refer to Appendix 1, test pattern set 1). For example, to present the query *likes(jane,X)* the RELATION and SUBJECT input units were set to the patterns for *likes* and *jane* respectively, and the OBJECT input units were set to all zeroes, i.e. the *'X'* is represented by '00000'. Then the OBJECT outputs were inspected. All of the outputs were checked to see if they matched the target values. If the correct number of output units that should be on is N, then a value of 3/(5N) or greater for an output unit is considered to be on, a value of 2/(5N) or less is considered to be off and any values in the region between 2/(5N) and 3/(5N) can be seen to be "partially on". The output thus falls into one of three categories: 1) Either the output is *correct* and all of the outputs units are correctly on or off (as defined above), or 2) The output is *incorrect* and at least one output unit that should be on is clearly off and vice-versa, or lastly, 3) The output is *uncertain* or partially correct, and output units that should be on are only "partially on". For example, if *likes(fred,pizza*) and *likes(fred,dog)* are facts, then if presented with the query *likes(fred,X)*, the answer would be pizza and dog, i.e. N=2. Therefore, the units representing both dog and pizza need to be on and a value of 0.3 (3/(5N)) or greater for both units is needed for the answer to be accepted as correct. Moreover, output units that need to

be off should be less than 2/(5N) or in this case less than 0.2.

With training set 1, correct scores were obtained for all of the test queries. The system was able to handle all of the single and double query test patterns. Therefore, overall an excellent degree of accessibility was achieved with the first training set.

When there is little or no overlap between the elements of the relational instances, the system is able to learn and access elements of the relations with ease. This would correspond with human learning, where the less related information is to other information, the easier it is to understand and learn (Marcus, Cooper & Sweller, 1996; Sweller, 1994).

Training set 2

The next training set the system was given to learn had a higher degree of interaction between the relational instances and their elements than training set 1. In particular, both Fred and Jane like pizza and Jane buys both dogs and books. For the first two instances the same OBJECT is liked by two SUBJECTS and can be characterized as a many-to-one mapping, and for the last two instances the same SUBJECT buys two different OBJECTS, a one-to-many mapping. In contrast, *hates(mary,icecream)* is the only instance that does not overlap with the other four, and is a one-to-one mapping. The OBJECT and SUBJECT in this instance are unique and are not contained in any of the other instances. The five relational instances contained in training set 2 are shown in Table 2. The overlap or interrelations between the elements of the relational instances can be seen graphically in Figure 3 (see training set 2).

The system was trained for 20 000 epochs. At around 2000 epochs the error stabilized at around 0.6 in terms of Tlearn's error measure. The trained net transformed the training patterns as follows:

input		*output*
likes(jane, pizza)	→	likes(fred+jane, pizza)
likes(fred, pizza)	→	likes(fred+jane, pizza)
buys(gina, book)	→	buys(gina, book+dog)
buys(gina, dog)	→	buys(gina, book+dog)
hates(mary, icecrm)	→	hates(mary, icecrm).

It can be seen that the four (related) assertions have now been combined into two assertions. What has been learned is intelligible - *likes(gina,book+dog)* is easy to interpret as signifying that gina likes both books and dogs.

A set of test patterns (see Appendix 1, test pattern set 2) was then given to the system to assess performance on the accessibility property. All output units were then inspected to see if they matched the target units. Using the scoring criterion described above, output patterns were either considered to be 1) correct, 2) incorrect or 3) uncertain. All of the queries with a single unknown element were correctly answered by the system and some of the queries with two unknown elements were correct. None of the queries were considered incorrect, however, four queries obtained uncertain or partially correct scores. These queries were *likes(X,Y), buys(X,Y), X(gina,Y),* and *X(Y,pizza)*. It is interesting to note that all of the responses of questionable correctness need to access information that is contained in more than one relational instance, i.e. information from the many-to-one and one-to-many mappings. For instance, the answer to *likes(X,Y)* is that both Fred and Jane like pizza. This can be clearly expressed in the representation available, but the trained system does not do so. Thus although, accessibility is still relatively good, the net struggles with the queries that access information that has to be integrated from two relational instances.

Table 2 — The instances and patterns in training set 2.

Relational instance	*Action*	*Subject*	*Object*
likes (jane, pizza)	10000	10000	00100
likes (fred, pizza)	10000	01000	00100
hates(mary,icecrm)	00100	00100	10000
buys (gina, book)	01000	00010	00010
buys (gina, dog)	01000	00010	00001

We also tried training the network with the 3 patterns: *likes(fred+jane,pizza*), *buys(gina,book+dog*), and *hates(mary,icecream*), that is, the 3 outputs the net just discussed (call it net 2A) produced in response to the training patterns. The network rapidly learned these patterns, not surprisingly. We tested this network (net 2B) on the queries shown in Appendix 1, test pattern set 2, and found that it had inferior accessibility performance compared with net 2A.

The greater number of uncertain or partially correct scores obtained during testing, for training set 2 (net 2A) reflects the fact that these five assertions may be considered harder to learn. These findings suggest that as the degree of overlap between the relational instances and their elements increases and as the amount of related information that needs to be considered at once increases, so the level of accessibility that the system can cope with, decreases. This corresponds with our understanding of difficulty associated with learning for people. The more interactivity there is between different learning elements, the harder information is to learn (Sweller & Chandler, 1994). The more difficult it is to learn information, the harder it is to transform and use that information. It thus appears, that as the information becomes more complex and so more difficult to learn, the backpropagation system struggles to achieve a

reasonable level of accessibility. The next training set supports this hypothesis.

Training set 3

The last training set has the highest degree of interaction between the relational instances and their elements. The relational instance *likes(fred,pizza)* overlaps with two other instances. The SUBJECT *fred* performs the RELATION *likes* on both the OBJECTS *dog* and *pizza*, a one-to-many mapping. Also, both SUBJECTS *fred* and *jane* perform the RELATION *likes* on the same OBJECT *pizza*, a many-to-one mapping. The five relational instances contained in training set 3 are shown in Table 3. Figure 3 (see training set 3) contains a graphic representation of the relational instances and their interrelatedness.

Table 3 — The instances and patterns in training set 3.

Relational instance	*Action*	*Subject*	*Object*
likes (jane, pizza)	10000	10000	00100
likes (fred, pizza)	10000	01000	00100
likes (fred, dog)	10000	01000	00001
buys (fred, book)	01000	01000	00010
buys (jane, dog)	01000	10000	00001

The system was trained for 20 000 epochs. At around 3000 epochs the error stabilized at around 0.7 in terms of Tlearn's error measure. It should be noted that *buys(fred,book)* and *buys*(*jane,dog)* each have at most one attribute in common with the other instances. The trained net transformed the three more overlapping instances as follows:

input *output*

likes(jane, pizza) → likes(fred+jane, pizza)

likes(fred, pizza) → likes(fred+jane, pizza+dog)

likes(fred, dog) → likes(fred, pizza+dog).

Notice that from this output, there is no way to interpret these instances without inferring that Jane also likes dogs. The whole is not truly equivalent to the sum of the parts, which in this case are the three (and not four) given relational instances. Thus the pattern *likes(fred+jane,pizza+dog)* even if it were valid, would be unintelligible (in contrast to *likes(gina,book+dog)* in training set 2).

The test patterns shown in Appendix 1 (test pattern set 3) were used to test the trained net for accessibility properties. As before, output units were inspected to see if they matched the target units. Using the scoring criterion described above output patterns were either considered to be correct, incorrect or uncertain. All of the queries with a single unknown element were correctly answered by the system. However, only two of the queries with two unknown elements were correct. The two correct queries were *X(Y,dog)* and *X(Y,book)*. The rest of the queries with two unknown elements were incorrect. These queries all access information from more than one relational instance. For example, the query *X(jane,Y)* should have a response of *likes+buys, pizza+dog*. However, the system's response to this query is only *buys, pizza+dog*. As with all the other incorrect queries, some of the relevant information has been lost. It appears that as the information becomes more and more overlapping, the network finds it harder and harder to handle queries that access related elements of information. This type of network appears to be more suited to dealing with one-to-one relations, rather than many-to-many mappings.

Training set 4

A fourth training set was given to the system to learn. It consisted of the relational instances *likes(jane,pizza), likes(fred,pizza), likes(fred,dog), buys(fred,dog),* and *buys(jane,book)*. The amount of overlap between these instances, and the test results, fall somewhere between training sets 2 and 3. All the single unknown element queries were answered correctly. Three of the two unknown element queries were answered correctly, two were uncertain and two were incorrect.

Conclusion

As the degree of overlap between the arguments and predicates of the relational instances in the training set increases, the degree of accessibility provided by the nets simulated decreases. It is well-known that when trained on data that corresponds to a one-to-many mapping, the activations of the output units corresponding to the "many" will be reduced in comparison to a one-to-one mapping. To us, the interesting thing is the effect of argument and predicate overlap on accessibility, and the fact that beyond some critical level of overlap, the trained net starts to produce "generalizations" which, seen from the relational-instance point of view, mean that the net has learnt false propositions e.g. *likes(jane,dog*).

By way of contrast, tensor product networks (Halford et al., 1998) provide full accessibility for arbitrary sets of relational instances, and do not lose critical information when tested.

Backpropagation nets can handle propositional information that is in the form of distinct functions. For example, the model of Rumelhart and Todd (1993) handles propositions such as "canary can fly" in the sense that, given an input "canary can" it produces the output "fly". However, it was not tested for the accessibility property. Our backpropagation net was tested for accessibility, but succeeded in only a limited sense. It could only handle queries to data sets that are relatively simple, in terms of the overlap and relatedness of information. As the relational instances

in the data set become more and more related, so accessibility deteriorates. Consequently the net could not model propositional knowledge adequately. In contrast, a tensor product net can process more complex data sets and still have full access to all the elements of the relational instances.

In a sense, it is not surprising that a backprop-trained net does not do as well at this task - backprop tends to do well at perceptual tasks where generalization of an interpolative type is useful, whereas the data used in this is discrete. Since their introduction, backprop nets and variants have been used in cognitive modeling tasks including those concerned with discrete relational knowledge (Hinton, 1986; Rumelhart & Todd, 1993). This paper has attempted to explore the boundaries of applicability of such models.

What has come out in the wash is evidence from the model's performance of a new dimension of task difficulty. This dimension measures component overlap in a set of facts to be learned. This type of difficulty seems to correlate with model performance at the boundary between rank 1 and rank 2 tasks (in the sense of Halford et al., 1998).

It is clear that humans do have accessibility with respect to their relational knowledge. What might be interesting to investigate is whether they have greater difficulty learning sets of facts like those in training set 3 than those in training set 1, and whether accessibility also takes longer to develop (see Sweller & Chandler, 1994 for a discussion of element interactivity and its effects on learning).

Acknowledgments

This work was supported by a grant from the Australian Research Council. We wish to acknowledge helpful discussions with Steve Phillips, and helpful comments made by a reviewer of a previous version of the paper.

Abstract

Empirical results on the meaning of accented pronouns often conflict. This is a problem for formal semantic models. In this paper, we intend to broaden the empirical basis of two of these models. First, in a corpus study, we checked whether properties of the antecedent influence whether a pronoun is be accented. We found that pronouns with NP antecedents are more likely to be accented than those with pronominal antecedents. In a production experiment, we investigate whether accented pronouns signal topic shifts. Although this effect is present in our data, it is very weak. We conclude that a comprehensive model of pronoun accentuation will need to account for the fact that in most cases, that accent appears to be optional. In fact, most instances of accented pronouns in our data could be explained as signs of a rhetorical contrast.

Introduction

In order to interpret a personal pronoun, a listener needs to determine which discourse entity or entities the pronoun specifies. Since pronouns themselves carry very little semantic information, the listener needs to tap into a variety of information sources in order to find out which discourse entity a given pronoun specify: lists of salient discourse entities, grammatical conventions, discourse structure, assumptions about the discourse model of the speaker, and so on.

Formal work on pronoun interpretation has focussed on written language. In this paper, we explore how the insights gained so far can be translated to speech, where phrasing and accentuation might provide important cues to resolution algorithms. Most semanticists take accent on pronouns to signal somewhat "unusual" resolution strategies. In particular, accented pronouns are assumed to signal topic shifts. But do the theories developed so far describe successfully how accented pronouns actually used in speech? This is the question we ask here.

Our paper is organised as follows: First, we sketch the theoretical basis of our analyses, the work of [Nakatani, 1997] and [Kameyama, 1997]. Then, we explore to what extent the patterns postulated by the theories can indeed be found in corpus data and experimental data. Finally, we discuss the consequences of our results for semantic and cognitive approaches to resolving accented pronouns.

Theoretical Claims

It is not clear what exactly speakers mean when they accent a third person personal pronoun. Some people apparently accent a pronoun if the distance in clauses between pronoun and antecedent is larger than usual [Givón, 1983]. A number of sample discourses that have been discussed extensively in the literature [Kameyama, 1997, Beaver, 2000] show that when substituted for their unaccented counterpart in a given discourse, accented pronouns are frequently resolved to a different discourse entity. In the following example, most listeners would resolve the unaccented pronoun in (2) to Ian, whereas the accented pronoun in (3) would be resolved to James.

(1) Ian$_i$ often meets James$_j$ for dinner.
(2) He$_i$ prefers Italian restaurants.
(3) HE$_j$ prefers Italian restaurants.

We will now examine two theoretical analyses of accented pronouns.

Nakatani: Shifts in Attentional State

Christine Nakatani develops a model of stressed pronouns in terms of attentional state [Nakatani, 1997]. Her framework is Centering Theory [Grosz et al., 1995]. The goal of Centering is to develop a theory of *local* discourse structure, i.e. to describe what makes a discourse segment coherent. From a psycholinguistic point of view, Centering models how the attentional state of speaker and hearer change during a discourse. Each attentional state contains a set of discourse entities which are the current "centers" of attention – hence the name "Centering".

In the Centering model, each sentence is associated with a list of the discourse entities which have been realised in that sentence. These discourse entities constitute the list of *forward-looking centers*. The forward-looking centers are ranked according to their salience. The most salient center on the list is called the *preferred* forward-looking center C_p. The most salient entity of the previous utterance U_{n-1} that is realised in the current utterance U_n is the *backward-looking center* C_b. Each sentence has at most one C_b. Transitions between sentences can be classified according to two criteria:

1. whether the backward-looking center of the current sentence is the same as that of the previous sentence

$(C_b(U_n) = C_b(U_{n-1}))$

2. whether the backward-looking center of the current utterance is also the most salient entity of that utterance, i.e. the preferred forward-looking center $(C_b(U_n) = C_p(U_n))$

When the C_b is both maintained and $C_p(U_n)$, we get a *continue* transition. When the C_b is no longer $C_p(U_n)$, the transition is classified as a *retain*, and when the C_b changes, we have a *shift* transition. [Brennan et al., 1987] introduce two kinds of shifts: in *smooth* shifts, the new C_b is also C_p, in *rough* shifts, the new C_b is not the most salient entity in the utterance.

In order to determine the connection between accented pronouns and attentional state, Nakatani analysed a monologue by a gay male native speaker of American English in terms of local and global discourse structure. She found 25 accented subject pronouns; accented object pronouns were even rarer. Of these, 7 occurred when the transition was a smooth shift, and 9 co-occurred with shifts to the backward-looking center of the preceding discourse segment. 6 of the 9 remaining cases were contrastive, 3 required limited inference. Within the Centering framework, accent on a subject pronoun means that the speaker has shifted to a new C_b, to a new "main center of attention". Whether the C_b comes from the same or the preceding segment appears to be irrelevant. The results of [Brennan, 1995] support this analysis. In her spontaneous monologues, pronouns tended to be accented when the antecedent was not the backward-looking center.

Kameyana: Competing Influences

In contrast to Nakatani, [Kameyama, 1997] presents an integrated model of pronoun resolution that draws on several sources. Her approach has the advantage that it sits well with current constraint-based approaches to linguistics such as Optimality Theory [Prince and Smolensky, 1993].

Centering Theory provides the backbone of Kameyama's work: the discourse entities of each utterance are grouped into a partially ordered list, and when a pronoun occurs, it is resolved to the most salient discourse entity in the preceding utterance that is mentioned again in the current utterance. Kameyama calls this discourse entity the *center*. The salience of the discourse entities in an utterance is determined by several potentially conflicting factors. In Kameyama's algorithm for pronoun resolution, the first step is to filter out all referents in the attentional state which violate the highest ranked syntactic and semantic constraints. An example for such a high-ranking syntactic constraint is agreement: masculine personal pronouns in English usually refer to male persons.[1] Then, parallelism, attentional structure (salience), and commonsense inference conspire to yield a basic preference order on the remaining referents which are compatible with the pronoun. The most highly ranked entity on that list becomes *center*, the preferred antecedent for a pronoun in the next sentence.

When the pronoun to be resolved is accented, this reverses the preference order imposed on the list of potential antecedents: the accented pronoun is then taken to refer to the least prominent DR on that list. Note that the order is only reversed *after* high-ranking syntactic and semantic constraints have been considered, so that the antecedents still in the list are indeed viable alternatives. Kameyama thus predicts that accentuation will have no effect when there is only one potential antecedent. She also predicts that stressing the pronoun will not resolve any ambiguity if all potential antecedents are equally salient.

In her paper, Kameyama focusses on two factors that affect salience: the form of the antecedent, which is captured by the *exp order* hierarchy, and the syntactic function of the antecedent, which is captured by the *gr order* hierarchy. On the *exp order* scale, pronouns are more salient than definite NPs, while on the *gr order* scale, subjects are more salient than direct objects, which are in turn more salient than indirect objects or adjuncts. The most salient discourse entity in U_{n-1} is the most likely antecedent for a pronoun in U_n. For example, Kameyama predicts that if a subject pronoun can be resolved to both the subject and the object of the preceding sentence U_{n-1}, and if both subject and object are definite NPs, then the pronoun in U_n will be resolved to the subject of U_{n-1} if it is not accented, and to the object if it is accented, because the subject is more salient than the object.

Bender, Mayer, and Dogil tested that prediction for German [Bender et al., 1996]. They synthesised various short discourses consisting of two sentences. The first sentences had SVO structure; in the second sentence, the subject was pronominalised. In half of the discourses, the second sentence also contained an object pronoun. The subject pronoun was either unaccented or bore one of a number of potential pitch accents. In a 60-minute experiment, listeners were presented with all possible combinations of discourses. For each discourse, they had to indicate the correct interpretation by pointing to a picture. There were four alternatives per discourse. One picture depicted the situation where the pronominal subject of U_n was resolved to the subject of U_{n-1}, one the situation where the pronoun was resolved to the object of U_{n-1}. The other pictures were distractors. They found that the listeners almost never resolved the pronoun to the object NP, even if it was accented. The experiments can be criticised on numerous counts. In particular, the prominence relations between subject and object in the target sentence may not have been realised appropriately [Mayer, 1997]. Still, the experiment demonstrates that the influence of accentuation on pronoun resolution might be more subtle than introspection and corpus studies suggest.

[1] Cases in which that constraint is violated, e.g. females are mistaken for males, are comparatively rare.

Conclusion: Which Evidence is Needed?

The evidence we have surveyed in the preceding paragraphs is conflicting. On one hand, the contexts in which accented pronouns occur do differ markedly from those in which unaccented ones occur. However, it is still not clear what the main function of a pitch accent on a pronoun is. Nakatani's and Brennan's speakers consistently used them to mark what we term "topic shifts"[2] , and Givón's speaker uses accents to mark that the discourse entity the pronoun co-specifies with was last mentioned two or more clauses ago. On the other hand, the listeners of Bender, Dogil, and Mayer apparently did not care whether a pronoun was accented or not, they just went for the default interpretation.

In order to untangle this confusion, we first of all need to supplement the published data with other analyses from a variety of speakers with different socio-cultural backgrounds. In this paper, we report results from two main lines of attack, corpus analyses and production experiments. First, in an analysis of the speech of American radio news readers, we tested some hypotheses that follow from Kameyama's theory. Second, we conducted a production experiment to check to what extent topic shifts influence whether a pronoun will be accented or not.

The Influence of *gr order* on accentuation

Goal of the Study

The goal of this corpus study is to determine some basic conditions under which subject pronouns can be accented. To this end, we examined three speakers from a large corpus of read speech, the Boston University Radio News corpus [Ostendorf et al., 1995]. Since our data comes from read speech, the results may be affected by the speakers' varying ability to read aloud—just as the monologue data is affected by the idiosyncrasies that the speakers exhibit in their speech.

The part of Kameyama's theory that is worked out in detail in [Kameyama, 1997] makes predictions about the accentuation of subject pronouns in cases where the antecedent occurs in the preceding sentence. The main problem with testing her hypotheses on corpus data is that in our radio news texts, almost all potentially ambiguous pronouns are disambiguated semantically by the sentence they occur in. Therefore, we can only examine to what extent violations of the two constraints *gr order* and *exp order* can predict whether a pronoun is accented.

Data

We chose the Boston Radio News Corpus because it is widely available and widely used in the speech community. It provides ToBI-labelled samples of seven professional American newsreaders who worked for the Boston, Mass., radio station WBUR at the time of the recordings. From the corpus, we analysed the prosodically annotated radio stories from three speakers, `f2b`, `m1b` and `m2b`. All speakers write their own copy. Table 1 provides summary statistics about the texts we used.

Table 1: Overview of Radio News Texts

Speaker	`f2b`	`m1b`	`m2b`
No. of Texts	32	9	4
No. of Sequences Analysed	229	45	19
No. of 3rd Sg. Pron. Subj. in U_n	122	22	8
% of These Accented	38.5%	32.8%	0

We look at sequences of two units, U_{n-1} and U_n. Following [Kameyama, 1998], our units are tensed clauses, with one exception: tensed relative clauses that modify NPs are assigned to the unit they occur in. We excluded all sequences of two units where the antecedent of the subject did not occur within the analysis window. This ensures that our analyses is restricted to just those contexts for which the theory we are testing can make any predictions. All sequences that conformed to our criteria were labelled according to four features, *grammatical function* of the antecedent in U_{n-1} (subject, object, adjunct), *form of the antecedent* in U_{n-1} (zero/pronoun/other), *form of the subject* of U_n (zero/pronoun/other), and *accentuation of the subject of* U_n (yes/no). [3] The annotations were performed by one of the authors, a trained linguist, and cross-checked by the other.

Since the brief reports we are dealing with here frequently present conflicting views and opinions on a certain topic, sentence topics are rarely maintained over several units. Secondly, many sentences are constructed according to the pattern "X said that Y", where, strictly speaking, "X said" and "Y" are separate clauses. The reason for this is that the journalistic code of conduct requires journalists to name the source of their information. `f2b`, who writes her own news copy and supplied most of our data, is particularly conscientious in this respect. Therefore, when the current or previous clause is of the form "X said", we extend our window of analysis to include U_{n-2}. Finally, in comparison to spontaneous speech, these speakers "overaccent". This is part and parcel of the distinctive, neutral speaking style is required of news readers. Hence, our results are restricted to a specific communication situation.

Results

The results are summarised in Table 2. Speakers do not tend to accent pronouns when their antecedent is not the subject (Fisher's exact test: $p<0.6$, df=1). Instead, the form of the antecedent, which is covered by Kameyama's *exp order* constraint, exerts a significant influence: whereas 40% of all subject pronouns with NP antecedents are accented, only 18.5% of pronouns with pronominal antecedents carry a pitch accent (Fisher's exact test: $p<0.05$,df=1). This result is surprising, given

[2] Following [Beaver, 2000], we make a terminological shift here and interpret C_b as the *topic* of a sentence.

[3] We did not calculate κ for our annotations since the features are extremely straightforward.

Table 2: Accentuation of 3rd Pers. Sg. Subject Pronouns

	subject	*other*	**total**
pronoun	58%	0.00%	18.5%
not pronoun	41%	22.73%	40%
total	37%	29%	36%

that most formal models operate heavily with salience orderings based on grammatical roles.

A further analysis reveals that although most of these accented pronouns cannot really be analysed as topic shifts, most are involved in some sort of contrast. Take for example text `s14`, read by `f2b`, which is about two democratic contenders for the post of state attorney. It has the highest number of stressed pronouns of all texts, five. In four of these cases, the accented pronoun implies a contrast between the two candidates. Only two of the accented pronouns occur in explicit contrasts. In the two other cases, the accent on the pronoun highlights a potential contrast between the two candidates, the exact nature of which has to be inferred from the text.

Does Accent Signal a Topic Shift?

Kameyama predicts that a subject pronoun in an utterance U_n should be accented if it co-specifies with the object of U_{n-1} only if a higher-ranking discourse entity in U_{n-1} would also be a possible antecedent. If there is only one possible antecedent, there should be no accent on the subject pronoun, because it does not make sense to re-order a list with only one element. On the other hand, Nakatani's data shows that speakers may accent pronouns to mark a topic shift. So, if the main motivation behind accent on pronouns is to signal topic shifts, we would expect speakers to accent pronouns even if they can be resolved unambiguously to the correct antecedent. If accent is a cue to topic shifts in general, we would expect a similar effect when the new topic is expressed by a definite NP.

We examined these questions in a small production experiment. The main hypothesis was that accent is a cue to topic shifts in general: if the subject of U_n co-specifies with the object of U_{n-1}, it is accented, but not when it co-specifies with the subject—even if subject and object differ in gender. We also wanted to find out whether that effect is stronger for pronouns than for full NPs, since the presence of a full NP in subject position is in itself a sufficient cue to a topic shift.

Design

In order to test our hypotheses, we created a set of four-sentence discourses. The first sentence in each discourse, S1, introduces a person P1 in subject position with a proper name. In the second sentence, S2, P1 appears again in subject position, and a second person, P2, is introduced in object position with a proper name. Both persons differ in gender.

The third sentence, S3, is the key sentence. Its structure is varied according to the two variables SHIFT and PRO:

SHIFT: The subject of S3 is either P1, i.e. the subject of S2 (+ SHIFT), or P2, i.e. the object of S2 (- SHIFT)

PRO: The subject of S3 is either a pronoun (+ PRO) or a semantically empty definite NP (- PRO), "the girl" for female, "the guy" for male referents.

Combining these variables yields four experimental conditions: +SHIFT+PRO, +SHIFT-PRO, -SHIFT+PRO, and -SHIFT-PRO

Apart from the subject, no other discourse entities from S2 are mentioned in S3. This way, we avoid potential violations of Centering's definition of C_b, which states that the highest-ranked center of U_{n-1} that is realised in U_n is the C_b of U_n. The final sentence, S4, maintains the subject of S3. The subjects of S2 and S4 are always pronouns. The key sentences S2 and S3 contained no left-dislocated arguments, and the subject in sentences S2 and S3 is always an agent.

We kept the structure of the sentences as simple as possible so that the subjects had less trouble reading them out loud. We also changed the content of S3 and S4 depending on the subject, so that the discourses were both semantically and syntactically unambiguous. There are four possible combinations of conditions, and for each of these combinations, we created three discourses. A sample set of discourses is given in Figure 1.

Method

We divided these discourses into four lists of six discourses each, so that each list contained each condition at least once. Each of these lists was mixed with a list of discourses for two other experiments on intonational meaning and presented to five readers, yielding a total of 20 subjects. We limited the number of discourses per speaker because the experiment was interleaved with two other production experiments and we aimed to keep the total duration of the experiment below twenty minutes, in order not to strain our subjects' voices too much. Because of the small scale of our study, we unfortunately cannot present data on subject-specific variation. All in all, we collected 120 discourses, 30 per condition.

All of our subjects were undergraduates at Stanford University who did not major in Linguistics. One or two of the subjects had a slight cold. Although their mother tongue was American English, they came from different parts of country. They were paid for their participation at a standard rate of $10 per hour. The discourses were recorded in a sound-deadended room. Before the recording was started, the subjects were asked to read through each dialogue. The list of discourses to be analysed later was preceded by four practice discourses. Each discourse was printed in large type on a separate page. The subjects were instructed to read each discourse silently first, make sure they understood what was meant, and then read it out aloud as if they were talking to a friend.

Figure 1: Sample set of four discourses with P1=Julia, P2=Nathan

S1: Julia$_{P1}$ went to a bar last night.
S2: She$_{P1}$ chatted with Nathan$_{P2}$ for a while.

		-SHIFT	+SHIFT
+PRO	S3	**She**$_{P1}$ also spent some time at the bar.	**He**$_{P2}$ had been waiting for this chance for ages.
	S4	Afterwards, she$_{P1}$ was really tired.	He$_{P2}$ had always thought that Julia$_{P1}$ was a nice girl.
-PRO	S3	**The girl**$_{P1}$ also spent some time at the bar.	**The guy**$_{P2}$ had been waiting for this chance for ages.
	S4	Afterwards, she$_{P1}$ was really tired.	He$_{P2}$ had always thought that Julia$_{P1}$ was a nice girl.

None of the subjects reported any difficulties in understanding any of the discourses.

Due to misreadings which were not caught at the time of the recordings, five discourses had to be discarded, which leaves us with a total of 115 discourses. We then randomly discarded another seven discourses, in order to achieve an equal number of samples in each condition. This brings the total number of instances per condition down to 27.

We analysed the discourses both acoustically and perceptually. On the acoustic level, we computed mean, maximum, and range (= maximum F0 - minimum F0) of the logarithm of F0 for all subjects of the third sentence of each discourse. This transformation yields an approximately normal distribution of F0 values. F0 was computed using the `get_f0` program of Entropic ESPS Waves [4] We transformed mean, maximum and range to z-scores based on the mean and standard deviation of a speaker's F0 during the current discourse. These z-scores were then submitted to a statistical analysis. We assume that accentuation will lead to a higher F0 maximum and a higher mean F0. We did not compare durations, since we did not find a satisfactory normalisation procedure.

On the perceptual level, we determined for all discourses whether the subject of S3 was accented, and whether it had been reduced. The definite NPs count as reduced if a speaker has shortened the nucleus of "guy" or "girl"; the pronouns count as reduced if a speaker has replaced the high front vowel of the citation form with a central vowel. These criteria allow for a wide range of dialectal and idiolectal variation in the realisation of the vowels in the target nouns and pronouns. All judgements were made by a trained phonetician; the transcriptions were checked using sonagrams and pitch contours. Table 3 summarises the frequency of accentuations and reductions of each word. The nouns are almost always accented, and rarely reduced. The pronoun "she" is reduced often, sometimes to just the alveopalatal fricative /ʃ/, and rarely accented.

Results

First, we examine the acoustic results. If our main hypothesis is correct, then both nouns and pronouns should be more prosodically prominent when SHIFT is violated.

[4]The target words were almost never spoken with creaky voice, although the register occurs frequently in our data: almost all female speakers use it to mark the end of a sentence.

Table 3: Frequency of accentuation and reduction

	girl	*guy*	**nouns**	*he*	*she*	**pron.**
total	25	29	54	23	31	54
% red.	24%	17%	20%	30%	64%	50%
% acc.	100%	97%	98%	26%	13%	18%

That is, mean and maximum F0 should be higher when the constraint is violated. The raw means presented in Table 4 support this hypothesis for pronouns, but not for nouns. Although the average F0 on pronouns in the +SHIFT-condition is about as high as the average F0 of nouns, this is not necessarily due to a pitch accent. Rather, what we have in many of these cases is a high onset, which is often used to mark paragraph boundaries. For definite NPs, the effect appears to be *reversed*; here, F0 is higher when the topic is maintained than when it shifts.

However, the clear tendencies in Table 4 are not statistically significant. Since the data are not normally distributed, we used the Kruskal-Wallis test to determine whether the presence of a shift significantly affects F0; the number of degrees of freedom is always 1. The test was computed over z-scores, not over absolute values, because z-scores help factor out a large part of the inter-speaker differences. For nouns, there is no effect of a shift, both for the z-scores of mean F0 (Kruskal-Wallis χ^2=0.0037,p<1) and for the z-scores of maximum F0 (K.-W. χ^2=2.01,p-value<0.2). We also do not see an effect for pronouns at the gradient level, neither for mean F0 (K.-W. χ^2=1.77,p<0.2) nor for maximum F0 (K.-W. χ^2=1.70,p<0.2). There is a slight effect on the categorical level: pronouns are more likely to be accented in cases of topic shift (Fisher's exact test, p<0.1, df=1, power 0.84). In the +SHIFT condition, 30% of all pronouns were accented, in the -SHIFT condition, 8%. Although the percentages appear huge, note that the absolute numbers are small, which leads to the realistic level of p<0.1.

Discussion

The patterns we found in the data suggest the hypothesis that speakers may signal topic shifts by accenting pronouns—or at least by making them more prosodically prominent. However, this cue is restricted to pronouns; if a full NP occurs in the subject position, it need not be

Table 4: Effect of conditions on mean and maximum F0 (in Hz; mean standard deviation)

	-SHIFT				+SHIFT			
	mean F0		max F0		mean F0		max F0	
-PRO	180	54	221	65	179	53	211	62
+PRO	173	77	183	78	199	69	212	85

accented, because the switch from pronoun to full NP is enough.

There are several reasons why these patterns did not turn out to be significant. For one, we need to control the potential emphatic or contrastive foci in S3 more stringently. For example, in the sentence "X had to explain all the algorithms twice." almost all of our subjects stressed "all", "algorithms", and "twice". But the main problem was that speaking styles vary considerably. Some speakers produced very stereotypical, monotonous intonation contours, while others read the discourses almost naturally. Therefore, we will switch to a design based on spontaneous speech in follow-up experiments, which will also incorporate a dedicated speaker factor. The power of the statistical tests, which was between 0.3 and 0.4, will also need to be increased.

Conclusion

What does it mean to accent a pronoun? The data we have examined, both in the corpus study and the production experiment, do not support either Nakatani's or Kameyama's models of pronominal accent. Thus our studies underline the need for further theoretical and empirical work in this area.

In our data, two trends can be discerned: Firstly, any formal semantic theory of accented pronouns needs to deal with the fact that in many cases, this accent may be *optional*. To what extent speaking style influences whether speakers will choose to accent a pronoun, and to what extent accented pronouns aid comprehension, needs to be investigated by future experiments. Secondly, most of the accented pronouns in our corpus data could be interpreted as cues to some sort of contrast. Often, that contrast was not directly obvious from the context; Listeners need to construct a contrast based on their interpretation of a text to accomodate the presence of the accent on the pronoun. We are currently working on an optimality theoretic account of stressed pronouns that incorporates this finding.

Abstract

In this paper we explore the hypothesis that the processes underlying the matching and use of knowledge during counterfactual reasoning are the same as those that underlie reasoning by analogy. We report two experiments which indicate that, in common with analogical reasoning, counterfactual reasoning exhibits the following properties: (i) it is sensitive to systematic structural congruencies between representations; (ii) when background knowledge has to be retrieved before it can be exploited, the impact of structurally congruent background knowledge on the counterfactual inferencing process is mediated by featural commonalities.

Introduction

If it had not been for a young student at the University of Chicago in 1960, the Cuban missile crisis might have escalated to a nuclear war. At first blush this counterfactual sounds absurd, a *non sequitur* – how can there possibly be a link between a single student and the avoidance of nuclear war? It turns out, though, that the assertion isn't quite as far fetched as one might initially think:

> "Not yet twenty-one and too young to vote, the student worked in the Kennedy campaign. He was asked by the local Democratic organization if he would vote on behalf of a dead voter whose name was still on the rolls. He readily agreed and, refusing the small remuneration that was offered, forged the dead voter's signature and voted a straight Democratic ticket. The Illinois vote was close – Kennedy took the state by fewer than 10,000 votes – and critical. Illinois gave Kennedy the necessary electoral votes to win the presidency." (Lebow and Stein, 1996, p.119).

This additional knowledge connecting the student's actions to Kennedy's electoral success allows the rest of the story to fall into place. Had the student – and, crucially, others like him – not forged votes, Nixon may have been elected instead of Kennedy; if Nixon had been elected he would have established a much less liberal administration; a less liberal administration would have responded more forcefully to Khruschev's deployment of missiles in Cuba; and the odds are that this would have led to further military escalation and, ultimately, nuclear war.

This is not a watertight argument of course – the strength of some of the links in the argumentative chain is questionable – but it does serve to make apparent the relation between the two events which at first appeared utterly disparate.[1] And understanding that there is a connection between the existence of a group of students and the avoidance of nuclear war makes the initial counterfactual seem much more plausible than it did before: if those students hadn't existed then we can now see that this might just have tipped the balance in the favour of nuclear war. Background knowledge is clearly crucial to our assessment of counterfactuals, then, but how it is matched and used during counterfactual reasoning?

In this paper we explore the possibility that the processes underlying the matching and use of knowledge during counterfactual reasoning are the same as those that underlie reasoning by analogy. Although there has been extensive research into counterfactual reasoning over the last two decades from a cognitive-functional perspective (for representative overviews see Roese, 1997; Kahneman & Miller, 1986; Byrne & Tasso, 1999), no-one has explicitly investigated the effect of structural congruency on the inferencing process. We report two novel findings in support of the hypothesis that analogical mechanisms do underpin counterfactual reasoning in at least some contexts.

In Experiment 1 we show that an analogical match between background knowledge and a scenario about which subjects have to reason counterfactually significantly boosts their assessments of the soundness of related counterfactual inferences. This suggests that when engaged in counterfactual reasoning subjects rely on systematic structural matches between representations just as they do when making analogical inferences (Gentner, 1983; Holyoak and Thagard, 1995). Furthermore, previous studies in analogical inference and problem solving have found that it is difficult to exploit the information contained in analogies during real-life problem-solving because analogies are typically difficult to retrieve (Gick and Holyoak, 1980; Gentner, Ratterman and Forbus, 1993). In Experiment 2 we add a retrieval requirement to the task investigated in Experiment 1, and show that this same finding also applies to counterfactual reasoning.

Why Analogy?

Theories of counterfactual reasoning agree that similarity plays a core role in determining legitimate inferences – in order to evaluate what would be true if A were the case, it makes sense to consider only the state of affairs that is most similar to the way things actually are, except that in

[1] See Lebow and Stein (1996) for a fuller analysis of the plausibility of this counterfactual sequence of events.

it *A* is true instead of false. This similarity constraint prevents unnecessary or extraneous alterations to the situation under consideration that could otherwise bias the inferencing process, and is what makes counterfactual reasoning distinct from the idle entertainment of hypothetical situations. For example, consider the relatively uncontentious counterfactual 'If this match had been struck, it would have lit'. As it stands this is most likely a true thing to say (depending on the precise context of utterance), but without the similarity constraint one can trivially refute it by making unwarranted changes to the basic situation and hence considering situations where matches are non-flammable, or where all matches are underwater, and so on.

However, despite the central role that similarity plays in theories of counterfactual reasoning, no consensus exists on how it should be defined. Possible world theorists treat it as a primitive partial ordering between possible worlds (Lewis, 1973; Stalnaker, 1968); law-based theorists treat it as the preservation of consequences of natural laws (Chisholm, 1946; Goodman, 1947; Pollock, 1976); whilst others treat it as minimal adjustments to autonomous causal mechanisms represented in dependency structures (Pearl, 2000). These formal characterisations of similarity and the constructs they rely on make no claim to being cognitively plausible, and are furthermore open to charges of underspecification (Lewis, 1973, §4.2; Pollock, 1976, p.17; Fine, 1975; and Bowie, 1979).

In contrast, work on the notion of similarity in cognitive science has concentrated on the empirical testing of concrete proposals about what it means for two things to be similar to one another. One finding is that the shared and distinct features of two representations play an important role in determining their similarity (Tversky, 1977), but more recent work has also shown that the *relational structure* holding between features also affects judgements of similarity (Gentner & Markman, 1997; Love, 2000).

Gentner and Markman (1997) point out the effect of structure on similarity judgements is consistent with the idea that analogical alignment plays a role in the evaluation of similarity. If analogy really does play a role in determining similarity then, given that similarity is so central to counterfactual reasoning, it makes sense to investigate whether analogy plays a role in counterfactual reasoning by testing for effects of structure on the inferencing process. Furthermore, the account of similarity provided by the analogy-based *structural alignment* framework (Gentner, 1983) has several merits from a cognitive perspective.

Firstly, the structural alignment framework has been subject to a program of empirical testing which provides evidence regarding its plausibility as an account of the way that people compare representations (see Gentner & Markman, 1997, for a review). Secondly, the structural alignment process can be modelled computationally (e.g. SME; see Falkenhainer, Forbus and Gentner, 1989) meaning that the processes it relies upon are tractable. The final reason for preferring the structural alignment account of similarity over alternative accounts is that the analogical mechanisms that it is founded upon have been explicitly connected with many other cognitive skills – most relevantly inference (see Holyoak and Thagard, 1995, for a good review of the many applications of analogy) – offering yet further reason to believe that it may also be implicated in the process of counterfactual reasoning at the cognitive level.

	+ Structure	− Structure
+ Features	Literal Similarity	Surface Similarity
− Features	Analogy	First-Order Relations

Table 1: The commonalities each variant category shares with its base in the materials used by Gentner, Ratterman & Forbus (1993).

Given these reasons, the question of whether the same empirical findings about analogical inference can also be identified in counterfactual reasoning tasks is a pertinent one. If commonalities between counterfactual and analogical reasoning could be established empirically, this would undoubtedly be profitable to our understanding of counterfactuals due to the mature status of research into theories and models of analogy.

Previous Work on Analogical Matching

Experiments conducted by Gentner, Ratterman and Forbus (1993) investigated the effect that systematically varying featural and structural matches between two representations of knowledge had on three measures: the *retrievability* of one item given the other as a prime; on assessments of *inferential soundness*[2] between the two items; and on the perceived *similarity* of the two items. Their series of studies used materials consisting of a *base* scenario and four *variants* of this base in the 2×2 design depicted in Table 1. The systematic variation of featural and structural matches in this design allowed the influence of both factors on a range of tasks to be assessed, and results in a taxonomy of four different types of variants to a base: literal similarity (LS), surface similarity (SS), analogy (AN) and first-order relations (FO).

An important finding reported in this series of studies was that the inferential soundness of two domains is determined primarily by the sort of systematic structural congruencies that analogy is sensitive to. Experiment 1 tests whether this result applies to counterfactual reasoning too, by measuring whether analogical matches to background knowledge boost evaluations of the soundness of counterfactual inferences in the same way as they do in analogical reasoning.

An additional finding about analogical inference is that structural matches can only be exploited in the inferencing process if they are first retrieved, which is typically a difficult thing for people to do (Gick and Holyoak, 1980). This suggests another hypothesis that can be tested: if the cognitive processes underlying counterfactual reasoning are really like those underlying analogy, then in contexts that demand retrieval we would expect analogy based inferences to occur relatively infrequently, because the impact of structural matches on the counterfactual inferencing process is mediated by the featural similarities that drive retrieval (Gentner, Ratterman and Forbus, 1993; Ramscar and Yarlett, 2000). This prediction is tested in Experiment 2.

[2]Inferential soundness is defined as the degree to which knowledge about one domain can be used to generate appropriate inferences about another domain.

Experiment 1

Analogy is universally held to be determined by systematic congruencies in the relational structure of two representations. If analogical mechanisms really do underpin counterfactual reasoning then we would expect to find that structural matches support counterfactual reasoning in exactly the same way that they support analogically based reasoning (Falkenhainer, Forbus & Gentner, 1989; Gentner, Ratterman & Forbus, 1993). Moreover, we would expect a simple featural match between a counterfactual reasoning problem and background knowledge to have no such facilitatory effect.

The simplest test for an effect of shared structure as opposed to shared features in counterfactual inference, as predicted by the hypothesis that analogical mechanisms underpin counterfactual reasoning, is to place subjects in two conditions: one in which they have information that counterfactually matches the problem scenario structurally but not featurally (AN condition); and the other in which the opposite is the case (SS condition). The effect of the knowledge on the soundness ratings assigned a counterfactual inference related to the two sets of background knowledge can then be measured relative to a pre-test condition (the *a priori* or AP condition) in which subjects are provided with *no* background knowledge relevant to the counterfactual in question. If counterfactual reasoning really is sensitive to analogical matches then we would expect a significant increase from the pre-test soundness ratings in the AN condition, but no such increase in the SS condition.

Method

Subjects read either the SS or AN match to a base scenario, and were then asked two comprehension questions about it to ensure they had read it properly. They were then asked to read the corresponding base, and reason counterfactually about it: subjects had to rate the soundness of four counterfactual inferences which undid a key event described in the base. Both SS and AN variants were designed to promote the same counterfactual inference by featuring it as the outcome of the sequence of events they described. The relative effect of a featural versus a structural match between the base problem and background knowledge on the inferencing task could therefore be measured by comparing the soundness ratings for the same inference in each condition. Soundness ratings were elicited by asking subjects how likely the counterfactual inference was to be true. Ratings were provided on a 9 point scale anchored by 'extremely unlikely' at the lower end, and 'extremely likely' at the upper end.

Participants Participants were 40 undergraduate students of the University of Edinburgh, completing an introductory course in psychology. All participants were volunteers, and no reward was offered for taking part in the experiment.

Materials The materials were designed to replicate the experimental design used in Gentner, Ratterman and Forbus (1993) as summarised in Table 1, while also being compatible with a counterfactual reasoning task. 5 base descriptions and 4 variant categories for each base (corresponding to the LS, SS, AN, FO categories described earlier) were designed, resulting in 25 scenarios in total. Only the SS and AN variants were used in Experiment 1.

> Ostavia, Grern and Donnol were three neighbouring and hostile states that seemed to take a particular delight in antagonising one another. It wasn't uncommon these days to hear of one country criticising the others, and threatening them with military action. The trouble had begun several decades ago when Ostavia had attacked both Grern and Donnol in a failed attempt to invade them. Since then relations between the three states had gone downhill, and just recently things appeared to be getting even worse.
>
> **Ostavia had recently launched an attack against Grern**, and although resistance was fierce it looked as though Ostavia was soon going to conquer the Grern forces. However, Grern approached Donnol for help in the conflict, arguing that if they didn't prevent the onslaught then Ostavia would be coming for them next. Donnol considered Grern's argument and saw that its conclusion was probably correct. Therefore Donnol sent its troops to reinforce Grern's units, and after an intense struggle the Ostavian attack was repelled. *Soon after, Grern and Donnol formed a long-lasting alliance, and occupied Ostavia enforcing harsh sanctions on its citizens.*

Figure 1: Example base description. The key event for this description is shown in bold type, and the outcome altered in the variant conditions in italics (distinctions were unmarked in experimental materials).

Each base was structured so that it described a key event which led to a specific outcome (see Figure 1 for an example). For each base, four alternative counterfactual outcomes to the actual outcome described in the base were selected (these were the alternatives rated for soundness by subjects). The counterfactual analogy (AN) variant to the base in Figure 1 is shown in Figure 2. The counterfactual inferences corresponding to the example base scenario that subjects had to rate for soundness are also shown, in Figure 3.

Each of the four variants of a particular base was designed to undo the key event described in the base while either sharing or not sharing featural and structural commonalities with it, depending on which of the variant categories it belonged to. All variants in a material set were constructed to end in an identical outcome, different from that occurring in the base of the set (in the example materials shown the four variants ended with some form of reconciliation between the parties involved, instead of the 'harsh sanctions' mentioned in the base). The four variants can thus be regarded as providing different types of background knowledge, each of which could serve to promote the plausibility of the same counterfactual inference. The issue of interest in this paper is how these four categories of background knowledge, and the different ways that they are related to the base scenario, affect subjects' soundness judgements about the counterfactual outcomes they describe.

The four variants to a base were created in the following manner. First, a key event in each base was identified. In those variants to a base in which a counterpart to the key event should be easily discernible (i.e. in the LS and AN structurally congruent variants), the appropriate counterpart was explicitly negated to make it counterfactual to the base with respect to the key event. In those variants in which a counterpart of the key event should not be easily identifiable

A chess-playing craze had recently swept through the inhabitants of Chesterton, and as a result three chess clubs had sprung up in the sleepy town over the last few years. The clubs were, unimaginatively enough, called the Maters, the Gambit Players and the Rank and Filers. Times were hard for the clubs, because there simply weren't enough players to go around. The problems had been started by the antagonistic members of the Maters. Several months earlier the Maters had scandalously offered reduced subscription rates to members of the Gambit Players and Rank and Filers. Since then an air of hostility had descended upon the chess-playing community in Chesterton.

The Maters thought about trying again to gain extra members from the other two clubs, this time by promising them extra facilities as well as reduced subscription rates. **However, eventually the Maters thought this was a bad idea because it seemed too underhand and risky.** Unbeknownst to the Maters, the other two clubs had formed a pact with one another that they would merge and drive the Maters out of town if they tried to steal any of their members again. *However, because the Maters thought better of their plan everyone relaxed a little, and a couple of years later the clubs were on very friendly terms.*

Figure 2: Example analogy (AN) variant. The counterfactual counterpart of the key event is shown in bold type, and the counterfactual outcome is shown in italics (distinctions were unmarked in experimental materials).

If Ostavia hadn't decided to launch an attack against Grern and Donnol, it wouldn't have been defeated in war *and something else would probably have happened*. Rate the following outcomes according to how likely you think they would have been to occur if Ostavia hadn't launched its attack (please circle *one* number for each of the four options):

1. **All three countries would have ended up disarming, and developing friendly relations.**
2. The countries would have organised a yearly carnival in celebration of newfound connections.
3. The countries would have merged under an even greater threat.
4. The countries would not have learnt from their mistakes, and would end up fighting one another again.

Figure 3: Example counterfactual outcomes that subjects were asked to rate for soundness. The inference promoted by the base's four variants is shown in bold type.

(i.e. in the SS and FO conditions, where there is no structural congruity with the base), no event was described that could be construed as being an instance of the key event.

Procedure Subjects were exposed to four of the material sets, two in the SS condition and two in the AN condition. Materials were randomised across subjects, and order of presentation was counterbalanced.

The written instructions to the experiment informed participants that they were taking part in a study investigating general reasoning, and that they were going to be shown a series of scenarios and asked to make some inferences about them. Participants were further told that for each problem they were going to be provided with some background information (this information corresponding to the SS and AN conditions of the experiment), and then asked to reason about a problem scenario. They were explicitly informed that the background information **may** be of use, and that they should only make use of it if they thought it was relevant to the problem in hand.

Pre-test

A pre-test condition was run before Experiment 1 to allow the facilitatory effects of providing various categories of background knowledge to be compared to the case in which subjects are provided with *no* relevant background knowledge. 20 postgraduate students of the Division of Informatics, University of Edinburgh, were provided with the 5 base descriptions in a semi-randomised order, and asked to evaluate how sound it seemed that each of 4 counterfactual alternatives would occur had the key event in each description been undone. Ratings were elicited on a 9 point scale. Two sets of booklets presented all 5 base descriptions and the corresponding counterfactual inferences to be rated in reverse orders to minimise order effects. Subjects were randomly assigned to either of the two booklet conditions.

Results

The mean soundness ratings of the promoted inferences in the SS- and AN-exposure conditions from Experiment 1, along with the pre-test (AP) soundness ratings for the same inferences, are shown in Figure 4. T-testing revealed no significant shift in soundness ratings from the pre-test to the SS condition (Welch's $t = 0.36$, $df = 58.05$, $p > 0.025$, one-tailed). In contrast, soundness ratings did increase significantly from the pre-test to the AN condition (Welch's $t = 2.00$, $df = 58.64$, $p < 0.025$, one-tailed).[3]

Discussion

The results of this experiment indicate that subjects will reason counterfactually on the basis of an analogical match to background knowledge when one is available, and that a featural match to background knowledge alone is insufficient to support a counterfactual inference. The fact that an analogical match to background knowledge makes a counterfactual inference seem more sound shows that people are sensitive to the sort of systematic structural correspondences found in analogy when engaged in this form of reasoning, and therefore supports the hypothesis that analogical mechanisms underpin counterfactual reasoning at the cognitive level.

Experiment 2

Gentner, Ratterman and Forbus (1993) present evidence that in contexts where subjects first had to retrieve knowledge in order to be able to exploit it to make an analogical inference

[3]Both tests involved samples with unequal variances by Levene's test, and hence Welch's corrected t statistic was calculated. Tests were conducted at adjusted α levels to keep the overall risk of a Type I error at the 0.05 level, by solving $1-(1-\alpha)^2 = 0.05$ for α.

(i.e. where relevant knowledge is not presented in association with the base it pertains to as it was in Experiment 1), both structural *and* featural matches play a role in determining the usefulness of that knowledge in the inferencing process. The effect of featural commonalities is introduced because the process of retrieval is sensitive to featural, but not structural, matches (Gentner, Ratterman and Forbus, 1993; Ramscar and Yarlett, 2000). Therefore, if counterfactual reasoning really is similar to analogy at the cognitive level, we would expect the addition of a retrieval requirement to the inferencing task of Experiment 1 to have the following effects.

First, the AN condition should no longer produce a significant boost in soundness ratings compared to the pre-test condition. We expect this because AN matches are typically difficult to retrieve (see, for example, Gick and Holyoak, 1980), and are therefore less likely to be used in the counterfactual inferencing process in this context. Second, the soundness ratings of SS condition inferences should remain the same as in Experiment 1 (because SS materials have high retrievability the additional retrieval requirement should make no difference to the availability of this knowledge in the inferencing process). Third, and finally, the overall pattern of results over the 4 variant categories should exhibit sensitivity to both featural and structural factors, instead of just structural factors as in Experiment 1 (because featural matches facilitate retrieval, which mediates the influence of structure on the inferencing process).

Experiment 2 was accordingly designed to test these hypotheses by adding a retrieval task to Experiment 1, so that background knowledge had to be successfully retrieved before it could be used as the basis for supporting a counterfactual inference.

Method

In the first phase of the experiment subjects were asked to read 5 variants, one from each material set. Two multiple-choice comprehension questions were asked after each story had been read, in an attempt to ensure that subjects read the information thoroughly. They were next asked to complete one of two short distraction tasks. The distraction tasks were unrelated to the present study; one investigated a spatio-temporal priming phenomenon, and the other morphological inflection. In the second phase of the experiment subjects were asked to perform exactly the same inferencing task as described in Experiment 1, except that this time they had also been provided with the LS and FO variants of background knowledge, in addition to the SS and AN categories. However, because the connection between the base problems and the background knowledge they were provided with in the variants was not made explicit, subjects had to retrieve relevant knowledge before being able to use it in the inferencing process. Subjects were not told that there was any connection between the first and second part of the experiment. This was done to determine whether subjects would be able to *spontaneously* recruit (Kahneman and Miller, 1986) background knowledge in order to make their soundness judgements for the counterfactuals.

Participants Participants in this study were 148 undergraduates and postgraduates at the University of Edinburgh. All participants were volunteers. The undergraduate students were awarded class credit for taking part in the study.

Materials All 5 bases, with their corresponding 4 variants (LS, SS, AN and FO categories), of the materials described in Experiment 1 were used.

Procedure 1 variant was taken from each of the 5 material sets, to result in each prime set. This meant that there were 4 prime sets in total. Two random orderings of each prime set were combined with two random orderings of the question set (which was the same as that used in the pre-test and Experiment 1), to create four distinct material orderings for each of the four prime sets. This was done to minimise the potential for presentation effects, and resulted in 16 types of booklet in total. The 2 distractor tasks were randomly included in the booklets, and took subjects less than five minutes to complete.

In the first part of the experiment subjects were instructed only that they were taking part in a memory experiment, and that they should therefore read the stories they were presented with carefully. In the second part of the experiment no reference was made to the stories in the first part; subjects were merely asked to provide soundness ratings as they saw fit.

Results

The results of Experiment 2 are shown in Figure 4 (along with the results from Experiment 1).

A 2×2 ANOVA was conducted on the four experimental conditions. This revealed a significant effect of featural matches ($F(1,147) = 8.75, p < 0.01$), a significant effect of structural matches ($F(1,147) = 16.76, p < 0.01$), and no significant interaction between the two factors ($F(1,147) = 3.72, p > 0.05$) consistent with the predictions of the analogy-based account of counterfactual reasoning.

The soundness ratings in neither the SS (Welch's $t = 0.81$, $df = 49.03$, $p > 0.025$, one-tailed) nor the AN (Welch's $t = 0.90$, $df = 51.61$, $p > 0.025$, one-tailed) conditions differed significantly from those in the pre-test.[4] Whilst the effect of SS knowledge on the counterfactual inferencing process is unchanged between Experiments 1 and 2, the facilitation of soundness ratings produced by the analogical knowledge observed in Experiment 1 has disappeared. The best explanation of this difference is that the retrieval requirement introduced in Experiment 2 has prevented AN matches from being successfully retrieved in the counterfactual inferencing process, a finding paralleled in analogy research.

Discussion

The results of Experiment 2 were consistent with those predicted by the analogy-based account of counterfactual reasoning. Whereas the provision of analogical knowledge in Experiment 1 was sufficient to boost the soundness of related counterfactual inferences, the same effect of analogical knowledge was not observed in Experiment 2. The best explanation of this seems to be that retrieval does appear to mediate the effect of structural congruency in the solution of

[4] Corrected α values were used as before. Levene's test indicated both t-tests involved samples with unequal variances, and so Welch's corrected t was calculated.

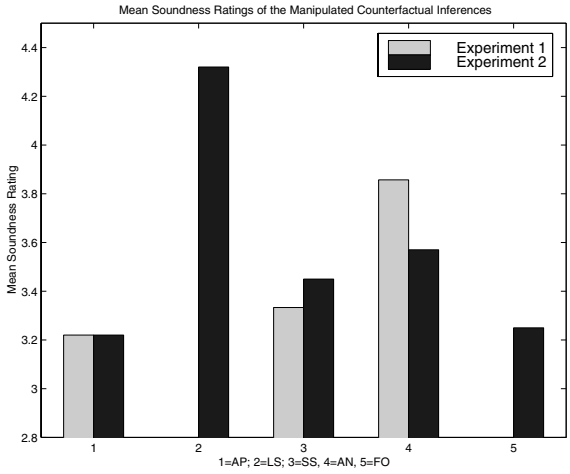

Figure 4: A bar chart plot of the mean plausibility of the manipulated counterfactual inferences in the pre-test and Experiments 1 and 2.

the counterfactual reasoning problems. Furthermore, both featural and structural factors were shown to have a significant effect on the soundness ratings provided by subjects, suggesting that both a feature sensitive retrieval process and structural alignment have a role to play in accounting for the way in which background knowledge is exploited during counterfactual reasoning. This pattern is in accordance with the research on analogical reasoning reported by Gentner, Ratterman and Forbus (1993).

General Discussion

We have presented evidence that there are deep similarities in the ways in which knowledge is exploited during both analogical and counterfactual reasoning. Specifically, we have shown that an analogical match to stored knowledge of an appropriate kind is sufficient to significantly boost the plausibility of a counterfactual inference, and that the structure-matching process that we hypothesise underpins counterfactual inference is mediated by a retrieval process sensitive to featural-matches, just as in analogical reasoning. The former finding is most significant, perhaps, because it is unpredicted by current theories of counterfactual reasoning.

Whilst there are limitations to the current work – chiefly that it doesn't explore what occurs when complete matches to stored counterfactual knowledge are unavailable, and counterfactual representations have to be *constructed* – we nevertheless feel that the current research presents the intriguing possibility of applying existing findings about to counterfactual reasoning, in order to improve our understanding of this important cognitive process.

Abstract

Past research on children's categorizations has centered on the question of whether categorization is based primarily and /or strictly on perceptual properties or on more conceptual notions of kinds. This paper reports new data pertinent to this issue by examining the influence of linguistic cues and perceptual cues. The results showed that the linguistic cues strongly influenced English-and Japanese-speaking children's judgments in systematic manner. This suggest that for both language groups, linguistic cues activated different conceptual understanding that direct children's attention to different properties. Nevertheless, the linguistic cues had their effect only given named things with ambiguous properties.

Introduction

Children categorize the world systematically. The systematicity of early categories has been well documented by many researchers (Mandler, Bauer and McDonough, 1991; Landau, Smith and Jones, 1998a, 1998b; Samuelson & Smith 1999; Soja, Carey & Spelke1991; Markman, 1991; Bauer & Mandler, 1989.) Yet the mechanisms responsible for this systematicity in performance are not yet specified. The research reported in this paper seeks insights into these mechanisms and is motivated by both contemporary and traditional ideas about the nature of categories. The first idea is the more modern one of emergent categories that reflects momentary goals as well as long term knowledge. The second idea is the more traditional one of stable categories that reflects regularities in experience. Considered jointly these two ideas suggest a new way of thinking about how language influences children's category formation and fosters cultural differences.

Contemporary Idea

Barsalou (1983) introduced the idea of an ad hoc category, a category formed in the moment in the service of solving a specific problem, for example one might from a category of "all the objects on my desk I can use to draw a straight line" or "all the things I can eat in this restaurant that I can afford." Our ability to form coherent ad hoc categories clearly depends on long-term knowledge of objects, their properties, and goals. The idea, however, is that specific bits of knowledge and the current input are melded to form a category adaptively fit to the moment. "Ad hoc categories should come to mind only when primed by current goals. Laurence W. Barsalou, 1983, (p. 223)"

Traditional Idea

The traditional idea of categories contrasts with the on-line flexibility of Barsalou's ad hoc categories. Traditionally, categories have been seen as fixed, mental structures that one either has or does not. It is this traditional idea about categories that make Whorf's (1956) claims about the role of language in categorization so contentious. Whorf argued that concepts are the product of language and so speakers of different languages "have" different concepts. But viewed through a more modern lens, Whorf's ideas present another possibility. "… all observers are not led by the same physical evidence to the same picture of the universe, unless their linguistic backgrounds are similar."(1956:214)—(p. 6 Gumperz & Levinson, 1996) Here is the idea: Language operates both as a contextual and long-term force an on-line category formation, causing speakers of different languages to attend to different properties in the task and thus to create different ad hoc categories. We test this idea in a study of English- and Japanese-speaking children's attention to cues distinguishing animates and inanimates.

Animates and inanimates

All languages distinguish between animates and inanimates and do so in a variety of ways. However, English and Japanese differ in their systems for individuating objects, and specifically in whether they treat animates as special discrete kinds. English treats both animate and inanimate objects as discrete and countable, that is, names for animate and inanimate objects are count nouns that take the plural. Substances,

in contrast, are named by mass nouns and not pluralized but instead take continuous quantifiers. In contrast, Japanese treats only animates as discrete. Nouns in Japanese are not pluralized, but names for animates can take an optional plural form. Further, the classifier system used for counting distinguishes animates from inanimate objects, but does not distinguish substances from inanimate objects. If Whorf is right, these linguistic differences might lead Japanese speakers more than English speakers to attend to properties relevant to animal categories. If instead Barsalou is right about the online creation of categories, cues suggesting the relevance of animacy properties should make speakers of both languages attend to properties relevant for animal categories. Finally, if both Whorf and Barsalou are right, speakers of both languages may be differentially sensitive to these cues and thus form different categories online.

Task

One task commonly used to examine children's category formation is the novel noun generalization task (e.g., Landau, Smith & Jones, 1988.) In this task, children are presented with a novel object, told its name, and then asked what other objects have the same name. Since both the objects and names are novel, this task measures category creation. Research has shown that children smartly use information about the objects and information from linguistics in the category formation (See, Smith, 1995, for a review). Critical to the present research are well replicated findings showing that when the named novel object has the properties of an artifact (solid, angular, complex shapes), children from categories based on shape but when the named novel object has properties of animals (e.g., eyes), children form categories based on a joint similarity in shape and texture (Jones et. al, 1991). We use this task and children's creation of shape-based versus shape plus texture based categories as a measure of the role of language history and on-line linguistic cues in children's category formation. More specifically, the experiments examine the interaction of the immediate linguistic cues, the individual's history of using those linguistic cues, and perceptual properties of the to-be-classified objects.

Experiment 1

The first experiment examined Japanese-speaking children's use of both linguistic cues and perceptual cues in category formation. The design crosses two levels of linguistic cues, one clearly marking the object as animate, one clearly marking the object as inanimate—with three different perceptual cues, cues that strongly suggest an animate thing, cues that weakly suggest an animate thing and cues that strongly suggest an inanimate thing.

The linguistic cues are *aru* and *iru* . In locative constructions (e.g., There is a cup) *aru* is obligatorily used with inanimate objects and *iru* is obligatorily used with animate objects. This is a highly salient and pervasive lexical contrast in Japanese. Figure 1 illustrates the 3 kinds of perceptual cues: rounded objects with eyes, rounded objects with appendages that might be viewed as legs, and angular objects with no properties suggestive of animate things. We ask: How do Japanese-speaking children combine these perceptual and linguistic cues when forming a new category?

Method

Participants Sixty monolingual Japanese-speaking children who were 21.06 to 45.7 months old participated. Participants' mean age was 34.51 months. All the participants were recruited from Niigata, Japan. All children participated with their parents.

Stimuli, materials and procedure Children participated in one of the six conditions that resulted from crossing the two linguistic cues (*iru/aru*) with the three levels of perceptual cues. In each condition children were tested in two blocks of 12 trials. In each block, a unique exemplar was named with a novel name and the child was asked whether that name also labeled each of 6 test objects. These six test objects were each queried twice in a randomly determined order. Three of these were control objects designed so that children should respond the same way regardless of whether they perceived the named object as depicting an animate or inanimate. One control object matched the exemplar in all features thus all children should say "yes" the name of the exemplar applies to this object. Two control objects differed from the exemplar in both shape and texture (or shape and color), thus all children should say "no" the name of the exemplar does not apply to these objects. The three diagnostic test objects matched the exemplar in shape and texture, shape and color, or only shape. If children perceive the exemplar as an animate, they should say the name applies only to the shape-and –texture matching object. If children perceive the exemplar as an artifact, they should say " yes" the name of the exemplar applies to all three diagnostic objects.

The sentence frames used in the experiment were presented in the following in the Iru and Aru conditions, respectively: "*Kokoni ____ ga iru yo*" and "*Kokoni ___ ga aru yo*." Test objects were queried as follows in the Iru and Aru conditions respectively: "*Kokoni ____ga iru kana*?" and "*Kokoni _____ ga aru kana*?"

The objects used in this experiment are, illustrated in Figure 1. The 3 control objects and 3 diagnostic test objects for the two test sets were constructed in the same way and are labeled in Figure 1 by the properties on which they match the named exemplar. All objects

were 3-dimensional, approximately 7cm x 7cm x 7cm, in size. The sample set illustrated in Figure 1 is stimuli with suggestive of animate cues: all objects in the pre-training set, the keppuru set, and tema set had appendages made of pipe cleaners.

Results

When the exemplar had eyes, a clear cue indicating the depiction of an animate, children generalized the name to new instances that matched in both shape and texture. The linguistic cues of *iru* and *aru* had no effect on performance. When the exemplar was angularly shaped and presented no cues suggesting an animate thing, children generalized the name to all test objects matching in shape. The linguistic cues of *iru* and *aru* had no effect on performance. However, when the exemplar presented weak perceptual cues suggesting an animate thing, the linguistic cues had a dramatic effect. The children generalized the name in the context of *iru* (the animate form) only to test objects that matched the exemplar in shape and texture just as they did when the exemplar had eyes. However, in the context of *aru* (the inanimate form) , the children generalized the name to all objects that matched the exemplar in shape just as they did when the exemplar was clearly an artifact. These conclusions were confirmed by analyses of "yes" responses (the name applies) on the diagnostic trials.

Children's proportions of "yes" responses on these trials were submitted to analysis of variance for a 2 (Linguistic cues) X 3(perceptual cues) mixed design. The analysis revealed the main effect of Linguistic cues, $F\ (1,54) = 15.834$, $p < .001$, the main effect of perceptual cues, $F\ (2,54) = 14.132$, and the interaction between perceptual cues and linguistic cues, $F\ (2,54) = 9.073$, $p < .001$. The "yes" responses for these diagnostic test objects in the 6 conditions are shown in Figure 2. These results show: (1) clear effects of perceptual cues on category formation. (2) clear effects of linguistic cues, and (3) the dominance of perceptual over linguistic cues, at least for these children in this task context.

Experiment 2

Experiment 1 showed Japanese-speaking children's sensitivity to linguistic cues in category formation, when the perceptual cues were not strongly pointing in some other direction. The goal of Experiment 2 was to replicate this finding with English-speaking children. Specifically, children were provided with stimulus objects that presented weak cues suggestive of animacy, appendages that could be seen as legs. The exemplar was named in one of two sentence frames that used different verbs; one using a verb suggesting an animate kind, the other using a neutral verb. The verbs used were "wants" and "goes": The exemplar was named saying, "*This mobit wants to stay here."* or *"This mobit goes here"*

Method

Participants Twenty monolingual English-speaking children between the ages of 23 to 43 months participated. The mean age was 31.7 months. The experimental sessions were held in Bloomington, IN. Participation of children was voluntary.

Stimuli, materials, design and procedure All aspects of the stimuli, procedure and design were identical to Experiment 1 with the exceptions of the type of stimuli and the sentence frames in which the novel names were presented. We used only one perceptual level for stimuli: ambiguous objects (see Figure. 1). The sentence frames used in English were non-locative constructions that had plausible animate/inanimate distinction "wants" for animate and "goes" for inanimate or neutral. The novel words employed to name the exemplars in the Experiment 2 were slightly altered to sound natural in English (e.g., *mobito*/mobit; keppuru/kipple; tema/teema).

Results

As shown in Figure 3, the English-speaking children generalized the names for these objects in the same way in both linguistic conditions, to all test objects that matched the exemplar in shape. This suggests children saw the objects as artifacts. The key result, however, is that they were unaffected by the linguistic cues. This contrasts with the Japanese-speaking children of Experiment 1 who categorized these same ambiguous objects differently in the two linguistic contexts.

Experiment 3

Are English-speaking children just less sensitive to linguistic cues? Perhaps "wants" is not as strong a cue suggesting animacy in English as "*iru* " is in Japanese. In Experiment 3, we used a sentence context containing personal pronouns (he/she) in an attempt to encourage children to form animal-like categories.

Method

Participants Twenty monolingual English-speaking children between the ages of 24 to 43 months participated. The mean age was 32.95 months. The experimental sessions were held in Bloomington, IN. Participation of children was voluntary.

Stimuli, materials, design and procedure All aspects of the stimuli, procedure and design were identical to Experiment 2 with the exception of the sentence frames in which the novel names were presented. The sentence frames used in English had either pronoun "she/he" or neutral subject "it" to refer the object

Results

English-speaking children showed clear (and reliable) effect of linguistic cue. As is evident in Figure 4, in the context of "he/she," children generalized the name to test objects matching the exemplar in shape and texture. In the context of "it," children generalized the name to new instances the same shape as the exemplar. Thus, we see clear on-line effects of linguistic cues on category formation in English-speaking as well as Japanese-speaking children.

The analysis revealed that the number of 'yes' responses to the shape matching test objects for the two groups of children differed reliably, $t=3.851$, $p<.005$. Given objects with features suggestive of animal limbs, English-speaking children provided with pronoun *"she/he*" were significantly more likely to form a narrower category based on both shape and texture than children with the neutral subject "*it*" only new instances that matched in shape alone.

Clearly, these pronouns activated different conceptual understanding that directed children's attention to different properties.

Experiment 4

The evidence thus far fits the contemporary vision of systematic categories created on-line and in-the-moment from the combination of perceptual cues and linguistic cues. But what of the long-term effects of learning particular language with a particular structure on on-line category formation. Although both English and Japanese have many linguistic devices and contrasts organized around animacy, the Japanese language through its system of individuation is arguably more concerned with animacy than English. Are linguistic cues suggesting animacy thus stronger for Japanese-speaking children than English-speaking children? To test this, we presented both English- and Japanese-speaking children with a novel angular artifact with no cues even remotely suggestive of animate thing. We named the object with a novel name in a linguistic context loaded with multiple cues indicating the conceptualization of the object as an animate.: for English *"See, who do you think this is? He is a Mobit! Isn't this mobit cute? There might be some more mobits that came to play with us!"* and for Japanese, *"Hora, koko ni dare ga iru to omou? Kokoni iru nowa mobito kun. Mobito kuntte kawaii desyo? Hoka nimo motto ippai mobito ga asobini kiteirukamo shirenaiyo!*"

Method

Participants Ten monolingual English-speaking children who were 25 to 45 months old and 10 Japanese-speaking children who are 27.4 to 38 months old participated. English-speaking children's mean age at this study was 35.5 months, and Japanese-speaking children's mean age was 33.82 months. The English-speaking children were recruited from Bloomington, IN. The Japanese-speaking children were recruited from Niigata, Japan. All children participated with their volunteer parents.

Stimuli, materials, design and procedure All aspects of the stimuli, procedure and design were identical to Experiment 2 & 3 with the exceptions of the sentence frames in which the novel names were presented.

Results

As is evident in Figure 5, Japanese-speaking children generalized the name to all test objects that matched the exemplar in shape and texture, the pattern typical of animate things. In contrast, English-speaking children generalized the name to all instances like the exemplar in shape, the pattern typical of artifacts. The numbers of 'yes' response to the shape matching test objects for the two groups of children differ reliably, $t=7.577$, $p<.001$.

Apparently English-and Japanese-speaking children see these objects differently. English-speaking children form categories based on the perceptual cues, Japanese-speaking children follow the linguistic cues. It appears that different histories of using language lead children to make different use of on-line information, and thus, in-the-moment-of the task, form different categories.

General discussion

The Whorfian question is often conceptualized as asking whether speakers of different languages "have" different categories. This question does not make sense if categories are momentary creation. Certainly, children's categorizations in the novel noun generalization task used here are momentary creations, formed *de nouveau* from learning a single novel object named with a novel name. But both English- and Japanese-speaking 3 year olds readily and coherently create categories in this task using perceptual and linguistic information in the task as the basis for categorizing new instances. But how in-task, in-the-moment, information is used will also depend on the life time histories in using those cues in other contexts. In this way, we may see direct effects of the language one knows, not on the categories and concepts one has, but on the categories and concepts one creates to solve a specific task.

Base-Rate Neglect in Pigeons: Implications for Memory Mechanisms

Thomas R. Zentall (zentall@pop.uky.edu)
Tricia S. Clement (tcharb1@pop.uky.edu)
Department of Psychology, University of Kentucky
Lexington, KY 40506 USA

Abstract

In delayed matching-to-sample, there is an initial (or sample) stimulus and two test (or comparison) stimuli. When pigeons are trained to match, they presumably choose between the two comparison stimuli according to their ability to remember the sample. When the sample cannot be remembered, comparison choice should depend on the history of reinforcement associated with each of the comparison stimuli (i.e., the comparison base rates). In the present research, pigeons acquired two matching tasks in which samples S1 and S2 were each associated with one of two comparisons C1 and C2 (equal experience with both trial types), and samples S1 and S3 were each associated with one of two other comparisons C3 and C4 (equal experience with both trial types). As the retention interval increased, the pigeons showed a bias to choose the comparison (C1 or C3) associated with the more frequently occurring sample (S1). Thus, pigeons are sensitive, not just to the probability of reinforcement associated with the each of the comparison stimuli (i.e., the base rates) which were equal, but also to the (irrelevant) likelihood that each of the samples was presented (i.e., base-rate neglect).

Introduction

Humans are known to underestimate the effect of base rates associated with probability of being correct (Kahneman & Tversky 1972). In a classic problem proposed by Tversky and Kanemman (1980, p. 62), participants are told that 85% of the taxis in a city are green while only 15% are blue (the base rates). They are also told that a witness to a hit-and-run accident involving a taxi identified the taxi as blue. Furthermore, they are told that under similar conditions witnesses correctly identify the color of a taxi 80% of the time. When participants are then asked, "What is the probability that the taxi involved in the accident was actually blue?" most of them say that it is very likely that the taxi is blue. In making this judgement the participants fail to consider sufficiently the base-rate probabilities. When base rate is considered, the conditional probability of correctly identifying a blue taxi is p(blue|judgement correct) = p(blue) x p(correct) = .15 x .80 = .12, whereas the probability of saying it was blue when it actually was green is p(green|judgement incorrect) = p(green) x p(incorrect) = .85 x .20 = .17. This means that the probability of being correct under these conditions is only .12/(.12 + .17) = .41, or less than 50%. Thus, humans often fail to consider sufficiently the probability of being correct in the absence of the eye-witness information. Although there are certain conditions under which humans can be induced to perform more accurately (e.g., Gigerenzer & Hoffrage, 1995), base-rate neglect is likely responsible for many exaggerated fears such as air travel, walking the streets of New York City, and having one's children killed at school by a fellow student.

An analogous situation can be designed for an animal using a matching-to-sample task. Matching-to-sample is a conditional discrimination in which the identity of the initial or sample stimulus indicates which of two (or more) test or comparison stimuli is correct (Skinner, 1950). According to Hartl and Fantino (1996), comparison choice for pigeons should depend on two factors, the relative probabilities of reinforcement associated with the comparisons (i.e., the base rates) in the absence of the sample, and the conditional probability of each comparison being correct given presentation of one of the samples (i.e., the actual sample event or the evidence, given the base rates). In the case of matching-to-sample, the probability of reinforcement given the sample is typically 1.0. This ensures that the task has been adequately acquired and that the contingencies have been adequately experienced. Biases can be introduced by manipulating the ratio of samples and the probability of reinforcement for choices of the matching comparison (see Goodie & Fantino, 1995, for similar findings with humans, but see also Goodie & Fantino, 1996, for exceptions).

Control by the comparisons alone can be increased by degrading the samples at the time of comparison choice (i.e., by increasing the probability of poor memory, or in the taxi example, of an identification error). One way to degrade the samples is by introducing a delay between the offset of the sample and the onset of the comparisons. Assuming that the comparison stimuli are correct equally often over trials, and that the probability of reinforcement is the same for a correct response to each comparison, one would expect that with increasing delay, the slopes of the pigeons' retention functions would be quite similar (see Grant, 1991; White &

Wixted, 1999).

The analog to base rate in a matching task is the probability of being correct in the absence of information about the sample (i.e., the relative probability of reinforcement associated with each of the comparison stimuli). According to White and Wixted (1999), pigeons should be sensitive to base-rate probabilities, but generally the base rates and the probability of sample presentation are the same (both generally 0.5). In the present experiment we asked if pigeons are able to estimate the probability of a correct comparison response when the sample probabilities are different from the base rates. There are a number procedures that might be used to manipulate the relative frequency of sample (S) presentation while maintaining equal probability of reinforcement for comparison (C) choice (i.e., equal base rates). In the present experiment, we chose to introduce a second 2-sample-2-comparison matching task. Each of the two matching tasks involved a different pair of comparison stimuli but the two tasks shared a common sample. Thus, the two tasks can be represented S1-C1, S2-C2 and S1-C3, S3-C4 (with C1 and C2 always appearing together and C3 and C4 always appearing together). If each of the four trial types appears equally often, each of the comparisons would be associated with reinforcement on 25% of the reinforced trials. However, the same would not be true of the samples. S2 and S3 would each be presented on 25% of the trials, whereas S1 would be presented on 50% of the trials. Under conditions with no delay, one would expect a high level of matching accuracy and no bias. But if a delay is inserted between the offset of the sample and the onset of the comparisons, errors should increase. If comparison choice depends on the reinforcement contingencies associated with comparison choice, errors should not result in a comparison bias. In the absence of memory for the sample, the probability of reinforcement of comparison choice should be 50% for either comparison in either task. Furthermore, if there is memory for the sample, the conditional probability of reinforcement associated with comparison choice should be the same for either comparison in either matching task. However, if pigeons show a bias by using their reference memory of sample presentations, they should access more instances of S1 than of either S2 or S3 and a bias to choose C1 and C3 may result.

Method

Subjects

The subjects were eight White Carneaux pigeons, purchased as retired breeders (5-8 years old) from the Palmetto Pigeon Plant (Sumter, SC). The pigeons were maintained at 80% of their free-feeding body weights throughout the experiment and were caged individually with grit and water continually available in the home cage. The pigeons were maintained on a 12:12-h, light:dark cycle. All pigeons had previously served in an unrelated study involving simple simultaneous discriminations.

Apparatus

The experiment was conducted in a standard BRS/LVE (Laurel, MD) sound attenuating pigeon test chamber. Three rectangular response keys (2.5 cm high x 3 cm wide and 1 cm apart) were aligned horizontally and centered on the response panel. Mounted behind each response key was a 12-stimulus inline projector (Industrial Electronics Engineering, Series 10, Van Nuys, CA,) that could project a red hue or a green hue onto the any of the three response keys or a plain white field onto the center response key. In addition, the left and right projectors could project a white circle and a white dot. A houselight located at the center of the chamber ceiling provided general illumination. A rear-mounted grain feeder was centered horizontally on the response panel midway between the pecking keys and the floor of the chamber. When operated, the feeder was accessible through a 5.0 x 5.5 cm lit aperture in the response panel. Reinforcement consisted of 2.0-s access to Purina Pro Grains. White noise and an exhaust fan mounted on the outside of the chamber masked extraneous noise. The experiment was controlled by a microcomputer located in an adjacent room.

Procedure

Training All pigeons were placed directly on 0-s-delay matching-to-sample training. At the beginning of each trial, the center key (sample) was illuminated. Following 10 responses to the sample, the sample was turned off and the side (comparison) keys were illuminated. Comparison stimuli were presented randomly with respect to location, with the restriction that a particular hue could not occur on the same side key for more than three consecutive trials. One response to either comparison constituted a choice and terminated the trial. Correct comparison responses resulted in a 2-sec presentation of food and a 10-sec intertrial interval. Incorrect choices resulted in the 10-sec intertrial interval alone.

For each pigeon, training consisted of a hybrid matching task involving three sample stimuli (one per trial) and two pairs of comparison stimuli (one pair on each trial). On one fourth of the trials, one of the hues served as the sample (S1) with red and green comparison stimuli (C1 and C2) on the side keys and, for example, red was correct. On another fourth of the trials, a different hue sample (S2) was presented with the red and green comparison stimuli and, for example, green was correct.

On half of the remaining trials, S1 was again presented as the sample and circle and dot were presented as the

comparisons (with, for example, dot correct). On the remaining fourth of the trials a third hue was presented as the sample (S3) and circle and dot were presented as the comparisons (with circle correct).

The three sample hues were counterbalanced such that each hue served as the one-to-many sample for 2-3 pigeons and each of the remaining samples was associated with the hue comparisons for at least one pigeon. Sessions consisted of 96 trials and were conducted 6 days a week. For each pigeon, criterion was met when the correct comparison for each trial type was chosen on at least 90% of those trials for two consecutive sessions. Following criterion performance, each pigeon received five sessions of overtraining.

Retention test On the following session, each pigeon was transferred to a mixed-delay matching procedure in which the offset of the sample was separated from the onset of the side keys by a dark retention interval of 0, 2, 4, or 8 s. For each of the trial types, there was an equal number of trials involving each retention interval. The retention test consisted of 2 sessions and the reinforcement contingencies were the same as they were during training. In all analyses of results, the .05 level of statistical significance was adopted.

Results

Training

Sessions to criterion (two successive sessions at 90% correct) for the one-to-one portion of the task was 10.2 when the comparisons were hues and 11.1 when the comparisons were shapes. Sessions to criterion for the one-to-many portion of the task was 13.6 when the comparisons were hues and 13.8 when the comparisons were shapes. A mixed-effect analysis of variance performed on the acquisition scores, with task (one-to-one vs. one-to-many) and comparison dimension (hues vs. shapes) as factors, indicated that neither effect nor the interaction was statistically reliable, $F(1,7) = 2.08$, >1, and >1, respectively.

Retention Test

Data from the retention test were pooled over the 2 test sessions and were subjected to a repeated-measures ANOVA, with task component (one-to-one vs. one-to-many) and Delay (0, 2, 4, and 8 sec) as factors. Most critically, the ANOVA indicted that there was a significant Task Component x Delay interaction, $F(3,21) = 4.37$. There was also a significant effect of Delay, $F(3,21)$ 44.01. The effect of Task Component was not quite significant, $F(1,7) = 4.79$. The retention data are presented in Figure 1.

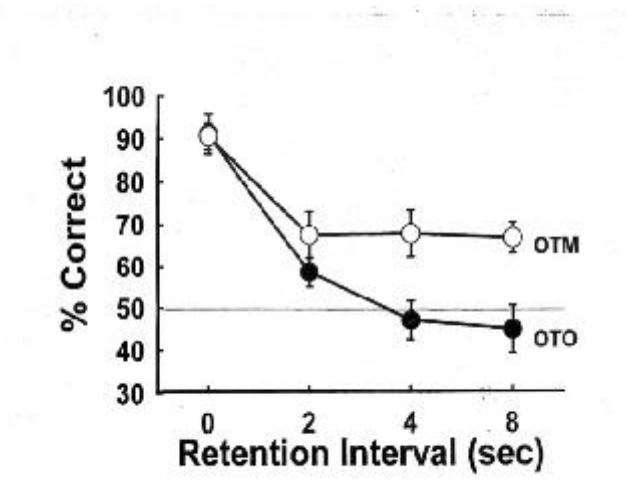

Figure 1. Retention functions following training in which two and samples, S1 and S2, were associated with comparison stimuli, C1 C2, respectively and S1 and S3 were associated with comparisons C3 and C4, respectively. Thus, S2 and S3 were involved in one-to-one matching (OTO) with C2 and C4, while the third sample, S1, was associated with two comparison stimuli, C1 and C3 (one-to-many matching, OTM). In training and test, each comparison was associated with reinforcement on 50% of the trials and C1 and C2 always appeared together as did C3 and C4.

Discussion

According to traditional instrumental views of conditional discrimination learning (i.e., Hartl & Fantino, 1996), the probability of a comparison choice should be determined by the conditional probability associated with each comparison stimulus, given the sample, and, if the sample is unavailable or forgotten, with the probability of reinforcement associated with each comparison (independently of the sample). Thus, the choice a particular comparison (e.g., C1) should depend on both the number of sample-comparison pairings (e.g., S1-C1) that are followed by reinforcement, as well as the number of reinforcements associated with that comparison, independent of the sample (Wixted, 1993). In the present experiment, the conditional probability of reinforcement associated with each of the comparisons, given one of the samples, was equal. Furthermore, the probability of reinforcement associated with choice of either comparison was also equal. Thus, in the present experiment, given presentation of C1 and C2, the only relevant sample-comparison associations determining comparison choice should be S1-C1 and S2-C2. If so, delay-induced sample degradation should have had a symmetrical effect on comparison choice and the retention functions should have been parallel and overlapping.

In the present experiment, clearly divergent retention functions were found. These results require the modification of current theories of delayed conditional discrimination performance (e.g., White & Wixted, 1999) because pigeons choice behavior is influenced not only by the probability of reinforcement associated with responding to each of the comparison stimuli and to the conditional probabilities associated with choice of the comparison stimuli as a function of memory for the sample but also by the relative frequencies of the samples. When delays are introduced, as the delay increases, pigeons have an increasing tendency to select the comparison associated with the more frequently presented sample, even though that sample was not presented more often than the alternative sample in the context of either comparison pair. It is as if, on trials when memory for the sample is poor, presentation of the comparisons causes the pigeons to consult their reference memory for the overall probability of sample presentation (independent of the comparison pair).

Of broader interest, such use of reference memory in delayed matching may be a general phenomenon. However, the use of sample frequency independently of other more relevant measures may be apparent only with a design such as that used in the present research because in the more typical design, either hypothesis makes the same prediction.

Alternatively, in the present experiment, although the pigeons had equal opportunity to acquire each of the four sample-comparison associations, the more frequent presentations of the S1 sample could have allowed it to be more efficiently coded, better maintained in memory, or more easily retrieved from memory. That is, at the time of comparison choice, when the S1 stimulus had been the sample, it may have been more accessible than the S2 or S3 stimuli were when they had been the sample. But if the difference in slope of the retention functions was attributable to differences in sample accessibility at the time the comparisons were presented, both the S1 and the S2/S3 functions should have approached 50% correct with increasing retention interval. Instead, the S1 retention function appears to have leveled off, while the S2/S3 retention function declines below chance at delays of 4 and 8 sec. Such retention functions suggest that rather than better retrieval of the S1 sample, the pigeons developed a comparison bias to choose the comparison associated with the more frequently presented sample.

This comparison bias in pigeons is analogous to the base-rate neglect shown by humans when they fail to consider sufficiently the base-rate probability of occurrence of an event.

Explanations of words and natural contexts: An experiment with children's limericks

Greg Aist (aist@cs.cmu.edu)
Project LISTEN, Carnegie Mellon University, 5000 Forbes Avenue
Pittsburgh, PA 15213 USA

Introduction

Project LISTEN's Reading Tutor listens to children read aloud, and helps them learn to read. Here, we used the Reading Tutor to study whether adding child-friendly definitions to natural text would help children learn new words. We compared four conditions:

1. No encounter
2. In a definition alone
3. In a story alone
4. In a story and a definition

This study took place at a July 2000 reading and math clinic at a low-income urban elementary school in Pittsburgh. Each student was scheduled to spend 30 minutes per weekday on the Reading Tutor.

Experiment design

We used eight children's limericks by Edward Lear (19th c.), with one target word each: *dolorous*, *laconic*, *imprudent*, *innocuous*, *mendacious*, *oracular*, *irascible*, or *vexatious*. The target word was always the second word in the last line. Our text selection controlled for genre, author, intended audience, (approximate) word frequency, part of speech, and general semantic class:

> There was an Old Man of Cape Horn,
> Who wished he had never been born;
> So he sat on a chair,
> Till he died of despair,
> That dolorous Man of Cape Horn.

We wrote target word definitions in a consistent style using ordinary language, following McKeown (1993). For example: "We can say someone is dolorous if they are mournful, or feel really bad." To reduce variance from first- or last-item effects, we held constant the order of presentation of the limericks. Each student saw two target words per condition. Word-to-condition assignment was set for each Reading Tutor computer.

One or two days later – depending on attendance – we gave each student a paper questionnaire with two items per word. "Have you ever seen the word *dolorous* before?" tested familiarity, and "If someone is dolorous they must be… angry; sad; tired; afraid." tested word knowledge. To exclude memorization, the definitions and the test answers used different words.

In all, 29 students who had just finished 2nd - 5th grades completed the experiment, for a total of 232 trials, 58 trials for each of 4 conditions.

Results and discussion

To explore the effects of explanations and limericks, we used logistic regression – modeling a binary outcome variable using several categorical factors as input. If a factor's coefficient was significantly greater than zero, than that factor affected the outcome variable.

Word familiarity. Seeing an explanation helped, at $p < 0.001$: coefficient $1.08 \pm .32$; 99.9% confidence interval (CI) .02, 2.15. Seeing the word in a limerick showed only a weak trend, at $.50 \pm .32$; 90% CI -.02, 1.03.

Word knowledge. The results for word knowledge were more nuanced: a (not significant) trend for explanations ($.24 \pm .31$), but none for limericks ($-.05 \pm .31$).

However, younger students were about at chance:

2nd grade, 19/72 right (26%) 3rd grade, 18/72 right (25%)
4th grade, 16/56 right (29%) 5th grade, 10/32 right (31%)

For 4th and 5th graders, however, in a main-effects-only model, explanations helped ($p < .10$): $.89 \pm .52$, with 90% CI .04, 1.74. There was not an effect for limericks, at $-.13 \pm .51$. (Disaggregation by grade is exploratory.)

Conclusions. Thus in terms of learning word meaning, only explanations seemed to help – and only for fourth and fifth graders. These effects are neither same-day recency nor simple memorization. Aist (Aist 2000 ch. 6) discusses further.

Understanding death as the cessation of intentional action: A cross-cultural developmental study

H. Clark Barrett (barrett@mpib-berlin.mpg.de)
Center for Adaptive Behavior and Cognition
Max Planck Institute for Human Development
Lentzeallee 94, Berlin, Germany

Introduction

Taken together, the developmental literatures on children's understanding of intentional action and on children's understanding of death present a sort of paradox: while the former literature shows that even very young children have an intuitive grasp of the goal-directed nature of behavior that characterizes animate, living things, the latter seems to show that children do not realize until a much later age that the capacity to act intentionally ceases irreversibly when an organism dies. From an adaptationist perspective, this is perhaps surprising, given the potential adaptive value of being able to judge the capacity or incapacity of an animal to act, and perhaps to do harm. In many states which are characterized merely by a lack of motion – sleep, for example – an animal may still wake up and attack. When dead, however, it cannot. It may thus be adaptive for young children to understand that death, as opposed to sleep and other states of temporary inaction, entails the permanent cessation of the capacity for intentional action. And, given that an intuitive grasp of the capacity for intentional action in animate living things exists at a very young age, it should be available to serve as a conceptual substrate for an early understanding of death.

Study design

The present study was designed to probe for an understanding of death as the cessation of the capacity for intentional action by comparing judgments of 3 to 5 year old children about hypothetical dead and sleeping animals (human and nonhuman). Children were first asked questions about an awake animal, then about the same animal either asleep or dead. The target questions required children to judge whether the sleeping or dead animal would be capable of movement in general or in response to being touched, awareness of an external stimulus (someone moving nearby), and / or of having an emotion. The intentional action theory of death understanding predicts that children will exhibit the clearest understanding of death in response to questions involving movement and movement in response to stimulus, as opposed to questions that do not involve intentional action (e.g., awareness only). There was no predicted lower bound on the age of emergence of reasoning abilities probed here.

The study was conducted in two parts, both using the same interview procedures and questions. The first part of the study was conducted with 70 preschool and kindergarten children, age 3 to 5 years, in Berlin, Germany. The second part of the study was conducted with 70 Shuar children, age 3 to 5 years, in six small rural villages in the Amazon region of Ecuador. Because these populations vary widely both in exposure to various kinds of cultural and environmental input (e.g., television and films, direct contact with animals, personal experience with death), they were selected for comparison to determine whether the development of the kind of understanding of death probed here depends significantly on cultural inputs such as television, and / or aspects of personal experience such as contact with animals or firsthand experience with death. Parents in both populations were surveyed about relevant experiences of their children which might have influenced understanding of death, such as religious background, exposure to representations of death on television, and personal experience with death of animals or people.

Results

Both Shuar and German children demonstrated an understanding of death as the cessation of the capacity for intentional action by the age of 4. By this age, the large majority of children clearly distinguish sleep from death in this regard. In addition, many of these children understand that the capacity for subjective experience independent of action ceases in death as well, though performance on these questions, as predicted, was not as high at this early age as performance on questions involving intentional action.

The results of the study show that by age 4, children understand at least one aspect of death which is crucially important from an adaptive perspective: dead things can no longer act. Although this result stands in contrast to much of the developmental literature on death understanding, which suggest that children's understanding of death at this age is poor, it is consistent with a view of cognitive development which holds that development has been shaped by a history of selection for adaptive reasoning and decision making abilities.

Working Memory Processes During Abductive Reasoning

Martin Baumann (martin.baumann@phil.tu-chemnitz.de)
Josef F. Krems (krems@phil.tu-chemnitz.de)
Department of Psychology, Wilhelm-Raabe-Str. 43
Chemnitz University of Technology

Introduction

Abductive reasoning is the process of finding a best explanation for a given set of observations. It is an essential feature of many real world tasks like medical diagnosis, discourse comprehension, and scientific discovery. Such problems often need the processing of an amount of information far beyond the capacity limits of working memory (WM). But on the other hand, working memory is expected to play a central role in human reasoning. On the basis of a computational model of abductive reasoning (Johnson & Krems, 2000) and of theories of text comprehension we propose a mechanism that reduces WM load during abductive reasoning. It suggests that only unexplained symptoms are kept in working memory with explained symptoms are transferred to long-term memory reducing WM load.

From this model it follows that unexplained observations should be more available in a recognition or recall task during abductive reasoning than explained ones. We tested this prediction in three experiments each using a different memory task to test the availability of observations.

Experimental Studies

The Experimental Task

In all experiments a task (BBX) was used where participants had to discover the hidden state of a system through indirect observations. The observations were presented sequentially to the participants. Only the current observation was visible. In each trial, after a variable amount of observations, the participants had to perform a memory task testing the availability of a given observation. The major manipulation in all experiments was whether this observation was already explained at the time of the memory task or not. That is, whether the participant had received the neccessary additional information to explain the observation and actually generated a hypothesis explaining this observation.

Results and Discussion

In the first experiment we used a recognition test as memory task to test the availability of the relevant observation. In the second experiment the recognition test was replaced with an implicit memory task. The mental availability of explained and unexplained observations were tested here by presenting a probe hypothesis that had to be judged with regard to its compatibility with observations presented until then.

The results of the first experiment showed that unexplained observations are recognised significantly faster than explained ones, consistent with model predictions. Regarding the recognition accuracy there was no significant effect of interval or explanation status. We also found that maintaining an unexplained observation in WM slows down the recognition and reduces the recognition accuracy for other observations.

The second experiment showed contrary to the model's predictions a tendency of explained observations being forgotten more often with increasing number of intervening observations than unexplained ones. This result suggested that observations are held actively in WM until they are explained. After an explanation was generated they are lost from WM. The result also indicates that explained observations are not integrated in a representation in long-term memory. This interpretation was confirmed in a third experiment showing that participants memory for explained and unexplained observations in an unexpected recall test after the interruption of the reasoning task was equally low.

General Discussion

The results confirmed the hypothesis that unexplained observations are actively hold in WM during abductive reasoning until a causal explanation can be generated. Contrary to the predictions of the model these explained observations seem not to become integrated into a representation in long-term memory, but are simply forgotten. But this could be due to the structure of the reasoning task we used, which makes the construction of an integrated representation rather difficult. Therefore in future investigations we need to use a task providing a richer structure, more comparable to real world tasks like medical diagnosis.

Organizing Features into Attribute Values

Dorrit Billman (dorrit.billman@psych.gatech.edu)
Carl Blunt (gte138r@prism.gatech.edu)
Jeff Lindsay (gte457e@prism..gatech.edu)
School of Psychology, Georgia Institute of Technology

The problem of representation change is important for understanding and developing both natural and artificial intelligence. People form new chunks or perceptual units from experience (Schyns & Rodet, 1997) and build up new, continuous, dimensions, (Goldstone, Lippa, and Shiffrin, 2001).

We investigate representation change reorganizing unrelated features into alternative values of the same attribute. For example, 'fins', 'wings', and 'legs' might initially be unrelated properties but people might learn to reorganize them as values of a new attribute, LIMB. Representing properties as attribute values may be importantly different from representing properties as a collection of uncoordinated features, for interpreting novel properties and for projecting inferences.

We investigated perceptually-based attribute formation, in the context of learning about cell-like organisms. We use stimuli where an initial analysis into features is highly available, but there are alternative ways of organizing these features into attributes.

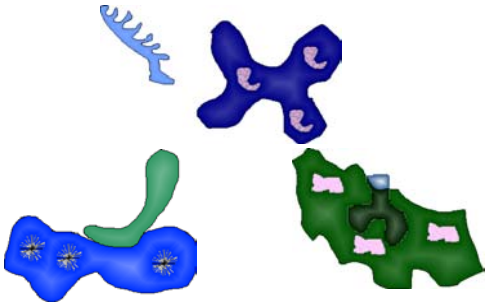

Figure1: Separate, Attached & Overlapping Units

Method

Stimuli were slides of cell-like organisms (*units)*, composed of a larger and a smaller element, each clearly bounded and differently colored. Units varied in the general shape of the larger element, its color, the small figures appearing internal to the larger element (e.g. its 'mitochondria'), and the shape of the smaller element. There were three values of each attribute.

We tried to influence whether participants saw the smaller element as parts of a larger organism versus as a buddy or other accompanying but distinct element, by spatial separation and by order of presentation. We predicted overlapping items would be most ambiguous and interpretation would be influenced by viewing order of Separate, Attached, and Overlapping blocks.

For initial exposure, subjects saw 3 blocks of six 1-unit displays (one block of each type) and described what they saw. Subjects then viewed 18 displays with one to five units ("slides with lower magnification") shown together and indicated how many organisms were on each slide, by circling and counting.

We varied the order subjects saw the Separate, Attached, and Overlapping blocks (Table 1). We expected the first exposure block to be influential. Does exposure order influence the final interpretation of the elements, as values of a new limb-like attribute or as values of a new buddy-like attribute?

Results & Discussion

Table 1 (col. 2) shows that displays had highest counts when subjects first saw the overlapping block, followed by the Attached and then Separated (item analysis $F(3,68)=181.9$). Interestingly, some subjects analyzed the small internal element as a separate organism, particularly in the Overlap First Conditions. Table 2 (col. 3) shows % of displays where subjects counted units all as 1 or all as 2 organisms; Overlap first subjects were less consistent ($F(3,48)=4.8$, $p<.01$)

Table 1

Conditions	Results	
Order of Blocks in Exposure Phase	AveCount /Unit	%consistent count strategy
1:Attach-Overlap-Sep (n=13)	1.75	78 %
2:Sep-Overlap-Attach (n=12)	1.88	81%
3: Overlap-Attach-Sep (n=9)	2.73	29%
4: Overlap-Sep-Attach (n=8)	1.88	60%

Presentation order influenced interpretation of elements as parts or separate organisms. The biggest influence of context came when the ambiguous displays were first. Further work will look at attribute change following concept learning.

Attention Shift and Verb Labels in Event Memory

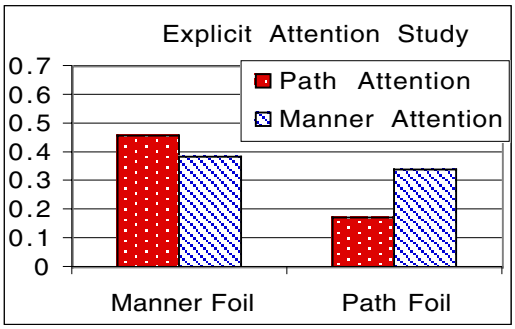
Dorrit Billman (dorrit.billman@psych.gatech.edu)
School of Psychology, Georgia Institute of Technology
Atlanta, GA 30332 USA
Michael Firment (mfirment@kennesaw.edu)
Psychology Department, Kennesaw State University
Kennesaw, GA 30144 USA

Events, unlike objects, pass by once and give only one opportunity to encode and retain information. How does the language accompanying events influence what is remembered? To what can people selectively attend, and what directs their attention?

In prior work (Billman & Krych, 1998) we found an interaction between type of visual recognition error and verb heard at encoding, such that people were more likely to notice changes in manner when they had heard an appropriate manner verb (e.g., hop, jog, skip) than an appropriate path verb (e.g., enter, cross, leave), and more likely to notice changes in path when they had heard a path verb than a manner verb. This effect was clearest when the foil events were changes such that the original verb would no longer appropriately apply to them. Thus, the effect of the encoding verb on memory might have resulted from using the verb as a discriminative cue during recognition, from using the verb to direct attention at encoding, or both.

Explicit Attention Study

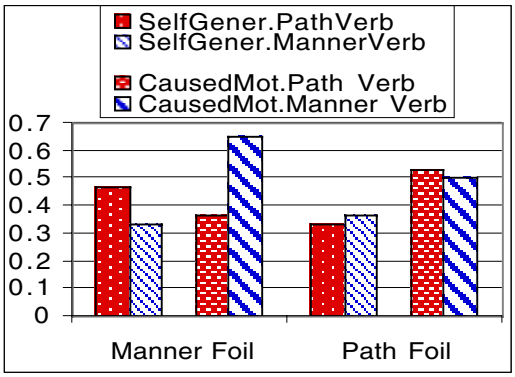
In the present studies we investigate whether attention can be directed to the manner or to the path of motion events. We used realistic, animated event clips of ordinary motion events. Half the events showed a self-generated motion (e.g. strolling man circles a car) and half a caused motion (e.g. cat rolls a pencil to make it



fall). Test items were very similar to the originals. In the Explicit Instruction Study we told participants to pay attention to path or to manner. As predicted, participants made fewer errors on items which changed the corresponding aspect of the event. (interaction of encoding condition x foil type, $F(2,32)=4.71$, $p<.05$). These data suggest a boundary for how much shifts of attention at encoding can aid recognition for our task and stimuli.

Verb Study

In the Verb Study, events were accompanied by a descriptive manner verb, path verb, or no language.



Verbs always described the moving figure (e.g. "rolling" or "falling"). If hearing a path or manner verb shifts attention this might benefit memory for the corresponding aspects, even when the verb itself provides no discriminative information at recognition. A three way interaction, $F(4,156) = 2.775$, $p < .05$, .among verb condition, type of event (self-motion or caused-motion), and type of recognition stimulus (path foil, manner foil, or original scene) on errors indicated the two types of events were affected differently. In the self-generated events, path verbs improved rejection of path foils and manner verbs improved the rejection of manner foils, as predicted, but the opposite pattern was found with the caused motion events. The mapping of the verb onto the moving figure is more complex in these events (it is the pencil not the animate entity which rolls) and this may be involved.

The Semantics of temporal prepositions: the case of IN

David S. Brée (bree@cs.man.ac.uk)
Computer Science Department, University of Manchester
Oxford Road, Manchester M13 9PL, U.K.

This poster presents an analysis of the different ways that the preposition IN is used to convey temporal information. IN is the most frequent preposition and so a solution to its semantics will be a good guide to the semantics of other prepositions that are used temporally.

The analysis is based on all 1,980 temporal uses of IN occurring in the Brown corpus (Kučera & Frances, 1967). The temporal use was recognized by the presence of temporal nouns in the IN phrase (Brée & Pratt, 1997). Each occurrence was coded by hand for various features of the phrase, such as determiner, number, qualifier, type of noun, and also for features of the verb in the matrix in which the phrase was embedded such as tense, aspect, modality, negation, superlatives, cardinal and ordinal nouns.

The different possible types of temporal information that IN can convey were found to be:

- a duration (207 occurences) v. an interval (1,653), eg. *in a minute* v. *in 1960*. Almost all (203/207) of the durations were signalled by an indefinite determiner (or no determiner in the case of plural nouns) with a measure type noun, provided the noun was not a qualified plural, nor the noun *time* post-modified. The only other nouns which occurred with an indefinite determiner were life nouns, eg. *youth*, and seasons of the year, but these always indicated an interval.

- a pure duration (58) v. a duration attached to the time of reference (114), eg. *was built in a day* v. *for the first time in 30 years; will report in a day*. Some durations were pure, others were attached to the time of reference. A duration was attached to before the time of reference (39/114) if and only if there was an ordinal, a negative or a superlative in the matrix, generally with a perfect aspect. This is not surprising as the matrix holds for every subinterval in the interval preceding the time of reference but this is not permitted with IN plus a pure duration, FOR being required instead. Generally, a duration was attached to after the time of reference (75/114) if the IN phrase was topicalized (Hitzeman, 1997), if there was a modal in the matrix or if the matrix was a state or achievement rather than an accomplishment.

- an interval attached to a noun phrase v. a verb phrase, eg. *spending in the Sixties* v. *spent in the Sixties*. NP attachment (322) occurred whenever the IN phrase was before the verb, when the matrix was a superlative, when there was some other temporal adverbial, etc.

- measurement (104) v. quantification over an interval (1,226), eg. *sold 7 tractors in August* v. *died in August*. For measure use, the matrix must be either a repeatable event or an activity with repeated outcomes.

- universal (260) v. existential (966) quantification, eg. *accepted in the Fifties* v. *born in the Fifties*. As IN cannot be used for giving the duration of a state or activity, it is surprising for it be used when a matrix state or activity was lasting the whole of an **interval**.

- unique (1,272) v. generic (152) durations and intervals, eg. *made in the 1940s* v. *would come home in the morning*. A generic use was indicated by a quantifying determiner, a season with no determiner, a plural part-of-day noun and sometimes when the tense in the matrix was the simple present, unless this tense was being used to describe a current attitude to a future event, or in the context of art criticism or history, etcetera.

The last four distinctions depend on general features of the matrix and not on the IN phrase at all.

These heuristics provide a means for extracting the temporal semantics of IN phrases that could be implemented in a natural language computer system used, for example, either to understand natural language, or to give deep machine translation into another language. They will generalize to temporal uses of other prepositions, eg. FOR, and also to other uses of IN, in particular spatial uses, which closely parallel the temporal use.

Thoughts on the Prospective MML-TP: A Mental MetaLogic-Based Theorem Prover

Why do automated reasoning systems fail to even *hint* at the power of a human mathematician or logician? (See, e.g., the comparison between the "real" Gödel and machine versions of proofs of his famous incompleteness theorems: Bringsjord 1998.) Why is it that the best machine-proved theorems are shallow when matched against minds? From the standpoint of psychology and cognitive science, this is an exceedingly difficult question to answer, in no small part because these fields don't offer a mature theory of mature reasoning. What they *do* offer are theories of *im*mature reasoning, that is, theories of — as it's said — untrained or ordinary reasoning. (We have no precise definition of the difference between expert and novice reasoning, of course; but the distinction seems to make intuitive sense, and we can resort to characterization by example. E.g., *reductio ad absurdum* is probably *generally* the province of expert deductive reasoners. Certainly, say, diagonalization is the province of such reasoners.) If we assume that these theories can scale to the expert case, then it's no surprise at all that automated reasoning systems, when stacked against mathematical minds, look pretty bad. The reason is that theories of ordinary reasoning, before the advent of our Mental MetaLogic, invariably put their eggs in one basket. For example, the representational system of current mental logic theory can be viewed as (at least to some degree) a psychological selection from *only* the syntactic components of systems studied in modern symbolic logic. For example, in mental logic *modus ponens* is often selected as a schema while *modus tollens*[1] isn't; yet both are valid inferences in most standard logical systems. Another example can be found right at the heart of Lance Rips' system of mental logic, PSYCOP, set out in (Rips 1994), for this system includes conditional proof (p. 116), but *not* the rule which sanctions passing from the denial of a conditional to the truth of this conditional's antecedent (pp. 125–126). So, a theorem prover based exclusively on mental logic would of necessity fail to capture human mathematical reasoning that is "semantic." And while it's certainly true that expert reasoners often explicitly work within a system that is purely syntactic, it's also undeniable that such reasoners often work on the semantic side. Roger Penrose has recently provided us with an interesting example of semantic reasoning: He gives the case of the mathematician who is able to see via an image of the sort that is shown in Figure 1 that adding together successive hexagonal numbers, starting with 1, will always yield a cube.

Now, as a matter of fact, nearly all theorem provers are essentially incarnations of mental logic, so it is unsurprising that such provers are impoverished relative to trained human reasoners. Mental MetaLogic (MML) (Yang & Bringsjord under review) is a theory of reasoning which draws from the proof theoretic side of symbolic logic, the semantic (and therefore diagrammatic) side (and hence owes much to Johnson-Laird's 1983 mental model theory), and the content in between: metatheory. Furthermore, while theories of reasoning in psychology and cognitive science have to this point been restricted to elementary reasoning (e.g., the propositional and predicate calculi), MML includes psychological correlates to modal, temporal, deontic, conditional, ... logic. Accordingly, MML-TP will be theorem prover that ranges over a diverse range of representational schemes and types of reasoning.

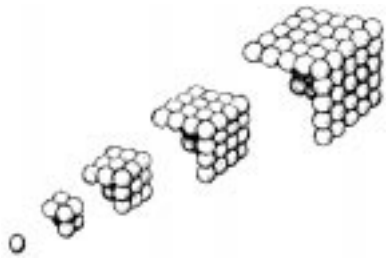

Figure 1: Viewed a Certain Way, the Cubes are Hexagons

[1] From $\phi \rightarrow \psi$ and $\neg\psi$ one can infer to $\neg\phi$.

Hemispheric Effects of Concreteness in Pictures and Words

Daniel J. Casasanto[1] (dcasasan@mail.med.upenn.edu)

Introduction

Functional Magnetic Resonance Imaging (fMRI) studies have demonstrated differently lateralized activation during episodic memory encoding for verbal and pictorial stimuli, as predicted by the material-specific model (1). Results are interpreted as consistent with Dual Coding Theory, which posits parallel verbal and imaginal systems by which a given stimulus may be represented (2), the neural substrates of which have also been shown to be differently lateralized (3). Whereas previous encoding studies have examined variation across material types, the present study investigated hemispheric effects within material types. FMRI was used to determine the laterality of encoding-related activation for verbal stimuli that varied in concreteness, and for pictorial stimuli that varied in verbalizability.

Methods

Task Design

Verbal task. Nine healthy, right-handed native English speakers viewed blocks of serially presented English nouns, alternating with blocks of control strings (2500ms presentation, 500ms ITI). Noun stimuli comprised two sublists: 40 concrete and 40 abstract nouns (mean concreteness ratings 6.31 and 2.61, respectively, on a 1-to-7 point scale (Toglia & Battig, 1978)). Each task block comprised ten nouns: eight from one sublist and two from the other. Subjects classified nouns as concrete or abstract, responding via a left-or-right button press. Control blocks comprised ten strings of Ls or Rs, eliciting the same proportion of left and right button presses as the preceding block of nouns. Subjects were instructed to remember noun stimuli for a post-scan forced-choice recognition memory test.

Pictorial task. For each of two face memory encoding tasks, eleven healthy, right-handed volunteers viewed blocks of unfamiliar face photographs, alternating with blocks of a repeatedly presented pixelated control image (six 40s task/control blocks, 10 stimuli per block, 3500ms presentation, 500ms ITI). For the first task, full-head photographs were shown, including hair, neck, and upper shoulders. In some cases, clothing and jewelry were visible. For the second task, the same set of face photographs was used, but each photograph was cropped so as to include the brow, eyes, nose, and mouth, but exclude ears, hair, and any extraneous objects. Subjects were instructed to remember the faces for a post-scan recognition test, and to attend the control images but not to memorize them. Scanning occurred during the encoding tasks but not during recognition testing.

Image Acquisition and Data Analysis

BOLD functional images were obtained at 1.5Tesla in 20 contiguous 5-mm-thick axial slices. Multisubject SPMs were constructed in Talairach space using the SPM99{t} random effects model. Cognitive subtraction revealed activation associated with encoding during blocks of predominantly concrete and predominantly abstract nouns, and during cropped-face and full-head encoding. For each task, activation exceeding a statistical threshold ($\propto$=.05) was quantified in two *a priori*-defined regions of interest. ROIs comprised the inferior frontal gyrus (IFG) and fusiform gyri (FG), as these structures have demonstrated reliable material-specific effects in previous encoding studies. Hemispheric asymmetry of activation in each ROI was assessed using an asymmetry ratio [AR = (VoxelsR–VoxelsL)/(VoxelsR+VoxelsL)].

Results and Discussion

Differing hemispheric effects shown previously across verbal and pictorial material types were demonstrated in the present study within material types. Average activation in the ROIs was bilateral during encoding of concrete nouns [AR(IFG)=-.06, *ns*; AR(FG)=.13, *ns*], which are amenable to both verbal an imaginal coding, but significantly left-lateralized during encoding of abstract nouns [AR(IFG)=-.22, P=.001; AR(FG)=-.80, P=.009], which are resistant to imaginal coding. Activation during encoding of full-head photographs was left-lateralized in the IFG [AR(IFG)=-.46, P=.001] and bilateral in the FG [AR(FG)=-.25, *ns*], but activation during encoding of cropped-faces, which are resistant to verbal coding, was significantly right-lateralized in both ROIs [AR(IFG)=.12, P=.001; AR(FG)=.71, P=.001]. Replication of these findings within verbal stimuli that vary in imageability and within pictorial stimuli that vary in verbalizability would suggest that hemispheric specialization during memory encoding heretofore described as material-specific might be more accurately described as code-specific.

Learning Statistics: The Use of Conceptual Equations and Overviews to Aid Transfer

Richard Catrambone (rc7@prism.gatech.edu)
Georgia Institute of Technology, School of Psychology,

Learners can carry out new procedures or solve new problems that are quite similar to those on which they were trained, but they have difficulty when the novel cases involve more than minor changes from what they had previously studied. This transfer difficulty seems to stem from a tendency by many learners to memorize the steps of how equations are filled out rather than learning the deeper, conceptual knowledge that is implicit in the details. One type of knowledge structure that appears to aid procedural generalization is one organized by subgoals (Catrambone, 1998). A subgoal represents a meaningful conceptual piece of an overall solution procedure and can serve as a guide to which part of a previously-learned solution procedure needs to be modified for a novel problem.

In the domain of mathematical problem solving there are often "computationally-friendly" solution approaches in which multiple solution steps are collapsed into a single formula. These formulas allow for the easy calculation of the solution by simply inserting the correct values into the formula. A major drawback of this approach is that it is restricted to solving a narrow range of problems that fall into predefined problem categories corresponding to solution formulas.

A good example of such a contrast is the process of calculating sum of squared deviation scores (SS) for the variance terms in t-tests and analyses of variance (ANOVAs). The conceptual formula for SS in a t-test, $\Sigma\ (X - \overline{X})^2$ translates directly into the sum of squared deviations. This clearly captures how the variance term measures the amount of spread about the mean. In contrast, the computational formula for SS, $\Sigma X^2 - (\Sigma X)^2 / N$ permits the learner to calculate SS directly from raw scores which can lead to more efficient calculations, however, the computational formula conceals the notion of spread.

We were also interested in the relative effectiveness of overview information presented to learners either before they studied an example or after they studied an example. Overview information offered as a pre-instructional aid might, like advance organizers, provide an organizing cognitive structure for receiving new material (Ausubel, 1968). However, a pre-example overview runs the risk of appearing too abstract and non-contextualized. A post-example overview might supplement or reinforce what was illustrated in the examples, thereby facilitating the integration and application of recently acquired procedural knowledge.

Procedure and Hypothesis

Participants (N = 112) studied a t-test example and a two-group ANOVA example that used either a conceptual or computational approach. Overview information either preceded or followed each example. Participants then solved two near transfer problems (a t-test problem and a two-group ANOVA problem) and a far transfer problem (a three-group ANOVA problem that required an adaptation of how variance was calculated). We hypothesized that consistent with a subgoal-learning approach, learners who studied examples with conceptually-oriented equations would transfer more successfully to novel problems compared to learners who studied examples using computationally-oriented equations.

Results and Discussion

The conceptual group outperformed the computational group on the 2-group ANOVA problem; this is a bit surprising because all participants studied a 2-group ANOVA example. One possible explanation for this finding is that the conceptual equations are easier to implement and to check for errors. The conceptual group was also more successful on the 3-group ANOVA problem which is consistent with the hypothesis that these participants were better able to modify the equation.

There was no effect due to the position of the overview. This suggests several possibilities including: the material simply was not very effective; positioning of such material does not matter for learning in this domain; learners may have been less inclined to pay attention to it because the overview material essentially recapitulates the information provided in the examples (with a bit of elaboration) but without numbers.

Infants' Associations of Words and Sounds to Animals and Vehicles

Eliana Colunga (ecolunga@cs.indiana.edu)
Computer Science Department; Lindley Hall 215

In a recent study, Woodward and Hoyne (1999) showed that 13-month-olds readily associate both words coming from the experimenter's mouth and non-linguistic sounds coming from a hand-held noisemaker with object categories. In contrast, 20-month-olds associate words but not non-linguistic sounds with object categories. Woodward and Hoyne suggest that words become privileged as possible names; that the forms a name can take are open at the beginning and become more restricted with development. Are children learning what forms count as words? If so, just what defining features are they learning?

In the research presented here, we attempt to answer these questions. In our account, words become privileged as names because of the special way they correlate with categories.

By our account, there are two parts to this specialness. First, there is one name (more or less) that goes with each category (more or less). So, the name of the category is a feature that all members of the category have in common while at the same time the name is a feature that distinguishes instances from members of other categories. Second, words *as a domain* have this special function of pointing to categories. The fact that there are many words that point to categories is what helps children generalize this expectation to novel words. Thus, our account makes two predictions:

1. Any strongly correlated feature of a name will become an integral part of what is a name. Words emanating from mouths is a highly systematic property of names. Thus, we predict that if a word comes out of a place other than a mouth, young children will not take it as a name.

2**.** Any event domain that systematically predicts category membership will be taken as a name as well. For example, animal category correlates with animal sound: dogs bark, cats meow, elephants trumpet and so on. Thus animal sounds should be taken as names for animals.

In Experiment 1 we test this predictions by looking at children's associations of words, animal sounds and motor sounds to animal categories. In Experiment we look at their associations with vehicle categories.

Experiment 1

Thirty-six 20-26 month-old children participated in a 3x3 mixed design with three different sound sources (mouth, animal, noisemaker) as between-subject variable and three different sounds (word, animal sound, motor sound) as within-subject variable. Thus, each child heard three different kinds of names for three different animal categories. In the Mouth condition, children heard the three kinds of label coming from the experimenter's mouth. The experimenter named the animal "Look at this toma" in the Word condition, "Look at this <frog clucking>" in the Animal Sound condition, and "Look at this <motor>" in the Motor Sound condition. In the Animal condition the three kinds of label came from recorders concealed in the toy animal. In the Noisemaker condition the labels emanated from hand-held recorders. The carrier phrase was always said by the experimenter.

During the test phase, children were presented with the target object and a distracter on a tray. The child was asked to "Get the <label>". The results show that 20-26 month-olds 1) associate both words and motor sounds to animal categories only when the words emanate from the mouth and 2) associate animal sounds with animal categories regardless of the source of the sound. In other words, the three kinds of labels coming from the mouth are taken as names, and animal sounds coming from any of the three sources are taken as names.

Experiment 2

The results of Experiment 1 match our predictions. However, an alternative explanation is that there is something inherently word-like about animal sounds. In Experiment 2 we explore this possibility by looking at children's learning of labels for vehicle categories. If babies in Experiment 1 linked the animal sound to the animal toy because of some perceptual property of the sound, we would expect them to link animal sounds to vehicle categories as well. However, if our account is correct, they will reject the animal sound as a label for a vehicle but accept the motor sound.

We used the same design but the stimuli used were novel vehicles. Our results show that, as predicted, 20-26 month-olds take motor sounds as labels for vehicle categories, but reject animal sounds as labels for vehicle categories.

Why this pattern? Because this pattern reflects the systematicity with which events correlate with categories in the world. Sounds from mouths typically name things; animal sounds correlate with animal categories in much the same way as words correlate with object categories. In conclusion, we suggest that it is the systematicity of prior learned pairings that determines what counts as a name.

A Connectionist Model of Semantic Memory: Superordinate structure without hierarchies

George S. Cree (gcree@uwo.ca)
Department of Psychology, 1151 Richmond Street
London, Ontario N6A 5B8 Canada

Ken McRae (kenm@uwo.ca)
Department of Psychology, 1151 Richmond Street
London, Ontario, N6A 5B8 Canada

Symbolic, spreading-activation models of semantic memory represent subset-superset relationships among concepts as distinct, hierarchical levels of nodes connected by "isa" links (e.g., Quillian, 1968). Numerous theoretical and empirical arguments have been leveled against this approach (e.g., Dean & Sloman, 1995; Rumelhart & Todd, 1993), including (1) the difficulty such models have in accounting for familiarity and typicality effects, (2) that category membership is often unclear, (3) that items can belong to multiple categories, (4) that some categories are more internally coherent than others, (5) that general properties do not necessarily take longer to verify than specific properties, and (6) that some general category membership relations can be verified faster than specific category membership relations.

We present a novel connectionist model of semantic memory that offers potential solutions to these problems. The model, an extension of McRae, de Sa & Seidenberg's (1997) and Cree, McRae & McNorgan's (1999) models of semantic memory, was trained to compute distributed patterns of semantic features from word forms. Semantic feature production norms were used to derive basic-level representations and category membership for 181 concepts taken from McRae et al's (1997) property norms. Basic-level (e.g., dog) and superordinate-level (e.g., animal) concepts were represented over the same set of semantic features.

The training scheme was designed to mimic the fact that people sometimes refer to an exemplar with its basic-level label, and sometimes with its superordinate-level label. Two types of training trials were used. In 90% of the training trials, basic-level word forms mapped to their semantic representation, instantiating a one-to-one mapping. The occurrence of each of the 181 basic-level exemplars during training was scaled by familiarity ratings that were collected from human participants. In the remaining 10% of the trials, a superordinate word form was trained by pairing it with one of its exemplars' semantic representations. Importantly, each semantic representation included in a category was paired with that superordinate word form with equal frequency (i.e., typicality was not built in).

The model was used to simulate data from typicality, superordinate-exemplar priming, and category-verification experiments. In explaining the human data, emphasis was placed on the role of correlations among features, the familiarity of concepts, category size, and on the distinction between off-line and on-line processing dynamics. Specifically, settled attractor states for superordinate-level concepts are composed of a greater number of units with states on the linear component of the sigmoidal activation function, making it easier, for example, for the network to move from a superordinate representation to any other during temporal, on-line processing.

Concept Generalization in Separable and Integral Stimulus Spaces

Nicolas Davidenko (ndaviden@psych.stanford.edu)
Joshua B. Tenenbaum (jbt@psych.stanford.edu)
Department of Psychology
Stanford University, Stanford, CA

Many models of human concept learning are built around a hypothesis space of possible concepts with an associated probability distribution (Tenenbaum, 1999). These hypothesis spaces are difficult to describe, even in the case of two-dimensional stimulus spaces. Garner (1974) distinguished two types of stimulus spaces: separable (where similarity judgments follow a city-block metric) and integral (where they follow a Euclidean metric). To explain why generalization contours from one exemplar are diamonds in separable spaces and circular in integral spaces, Shepard (1987) suggested two corresponding hypothesis spaces: the space of axis-aligned rectangles (for separable spaces), and the space of circular discs (for integral spaces). However, the generalization contours from one exemplar do not uniquely determine a hypothesis space (e.g. the hypothesis space of squares under all possible rotations produces the same generalization contours as the hypothesis space of circular discs). In this work, we attempt to constrain the choice of hypothesis spaces by analyzing concept generalization from multiple exemplars. Our preliminary findings are generally consistent with Shepard's formulation except for one significant difference: people show correlational concept generalization even in separable spaces.

Method

Fourteen subjects (ages 15 to 49) participated in a two-part experiment. Each part included 6 trials, and the order of the parts was counterbalanced across subjects. In each trial in part I (concept generalization in a separable space), subjects observed on a computer screen a group of five stimuli said to be "representative of a larger set." The stimuli were circles of variable size with radial lines of variable orientation. The parameters were chosen to fall on line segments embedded in the Size-Orientation space and were either axis-aligned (varying only in one dimension) or correlational (varying in both dimensions simultaneously). The five exemplars were evenly spread in the stimulus space. After observing the exemplars, subjects rated each of eight test items according to the perceived probability that it belonged to the same set represented by the exemplars, on a 0-10 scale. The test items were placed either on the linear extension of the concept or perpendicular to it. Part II (concept generalization in an integral space) followed the same design except that the stimuli were discs varying in two integral color dimensions: saturation and brightness.

Results and Discussion

Figure 1 shows the predictions using Shepard's hypothesis spaces of the 50% generalization contours for axis-aligned and correlational stimulus sets (dark dots).

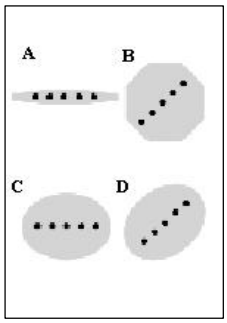

Figure 1

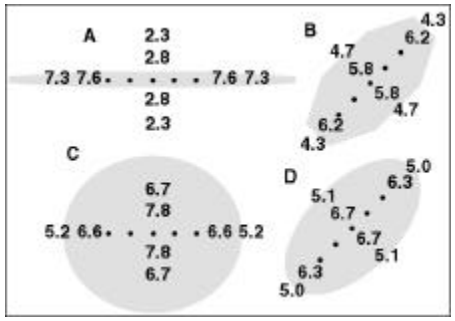

Figure 2

Generalization in a separable space (top row) is orientation-dependent; in particular, adaptation to the one-dimensional extent of the concept occurs only when the concept is axis-aligned (A). In an integral space (C and D), concept orientation is irrelevant.

Figure 2 summarizes the experimental data. Probability ratings of the test items (averaged across subjects) are shown as numbers. The contour regions were obtained by extrapolating the 50% probability boundary. In the separable space (top row), linear adaptation occurs more noticeably in the axis-aligned concept (A), but also occurs to some extent in the correlational concept (B), contrary to an axis-aligned rectangular hypothesis space. This finding suggests that the hypothesis space for separable dimension stimulus spaces is more complex than originally formulated by Shepard, perhaps including rectangular regions of all possible orientations weighted by some prior probability distribution. We are currently exploring this possibility through human experiments and mathematical modeling.

Linguistic Resources and " Ontologies " across Sense Modalities
A Comparison between Color, Odor, and Noise and Sound.

Dubois Danièle (daniele.dubois@inalf.cnrs.fr)
CNRS/LCPE, 44 rue de l'Amiral Mouchez, F-75014 Paris
&
Cance Caroline (caroline.cance@ivry.cnrs.fr)
Université de Paris 3 & LCPE, 44 rue de l'Amiral Mouchez, F-75014 Paris

After exploring categorization of color and other visual objects (Dubois, 1991; 1997), we have been recently investigating cognitive categories within other senses, such as olfaction and audition (Dubois, 1997b). We present here contrasted results concerning psychological representations of colors, odors, noises and sounds induced from their linguistic expression in (French) language.

Quantitative evaluations of occurrences, their morphological, syntactic and semantic properties were computed on a corpus of 108 definitions produced by native speakers, according to previous analyses theoretically based in Dubois (2000; Dubois & Grinevald, 1999). Only partial results and conclusions will be reported here.

Table 1: Number of nominal forms: Number of occurrences and number of single occurrences (Hapax) in the 4 corpora:

	forms	Occ.	Hapax
odor	78	158	54
color	67	117	48
sound	20	32	14
noise	14	24	10

Among other indicators such as the number of verbs, relative clauses, adjectival forms (simple or deverbal ('pleasant') or denominal ('noisy') constructions), the nominal forms reveal that French linguistic resources vary across sense modalities : acoustic representations show less productivity and more agreement between subjects than colors and than odors.

Table 2: Linguistic marks of "objectivity" and personal involvement (Percentage of subjects producing the word "*something*" and personal pronouns in their definitions)

	"something"	personal pronouns
odor	24,3	43,9
sound	25,9	35,2
noise	20,4	33,3
color	14,8	21,4

The lack of commonly shared naming for odors and acoustic phenomena correlates with the uncertainty of their definitions, stated as "something" that affects the subject, as reflected in the greater personal involvement for odor than for sound and noise, and lesser for color definitions.

Conclusion

Colors as visual objects seem to be processed as stimuli "standing out there", whereas odors are more likely to be structured as **effects** of the world on the subject, therefore less autonomous from the experiential context. Acoustics phenomena can be represented at different degrees of "subjectivity" (or objectivity), contrasting noises that are more subjective than sounds, these latter referring to a more expert, objective, technical and scientific knowledge.

If we always perceive "something", through the diversity of senses, language diversely objectivizes and "stabilizes" our cognitive representations of the world into a large variety of linguistic forms. These forms may constrain the "ontology" given to the entities and lead to different distances between the "subject" and the "objects" of the world, from complex phrasing expressing the effects of the world on the subject, to simple " basic " names, which suggest the idea that things are "crying out to be named".

What was the Cause? Children's Ability to Categorize Inferences

(ellefson@siu.edu)
Department of Psychology, Mailcode 6502
Southern Illinois University - Carbondale
Carbondale, IL 62901-6502 USA

Inferences have been utilized in a number of studies to further investigate the dynamics of comprehension in children (e. g., Casteel, 1993). An inference can be defined as the processing of information that extends beyond the initial processing of text (Inman & Dickerson, 1995). An inference is usually made when information is not specifically indicated in the text (McKoon & Ratcliff, 1992). An inference is a critical part of comprehension (e.g., Oakhill, 1984; Phillips, 1988). Often causal relations are not specified and an inference is needed. Children draw inferences with relative ease and the study of inferences has helped researchers understand the dynamics of comprehension in children. In previous research children have been able to generate their own responses from ambiguous text (e.g., Bonitatibus & Beal, 1996; Casteel, 1993). The current study examines children's ability to classify inferential statements.

Nineteen fourth-grade participants (9 males and 10 females) between the ages of 9 and 10, read stories with ambiguous endings. Each story was followed by 6 statements that elicited either an unlikely, neutral, or likely inference. After each statement, the children indicated, using a "Yes" or "No" key, whether they thought the statement could fit into the context of the story.

Responses and reaction time data were collected from each participant. There was a main effect of sentence type (F (2, 36) = 5.43, $p < .05$). Reaction times were significantly faster to the unlikely statements compared to both the likely (F (1,38) = 10.28, $p < .01$) and neutral statements (F (1, 36) = 5.13, $p < .05$).

Overall, children correctly classified unlikely inferences as not appropriate for the story (87%). Most children also rated the neutral inferences as not fitting into the story. Children were reluctant to classify likely inferences as fitting into the story. Overall, only 2/3 of the likely statements were classified as fitting into the story. The lower classification rate for the likely sentences was significant (F (2, 87) = 173.32, $p < .001$). The children's reluctance to classify likely sentences as fitting into the story is reflected by significant difference in reaction time between the "Yes" and the "No" responses (F (1, 88) = 16.73, $p < .001$).

The results indicated that children rejected unlikely inferences much faster than they accepted likely or neutral inferences. The children may have generated their own inferences during the story. After the story they had to compare their prior expectations with the likely, neutral, and unlikely inferences. If children have generated correct inferences than unexpected statements like those in the unlikely condition may have been quickly rejected. The additional time used to classify the neutral statements may have been necessary because the statement could have happened, but often did not fit with the context of the story. The likely statements may have been close to the children's expectations and would require additional processing to be sure that they really did fit with the story. Children were reluctant to respond "Yes", which might have been a strategy to ensure their accuracy. This research indicates that further work is necessary for a better understanding of how children process ambiguous information.

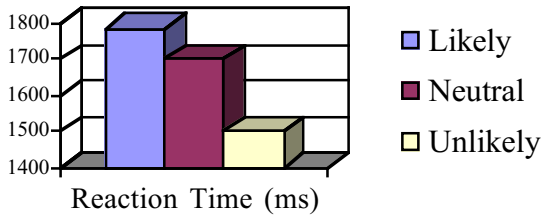

Figure 1. Reaction time (ms) for classification of Likely, Neutral, and Unlikely inferences.

Structural Alignment in Similarity and Difference of Simple Visual Stimuli

Zachary Estes (zcestes@princeton.edu)
Uri Hasson (hasson@princeton.edu)
Department of Psychology, Princeton University
Princeton, NJ 08544-1010, USA

The present investigation tested the predictions of Structural Alignment theory (Gentner & Markman, 1997) in similarity and difference judgments of simple visual stimuli. Alignment theory explains comparison as a process of aligning the structure of one stimulus with the structure of the other stimulus. The theory makes a critical distinction between alignable differences, which are related to commonalities in the structures of two stimuli, and nonalignable differences, which have no structural correspondence in the two stimuli. Examples are shown in Figure 1. The difference between the standard stimulus S and the NAD stimulus is nonalignable because S has no element that corresponds to the black triangle in NAD. The difference between S and the ADA stimulus, on the other hand, is alignable because the white circle in S is aligned with, or corresponds to, the black circle in ADA. Alignable differences may also occur in the form of a different object (ADO) or a different relation between objects (ADR).

Figure 1: Stimuli used in Experiments 1 and 2.

These distinctions are critical for predicting similarity and difference judgments. Alignment theory predicts that "alignable differences count more against similarity than nonalignable differences" (ibid, p. 50). That is, items with an alignable difference (i.e., ADA, ADR, and ADO) should be judged less similar to (and more different from) the standard than should items with a nonalignable difference (i.e., NAD). A second prediction is that the more different the alignable difference is from the standard, the more it will detract from similarity (see Markman & Gentner, 1996).

Experiments 1 and 2. Stimuli consisted of all possible pairs of items shown in Figure 1 (excluding the standard stimulus), thus creating 6 item pairs. For each item pair, participants judged which of the two stimuli was more similar to the standard stimulus (Experiment 1) or more different from the standard stimulus (Experiment 2).

Table 1: Proportions of similarity and difference choices.

Item pair	Similarity	Difference
(1) ADA & ADO	ADA = .65	ADO = .70
(2) ADR & ADO	ADR = .55	ADO = .58
(3) ADA & ADR	ADA = .74	ADR = .57
(4) NAD & ADA	ADA = .74	NAD = .72
(5) NAD & ADR	ADR = .69	NAD = .68
(6) NAD & ADO	ADO = .53	NAD = .50

Discussion. Comparisons (1) and (2) in the Table above show that, of the items with alignable differences, ADO was most different from S. Comparison (3) shows that ADA was the least different from S, with ADR falling in between. Having established this hierarchy of alignable differences, we next examined whether the degree of difference of an alignable difference from S did affect the degree to which that alignable difference detracted from similarity (when judged with a nonalignable difference). As predicted, comparison (4) shows that the least different alignable difference detracted the least from similarity judgments (i.e., ADA = .74), while (6) shows that the most different alignable difference detracted the most from similarity judgments (i.e, ADO = .53). These findings extend and replicate those of Markman and Gentner (1996).

However, as apparent in the Table, in no case did an alignable difference (i.e., ADA, ADR, or ADO) detract more from similarity judgments than did a nonalignable difference (i.e., NAD). On the contrary, ADA and ADR actually counted less against similarity (and conversely more against difference) than did NAD. This result does not support the prediction of alignment theory.

Potential explanations of this failure to support alignment theory are that (i) alignment theory is not applicable to simple visual stimuli, (ii) the alignable differences used in these experiments were not sufficiently different, or (iii) NAD was not really a nonalignable difference, but rather was an alignable difference in the number of elements in the item. We would be delighted to discuss these and other possibilities with you at our poster.

Music Evolution: The Memory Modulation Theory

Steven D. Flinn (s.flinn@manyworlds.com)
ManyWorlds, Inc., 510 Bering Drive, Suite 470
Houston, TX 77057 USA

Solving the Mystery of Music

The evolutionary basis for the development of advanced musical capabilities in humans has remained a mystery. Whereas language clearly confers obvious fitness advantages, music has resisted such an easy explanation. Current explanations tend to fall into the categories of either music as a by-product of the evolution of other facilities that do directly confer fitness benefits, or music as a sexual selection fitness indicator (Wallin, Merker & Brown, 2000).

We have found neither of these classes of explanations, nor any other of the previously proposed explanations compelling. Rather, we argue that advanced musical capabilities evolved because they directly confer specific fitness advantages. In particular, we argue that human musical capabilities are precisely those set of specialized mental capabilities that co-evolved with language to enable the sophisticated memory modulation of the receiver of information by the communicator of a message. In other words, music enables individuals and groups that are communicating messages to have a degree of control over how the messages will be retained in the memory of the receiver(s). Particularly in the pre-literate world, such abilities have obvious, direct evolutionary advantages.

Memory Modulation and Music

The consolidation theory of memory (McGaugh, 2000) continues to guide current memory research. The theory suggests that it takes time for long-term memories to consolidate. "Considerable evidence suggests that the slow consolidation of memories serves an adaptive function by enabling endogenous processes activated by an experience to modulate memory strength". In other words, it is optimal for long-term memory processes to be highly selective.

Key facilitators of memory modulation are emotional arousal, repetition, and structure. And these are exactly the essential attributes of music -- making it the ultimate vehicle for fine-tuned memory modulation.

In particular, music enhances the probability of long-term memory of coincident events and communications. It appears that music facilitates long-term memory primarily through the evocation of emotion, and with contributions from repetition and additional structure (Schulkind, Hennis & Brown, 1999)

An Information Theoretic Approach

From an information theory point of view, the generalized issue at hand is precisely how communications modes would co-evolve with increasing intelligence, given specific memory storage architectures.

If the architecture of the human brain had been such that there existed only one type of memory, then a communications capability relying simply on syntactical structures would have been sufficient. However, the durability of memories in the human brain (and other animals) can, as a first approximation, be divided into two categories: short-term and long-term memory. Syntactical structures of language alone offer limited ability for the sender of a message to effectively influence the strength of memory of the receiver.

However, the ability of communicators to directly influence strength of memory in receivers would be of exceedingly high fitness value as intelligence and the sophistication of associated messages increased. Indeed, the encoding of a message in very long-term memory significantly increases the probability that the message will be re-transmitted with high fidelity by the original receiver to others. This cascading of the original message vastly increases the evolutionary value of preferential memory selection by the message sender.

We argue, music is, therefore, just that (expected) mode of communication that co-evolved with language and overall intelligence that enabled finer and finer control of the memory modulation of message receivers by message sender(s). Music has all the right characteristics to fit this critical (and expected) role, and there is no other such communications mode that fills such a role as effectively. Nor do we find any other explanation for the evolution of musicality in humans that is as comprehensive and compelling.

Language affects memory, but does it affect perception?

Michael C. Frank (mcfrank@stanford.edu)
PO Box 15007, Stanford University
Stanford, CA 94309 USA

Lera Boroditsky (lera@psych.stanford.edu)
Department of Psychology, Jordan Hall, Building 420
Stanford, CA 94305-2130 USA

Does the language you speak affect the way you perceive the world? The strong Linguistic Determinism view — the idea that all aspects of thought (even low-level perceptual abilities) are determined by language — is most closely associated with the writings of Benjamin Lee Whorf (1956). Whorf s ideas have generated much interest and controversy, with much of the empirical work focusing on color perception.

Different languages divide the color spectrum differently; does this lead speakers of different languages to actually perceive colors differently? Early studies claimed no differences in color perception (Heider, 1972), but recent cross-linguistic studies (Davidoff et al., 1999) as well as studies of categorical learning (Goldstone, 1994) have claimed that linguistically learned categories can indeed affect people s perception of shapes and colors.

Although it would be exciting to discover effects of language in domains as low-level as the perception of color, we should be careful in establishing what counts as a test of perception. The studies mentioned above may best be characterized as tests of memory, rather than tests of perception. In these studies, subjects were shown a color sample, and then after a delay asked to either select the same color from a pair of alternatives, or to indicate whether a new color sample is the same or different from the one presented previously. Since these tasks rely heavily on subjects ability to remember the color over a delay, they may tell us more about the ability of language to interfere with color memory than color perception. Further, since language may interfere with color memory in trivial ways (e.g., it could act as a secondary code in memory, and thus affect memory performance without altering the actual perceptual memory trace) (Lucy & Shweder, 1979), more research is necessary to establish whether linguistic information is indeed capable of affecting color perception or even perceptual memories.

We have set out to distinguish the effects of linguistically learned distinctions on memory from effects on perception. In one study, we created a continuum of blue color samples, and taught subjects a categorical boundary in the middle of this space of blues (a boundary corresponding to the goluboy/siniy distinction made in Russian). Another group of subjects received comparable exposure to the color samples, but were not taught the categorical boundary.

In the test phase, participants saw pairs of color samples on a screen at the same time and were asked to determine whether the two colors were exactly the same or different as quickly as possible. We were interested in whether learning a category boundary would make people faster to say that two colors are different if they fell in different categories, or slower to say they are different if the two colors were from the same category. Unlike the earlier studies, this task does not rely on subjects color memory since both samples necessary for comparison were presented at the same time. We found no difference in performance between subjects taught the goluboy/siniy distinction and the control group. These preliminary results suggest that color perception may indeed be immune to modification by language. That is, while language may affect color memory, its ability to affect color perception is somewhat doubtful.

Acknowledgments

This research is funded by a URO grant from Stanford University made possible by the generous contribution of Mel and Joan Lane.

Pragmatic Knowledge and Bridging Inferences

Raymond W. Gibbs (gibbs@cats.ucsc.edu)

Tokyo, 181-8585 JAPAN

What kinds of pragmatic information are necessary for drawing contextually appropriate bridging inferences in conversation (e.g. linking statements such as "I prefer Italy to England. The pasta there was better")? We examined two contemporary pragmatic models of inference generation. One model, Levinson's (2000) view of "presumptive meanings", assumes that inference generation is governed by two default rules that access rich pragmatic knowledge later on in the comprehension process. Another view, Sperber and Wilson's (1995; Matsui 2000), claims that bridging inferences are efficiently generated as implicated premises given the expectation of particular relevant cognitive effects. These models differ, then, in their predictions of when enriched pragmatics shapes utterance interpretation. We report the findings from a series of experiments, measuring both participants' intuitions and reading-times for different bridging inferences. These data generally support the relevance-theoretic view.

The expectation of particular cognitive effects to be achieved by an incoming utterance may not always be generated in the hearer's mind. However, according to Sperber & Wilson, a question is an explicit way of communicating the cognitive effects to be achieved by an incoming utterance. This, in turn, suggests that the person who asks a question is entitled to have rather strong expectations of particular cognitive effects: namely, the relevant answer to his question. One of our experiments, therefore, is designed to compare the comprehension time of two utterance types: a question-answer pair and a juxtaposed utterance pair, each of which describes a state of affairs. Consider the following two sets of utterances, the first of which involve a classic example of bridging inference, namely, the beer was part of the picnic, and the second, a less likely variation:

(1a) Mary: How was the picnic?
John: Well, the beer was warm.
(1b) John: I unpacked the picnic. The beer was warm.

(2a) Mary: How was the job interview?
John: Well, the beer was warm.
(2b) John: I had a job interview. The beer was warm.

A relevance-theoretic view of questions predicts that it is faster to comprehend the utterance 'the beer was warm' in (1a) than (1b). The expected difference in processing time may be explained in terms of how highly accessible the implicature of each utterance is, which possibly facilitates the overall interpretation process. John's utterance in (1), combined with other assumptions and Mary's expectation that John is providing an answer to her question, straightforwardly yields an implicature that the picnic was not totally successful. By contrast, the second utterance in (1b) does not seem to yield any strong implicature, hence, it is predicted that there is no facilitation of the same type. We also predict that the difference in comprehension time is greater between (2a) and (2b) than between (1a) and (1b). In (2), where the relationship between 'job interview' and 'beer' is rather distant, without an expectation of particular cognitive effect, it may almost be impossible to find an acceptable interpretation for (2b). By contrast, in (2a), the interpretation of the second utterance is constrained by the question to the extent that the hearer has to construct the assumption, say, that the beer was offered during the job interview.

Our findings in support of relevance theory suggest that pragmatic information of roughly the same sort enters into listener's understanding of both what speakers say and what they implicate. Bridging inferences appear to be drawn as part of the implicated premises that arise from listeners' attempts to derive appropriate cognitive effects as part of their assumptions about relevance in ordinary communications. These results illustrate the critical importance of enriched pragmatic knowledge in early aspects of linguistic processing.

The AMBR Model Comparison Project: Multi-tasking, the Icarus Federation, and Concept Learning

Kevin A. Gluck (kevin.gluck@williams.af.mil)
Air Force Research Laboratory, 6030 S. Kent St.
Mesa, AZ 85212-6061, USA

Michael J. Young (michael.young@wpafb.af.mil)
Air Force Research Laboratory, 2698 G St., Bldg. 190
Wright-Patterson AFB, OH 45433-7604, USA

Introduction

In recent years, the Human Effectiveness directorate of the Air Force Research Laboratory (AFRL) has increased its investment in science and technology for human behavior representation. One beneficiary of this increase has been the Agent-based Modeling and Behavior Representation (AMBR) Model Comparison Project. The primary goal of the AMBR Model Comparison Project is to advance the state of the art in cognitive and behavioral modeling. It is organized as a series of model comparisons, orchestrated by a moderator team at BBN Technologies. In each comparison, a challenging behavioral phenomenon is chosen for study. Data are collected from humans performing the task. Cognitive models representing different modeling architectures are created, run on the task, and then compared to the collected data. This poster presentation will include results from the first two rounds of the comparison, ongoing work in Round 3, and future plans for Round 4.

Round 1: Multi-tasking

The first iteration of the AMBR Project is complete. The modeling goal in the first round was multi-tasking, and the task domain required a simplified version of en-route air traffic control. Modelers using ACT-R, COGNET/iGEN, D-COG, and EPIC-Soar participated in Round 1. All were able to approximate the trends and central tendencies of the data, but naturally the particular implementation of multi-tasking capability differed across architectures. Round 1 provided a motivation for extending and/or testing each of these architectures in a new way. It was particularly noteworthy that all four utilized some form of "embodiment" (e.g., eyes, hands), although at different levels of fidelity.

Round 2: The Icarus Federation

In Round 2 of the AMBR Model Comparison Project, the Defense Modeling and Simulation Office (DMSO) sponsored the conversion of the simulation environment and models from Round 1, so that they are compliant with DMSO's High-Level Architecture (HLA). Goals for Round 2 include the following:

- Develop an HLA-compliant testbed for research in human behavior representation (HBR)
- Assess the adequacy of the HLA for supporting HBR research
- Assess the adequacy of DMSO's FEderation Development and Execution Process (FEDEP) as a framework for creating and running federations for HBR research

Round 3: Concept Learning

To increase the cognitive requirements of the task used in Rounds 1 and 2, the air traffic control simulation is being supplemented with an embedded category learning task. Multiple aircraft will query the controller (the one that is being modeled) about the possibility of changing altitude. The controller will make a decision to authorize an altitude change based on a multi-dimensional attribute matrix that might include dimensions like aircraft size, level of atmospheric turbulence, and current altitude. The Controller must learn the appropriate responses on the basis of feedback received through the user interface concerning whether they made a correct decision or not. This concept learning task is based on the original laboratory study by Shepard, Hovland, and Jenkins (1961), and modeling studies reported by Nosofsky, et al. (1994).

Round 4: Under Development

The task for Round 4 will be fundamentally similar to the task used in Round 3, but the details are still under consideration. Based on the results of the Round 3 model evaluations, the Round 4 task will be designed to further stress the models and examine their capabilities. We anticipate a focus on the ability of models to adapt from one set of learned concepts to a new, changed set of concepts based on the same or a similar set of concept attributes. Other manipulations such as the workload of the perceptual motor task may also be explored as deemed appropriate given the results of Round III.

Does Adult Category Verification Reflect Child-like Concepts?

Robert F. Goldberg (rgold@pitt.edu)
Department of Psychology and Learning Research and Development Center,
University of Pittsburgh and the
Center for the Neural Basis of Cognition
3939 O'Hara St., Pittsburgh, PA 15260 USA

Introduction

Category verification tasks require subjects to respond as quickly and as accurately as possible as to whether a particular instance is a member of the given category. The variations in reaction time are then used as evidence for the structure of that category. This paradigm led to the view that category structure is based upon graded relations (e.g. Rosch & Mervis, 1975). More recently it has been argued that a theory-based approach is necessary for categorization (Murphy & Medin, 1985). In particular, children are shown to use naïve theories to guide their conceptual development (Carey 1985; Keil, 1989). But surprisingly developmental trends are not usually followed to the structure of the adult endstate (Coley, 2000).

The present research examines the adult endstate of the category living thing. That is, young children tend to conflate animacy, or generalized movement, with alive, while plants are seen as inanimate things and not as biological entities. Reaction times allow a fine-grained analysis to determine if this developmental foundation is present within the adult structure of living thing. The question is whether the acquisition of a well-developed biological theory completely overwrites the misconceptions of childhood.

Method

In each of three experiments, approximately 30 subjects (undergraduates at the University of Pittsburgh) were asked to confirm or deny in a category verification task whether the presented words represent living things. The words were drawn randomly from lists that reflected theoretically motivated contrasts (see below). Relevant lists were yolk matched according to average word frequency, letter length, and number of syllables. Subjects responded to each word three times across 480 trials.

Experiment 1 tested whether adults would be slower and less accurate in denying that animate things (e.g. cloud, car, etc.) are living than they are denying inanimate things (bed, coat, etc.). Experiment 2 predicted that adults would be slower and less accurate in affirming that plants (tulip, elm, etc.) are living things when compared to animals (robin, tiger, etc.). Experiment 3 differentiated the 'no' responses into four word lists: natural animate (ocean, blizzard, etc.), animate (yacht, airplane, etc.), natural inanimate (mountain, pebble, etc.), and inanimate (napkin, desk, etc.) things. It was predicted that instances more similar (e.g. natural animate things) to the category living thing would cause more difficulty in denying membership. Experiment 3 was also expected to replicate the findings of Experiments 1 and 2.

Results and Discussion

The predictions for Experiment 1 were supported. Adults were slower, by about 20ms (Paired samples t-test, $t=3.82$, $p<.001$), and less accurate, by more than 4% ($t=6.14$, $p<.001$), in denying animate things in contrast to inanimate things for the category living thing. In Experiment 2, subjects were slower, by more than 50ms ($t=7.52$, $p<.001$), and less accurate, by almost 10% ($t=8.31$,$p<.001$), in affirming plants than animals. These effects were replicated in Experiment 3. In addition, adults had significantly more difficulty with instances that are highly similar to the category of living things, yet cannot be considered members. Subjects were about 50ms ($t=8.07$, $p<.001$) slower and over 12% less accurate ($t=11.95$, $p<.001$) for natural animate instances than for inanimate things. Adults also had some difficulty denying membership to natural inanimate and animate things.

The results provide an intriguing view into the adult endstate for biological knowledge. It seems that feature associations learned early in childhood remain embedded in the adult structure of the category living thing, even after the formation of a well-developed biological theory. Developmental vestiges would seem to be at the heart of the adult category structure. Future work will be aimed at further clarifying these results in light of traditional views on conceptual change.

Zachary Estes (zcestes@princeton.edu)
Department of Psychology, Princeton University
Princeton, NJ 08544-1010, USA

Research on conceptual combination has followed two main paths. One has examined the representation of logical conjunctions of concepts, such as A FISH THAT IS ALSO A PET. The Attribute Inheritance model posits that conjoint concepts will inherit attributes that are necessary for (or salient in) either of the parent concepts, and will not inherit attributes that are impossible for either of the parent concepts (Hampton, 1987, 1997). The other path has considered the process of combining nonconjunctive concepts, such as ZEBRA CLAM. The Alignment model claims that conceptual combination entails an alignment and comparison of conceptual structures (Wisniewski, 1996). The aim of the current studies was to bridge these two paths by testing whether the alignment and comparison processes ordinarily used in nonconjunctive combination might be the mechanism by which attribute inheritance occurs in conjunctive combination as well.

With most conjunctive combinations, the necessary and impossible attributes of one constituent concept tend to be compatible with the necessary and impossible attributes of the other concept, thus producing a comprehensible combination. Because of this compatibility, unfortunately, such conjunctions do not provide clear evidence either for or against the use of alignment in attribute inheritance. That is, it is unclear whether the attributes are simply inherited by the conjunction, or whether the concepts must first undergo alignment and comparison processes.

One way that alignment and comparison can be observed in attribute inheritance is to present concepts that are incompatible in important respects. Where an attribute is necessary for one concept in a conjunction but impossible for the other, if alignment and comparison occur, then the incompatibility should be detected and somehow resolved. If alignment does not occur, then the incompatibility need not be detected. Thus, we asked participants to imagine the impossible – that is, to conjunctively combine concepts that are in reality disjunctive (e.g., A COMPUTER WHICH IS ALSO A TEACUP).

Study 1

Students were asked to imagine 9 conjunctions (e.g., A FRUIT WHICH IS ALSO FURNITURE) and to describe them in words or pictures. Analysis of the solutions suggested two main findings. First, concepts tended to be instantiated at the basic level (e.g. BANANA for FRUIT, COUCH for FURNITURE). And more importantly, there was strong evidence for alignment and comparison in conjunctive combination. Specifically, the concepts were aligned (e.g., the skin of the banana was aligned with the covering of the couch), conflicting attributes were identified (e.g., bananas rot, couches should not), and emergent attributes were constructed in order to resolve those conflicts (e.g., genetically modified bananas that do not rot). Thus, alignment did indeed appear to be the process by which attributes were inherited in concept conjunction.

Study 2

Given that superordinate classes impose fewer constraints on interpretation than do basic level concepts, one might expect greater success at conjoining superordinate concepts than basic level concepts. On the other hand, superordinate concepts tend not to be alignable with one another. If alignment is necessary for concept conjunction, then superordinates should instead be difficult to conjoin (Markman and Wisniewski, 1997). Study 2 independently manipulated whether the modifier and head concepts in a conjunctive combination were basic (e.g. BANANA) or superordinate (e.g. FRUIT). Solutions were rated by independent judges for their success in terms of conjunctive interpretation. Rated success of solutions did not differ between conditions, suggesting that any advantage superordinates may have had by way of less constraints was offset by their disadvantage of being less alignable as well. Across both experiments, then, there was evidence that attribute inheritance in concept conjunction occurs via alignment and comparison.

Understanding Negation – The Case of Negated Metaphors

Uri Hasson (uhasson@princeton.edu)
Sam Glucksberg (samg@princeton.edu)
Department of Psychology, Princeton University
Princeton, NJ 08544-1010 USA

Understanding negated statements is more difficult than understanding affirmative ones. People are slower to verify that negative statements are true and seem to understand them best in contexts that make them particularly plausible (see Horn, 1989). Little, however, is known of the online processes that take place during the comprehension of such statements. Particularly, the nature of the representation of negated statements is undecided. Two hypotheses have been raised regarding this issue: according to the first, representation of negation is representation of that which is not the case. This is well summarized by Fauconnier (1994): "negatives set up corresponding counterfactual spaces in which the positive version of the sentence is satisfied". According to the second hypothesis, comprehension of negation goes beyond the comprehension of the affirmative since it involves active inference-making (Manktelow and Over, 1990).

In both cases, negated statements should take longer to process than affirmative ones, since additional cognitive work is required. To explore this issue we presented participants with negated metaphors, e.g., "this train is not a rocket". Following each metaphor, we presented participants with a lexical decision task. The words presented for lexical decision were related either to the negated form of the metaphor (e.g., slow), or to the affirmative form (e.g., fast).

If negation involves processing beyond the affirmative, we would expect that the affirmative meanings of sentences be activated early on, with negation activated only later. Accordingly, we would expect affirmative-related words to be facilitated early on, with negative-related words facilitated only later.

Method

Eighty undergraduate students from Princeton University participated in the experiment for course credit. The variables manipulated in the study were: (a) the time between the endpoint of reading the sentence and the lexical decision task (150, 500 and 1000 ms), (b) the type of prime sentence (Negated metaphor, Affirmative metaphor and Control metaphor) and (c) the type of word presented for lexical decision (related to the negated metaphor or the affirmative metaphor).

Results and Discussion

Figure 1 presents difference from baseline response-times for affirmative- and negative-related target words after reading a negated metaphor. For present purposes, we will not consider response patterns for affirmative sentence primes.

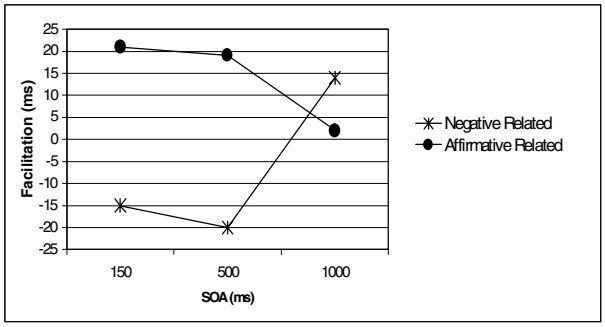

Figure 1: Target facilitation after negated metaphors.

Initially after reading a negated metaphor (e.g., That kindergarten is not a zoo), words associated with the affirmation (i.e., noisy) were facilitated, while words associated with the negation (i.e., calm) were not. This result was also found at 500 msec. By 1000 msec, negative related words were facilitated while affirmative-related words were at baseline level.

This pattern of priming suggests that negated statements are initially represented in their affirmative form. In a short time, however, the affirmative meaning is no longer active, and is replaced by the negated meaning. The findings are consistent with both Fauconnier's, and Manktelow and Over's hypotheses.

Introduction

While complex symbolic models of creative processes like music or poetry generation produce remarkable results (Cope, 1996), it may prove advantageous to model creativity more explicitly in terms of adaptive processes of "blind variation and selective retention" (Campbell, 1960)). One computational approach that seems to be particularly promising in this regard is genetic programming (Mitchell, 1996). However, when applying this approach to a complex domain like the creation of works of art, one fundamental problem that arises is the specification of a fitness operator for the selection of the surviving individuals. How can one specify what a good poem or musical piece or painting is? The current model tries to solve this problem by exploring the use of a neural network (NN), which was trained on human evaluations, as fitness evaluator for a genetic algorithm (GA).

Architecture of the Model

The specific domain chosen was limerick generation because of the shortness and clearly defined structure (AABBA) of this poetic form. A lexicon of 1,107 "limerable" words was created using the words of 50 naturally and artificially created limericks. The syllables of each word were represented as binary vectors coding the phonemes and the stress pattern. Information about word class and meaning were left out for the sake of parsimony and computational feasibility. The initial population of limericks was generated by selecting the rhyming words, and then filling each line in accord with the stress template.

Unlike Burton and Vladimirova (1997), who have interfaced an ART NN with a GA for music generation, we were interested in a fitness evaluator that simulates human judgments about limericks. To this end, we obtained quality ratings on a scale from 1 – 6 for 25 naturally and 25 artificially created limericks from 160 participants. A simple recurrent NN was then trained on 36 limericks to associate the median ratings. When tested on the remaining 14 limericks, it produced reliably higher values for natural (3.4) than for artificial limericks (1.9), $t(12) = 2.1$, $p = .05$, as did the human participants (natural: 4.8, artificial: 1.7, $t(12) = 5.4$, $p < .01$). This indicates that the NN clearly captured some important dimensions used by humans to evaluate the quality of limericks. The NN was then interfaced with the GA so as to provide the fitness measure, which was used as the basis for the selection of the fittest individuals from each generation. The selected limericks were then modified using mutation, crossover, and direct-copy operators to create the next generation of limericks.

Simulation Results

The model was run for 1000 generations. In order to determine whether there was improvement in limerick quality, we compared the fitness measures assigned by the NN to the first (1.2) and last 100 (1.6) generations, and observed a small but significant improvement, $t(198) = 9.3$, $p < .001$. This first result encourages us to suggest that training NNs to simulate human judgment in complex domains, and using them as fitness evaluators in GAs, may prove fruitful for the generation of products that typically are dependent on human insight and creativity.

Modeling the Effect of Category Use on Learning and Representation

Kenneth J. Kurtz (kjk@northwestern.edu)
John T. Cochener (cochener@howard.psych.nwu.edu)
Douglas L. Medin (medin@northwestern.edu)
Department of Psychology, Northwestern University, 2029 Sheridan Rd
Evanston, IL 60208-2710 USA

The formation of categories is based on learning to perform various cognitive tasks and not just categorization per se (see Yamauchi & Markman, 1998). Most models of categorization are committed to explaining the learning, representation, and use of categories solely in terms of taxonomic classification. Recent evidence shows that category structure can be derived from and organized to support the use of examples for particular tasks or goals (e.g., Ross, 1997; Medin, Lynch, Coley, & Atran, 1997).

The ORACLE model (One Representation Across Channels of LEarning) addresses concept formation from the perspective of learning how to represent examples in order to support performance on naturally occurring cognitive tasks. This "you are what you eat" approach stresses that concepts emerge not so much in order to represent the world as it is, but to represent the world relative to the learner's needs and demands. ORACLE is based on two key ideas: 1) input examples are re-represented through error-driven learning to improve task performance (Rumelhart, Hinton, & Williams, 1986); and 2) conceptual organization emerges from numerous iterations of parameter optimization on multiple interwoven processing tasks.

As in a traditional multi-layer network, inputs tend to become represented more closely in the constructed multidimensional space of a hidden layer to the extent they share the same teaching signal at the output layer. ORACLE has two further design principles: 1) different channels of learning lead to different sets of outputs, but share a single set of hidden units; and 2) an anchor channel is dedicated to auto-associative learning (reproducing input information at output). The number and nature of the channels depends upon the tasks or goals the inputs participate in for the learner. Classification is the function being approximated, but the output classes correspond to relevant uses, linguistic labels, or implications; not to established categories. ORACLE predicts that internal representations will tend to emerge that emphasize elements of the input which are most useful for performance across the channels of learning. Therefore, we attempted to simulate Ross' (1997, E1) category use effect.

Participants in Ross' study learned to diagnose fictitious diseases and to select the right treatment. Learning trials were: guess the disease, feedback, guess the treatment, feedback. Each patient consisted of one symptom perfectly predictive for both tasks, one symptom perfectly predictive for diagnosis only, and one non-predictive symptom. After study, participants tested on disease classification performed better on features relevant to both disease and treatment (96%) than on features relevant only to disease (80%). Learning to treat the diseases influenced diagnosis.

The ORACLE architecture consisted of an input layer and a hidden layer of three hidden units (n=3) with projections along three channels of learning to the task outputs (disease, treatment, and auto-association). The layers were feedforward and fully connected. A patient was presented to ORACLE by activating three input units in a 3x12 array based on the twelve possible symptoms and the three possible presentation positions.

Each epoch of standard back-propagation training consisted of randomly ordered presentation of the sixteen patients in all possible symptom orders at a low learning rate. To simulate the two types of training trials, an alternating scheme was used in which half the trials set targets on the disease outputs and half on the treatment outputs. Auto-associative targets stayed set.

The category use effect does not appear initially, but tends to emerge as training proceeds. After 10,000 epochs, 11 of 13 ORACLE runs performed better on features relevant to both tasks. Mean activation of the correct disease output was 96% for the double-relevant and 88% for single-relevance features. ORACLE produces the category use effect by learning anchored representations that support diagnosis and treatment.

Towards a Multiple Components Model of Human Memory: A Hippocampal-Cortical Memory Model of Encoding Specificity

Kenneth Kwok (kenkwok@cmu.edu)
James L. McClelland (jlm@cnbc.cmu.edu)
Department of Psychology, Carnegie Mellon University and the
Center for the Neural Basis of Cognition
115 Mellon Institute, 4400 Fifth Avenue,

Abstract

While many researchers studying memory today subscribe to a multiple memory systems view of human memory, most existing models of memory do not explicitly embody multiple interacting memory systems in their accounts of human memory performance. The present work is aimed at developing a connectionist model of human memory which: (1) takes into account known principles about the neural basis of human learning and memory; and, (2) is an instantiation of a multiple components memory system along the lines of a *components of processing* framework of memory (Roediger, Buckner, & McDermott, 1999).

The *Hippocampal-Cortical Memory Model* (McClelland, McNaughton & O'Reilly, 1995) comprises two memory components: a hippocampal component which supports rapid learning, and a cortical component which learns more slowly in order to develop integrative representations of the statistical characteristics of the environment across many learning episodes. It provides a suitable starting point for our endeavor because it addresses two important aspects of human memory: (1) the ability of humans to rapidly learn new arbitrary associations; and (2) the fact that memory performance is affected by pre-existing knowledge.

The memory phenomenon that we address here with the model is that of encoding specificity. An early statement of the *encoding specificity principle* (ESP) by Tulving & Thomson (1973) asserts that: *"…specific encoding operations performed on what is perceived determine what is stored, and what is stored determines what retrieval cues are effective in providing access to what is stored"*. This principle was used to explain a pattern of results from a paired-associate memory task in which target words were studied with cues which were weak associates, and memory for the target words was subsequently tested either by cued recall using novel cues which were strong pre-existing associates of the target words, or by recognition. Two key aspects of the results accounted for by the ESP were: (1) the relative ineffectiveness of extralist cues (strong associates of the target words) compared to intralist cues (weak associates) in facilitating recall of the target words; and, (2) recognition failure of words that had been recalled to extralist cues. The crux of this explanation lies in a belief that successful recall and recognition depends on the episodic trace of the event being sufficiently similar to the properties of the retrieval information.

We simulated the ESP experiments by presenting stimuli representing *context*, *relation*, *cue* and *target words* to our model in the form of patterns of activity. After the model had learnt the appropriate associations during a training phase, recall was simulated by presenting the model with cue and context patterns, with the network filling in the target word and relation patterns. Recognition was simulated by presenting the cue and target word patterns, with the network filling in the context and relation patterns.

Our model was able to reproduce Tulving and Thomson's pattern of results in simulations. However, unlike their original explanation which places the burden of successful recall and recognition on an episodic memory system, successful performance of our model in this task relies on both pre-experimental knowledge of word associations in the cortical system and newly learnt associations in the hippocampal system. Hence, in line with a *components of processing* framework, encoding specificity can be understood as a phenomenon that is neither purely episodic nor semantic but relies on both forms of memory.

Furthermore, as a mechanistic instantiation of the ESP, our model is able to make explicit what is meant by statements such as "the trace of the event is sufficiently similar to the properties of the retrieval information" – in a connectionist framework, this is simply pattern completion on a suitable retrieval cue. This in turn provides inroads for further exploration of the parameters and mechanisms which make up a multiple components memory model, and ultimately for characterizing the roles played by different components of the memory system and their interactions, in subserving human memory performance. Further work with the model is being directed at these issues.

Categorical Perception: An Adaptive Process

Research on expertise in sport has provided in the last twenty years explanations about the cognitive processing involved in decision making. The underlying processes of expert performance are known to be related to information stored in memory. Previous studies highlighted the richness of the content of expert conceptual knowledge and the organization of information in memory. This organization related to the chunking hypothesis is thought to reduce the informational load by limiting the number of units that we have to deal with. One hypothesis is that the unitization of elements depends namely on conceptual background of players. Recently, we (Courrieu, Baratgin, Ripoll, Ripoll, & Laurent) tested the assumption that this type of influence could occur in similarity tasks. In several studies, experts were better than novices at discriminating "structured configurations" (*i.e.*, semantically coherent configurations). However some differences (*e.g.*, small physical variations) were poorly detected by experts. Empirical evidence was also given that the influence of knowledge is likely to occur at a perceptually-grounded level. In order to explain this pattern of results we would to test the assumption that knowledge guide perception by modifying perceptual spaces of similarity. Research in the field of categorical perception (*e.g.*, Harnad, 1987) has supported this idea. More recently, Goldstone, Lippa, and Shiffrin (2001) found that the object representations themselves could be altered by category learning. In the same vein we have considered decision making as based on the determination of perception by categorical knowledge.

Building Categorical Material

In order to produce material we used a cluster encoding method validated by Courrieu (2001). Basket-ball coaches built schematic configurations with the following constraint: from one source configuration, drafting two target configurations with an equally physical distortion for both (relatively to the source), but in one case target should belong to the same category as the source and in the other case target should belong to another category.

Categorical Effects

Comparison of novice and expert basket-ball players performances in a same-different judgment task yields evidence for a dissociation of results. Differences between configurations belonging to different categories were particularly well identified by experts while these participants were weaker than novices for detecting differences between configurations belonging to the same category. These data support the idea of a perceptual adaptation constrained by conceptual knowledge and the one of human ability to acquire categorical perception in sport context.

Configural and Elemental Approaches to Causal Learning

M.E. Le Pelley (mel22@hermes.cam.ac.uk)
S. E. Forwood (sef26@hermes.cam.ac.uk)
I.P.L. McLaren (iplm2@cus.cam.ac.uk)
Department of Experimental Psychology; Downing Street
Cambridge, CB2 3EB UK

The nature of stimulus representation in associative networks is a hotly debated issue. On one hand we have elemental theories (e.g. Rescorla & Wagner, 1972) that propose that stimulus compounds are decomposed into their constituent elements, and that learning accrues to representations of these elements. The conditioned responding shown to a stimulus compound is then found by simply adding together the individual associative strengths of each of the elements of that compound. Configural theories (e.g. Pearce 1987) instead posit that a compound stimulus is best viewed as a unitary event separate from its elements, but able to generalise to them. Thus a compound AB is represented by a unit representing the unique configuration "AB". If AB is paired with reinforcement it is this configural unit that develops an association to the outcome (unconditioned stimulus, US). Generalised responding to other stimuli occurs to the extent that these stimuli are similar to experienced configurations.

In our poster we present evidence from a study of human causal learning that bears on this elemental versus configural debate. This study also relates to work on the phenomenon of retrospective revaluation, another research area currently receiving much attention. This involves changes in the strength of previously learned cue-outcome associations in the absence of those cues.

The results of our experiment pose difficulty for some models of human associative learning, particularly those that rely on a configural representation for the cues involved in learning. Taken in conjunction with other work from this laboratory (Le Pelley and McLaren, this issue) that cannot be easily accommodated by elemental theories (e.g. Rescorla & Wagner, 1972), the challenge posed by the data is now sufficiently severe as to require a model employing adaptive parameterisation to govern generalisation (McLaren, 1993, 1994).

The basic design of our experiment is shown in the Table below (other cues were also included so that there were equal numbers of reinforced and nonreinforced single cues and compound cues). Our experiment used an allergy prediction paradigm. This type of paradigm has been used successfully in a number of studies of phenomena of associative learning. However, in order to avoid problems with ceiling effects we adapted this normal allergy prediction paradigm. Thus during training, instead of being asked to judge whether or not an allergic reaction would occur following consumption of a meal, subjects were asked to rate the risk of allergic reaction resulting from these foods (using a four-point scale). Following training, subjects are asked to rate the probability with which a number of individual foods and food compounds will cause allergic reactions. The foods, then, represent the cues, and the allergic reaction is the US. The causal judgment ratings given on test are our index of associative strength.

Stage 1	Stage 2	Test
AB+	A+	A, B, E
CD+	C+	AB, AC, BD,
	EF+	BC, EF, CE&DF

The results are shown below (averaging over equivalent cues). The key findings are (i) retrospective revaluation of cues B&D (backward blocking), (ii) the low rating given to compound BD relative to BC, and the higher rating given to AC, (iii) the high rating of AC relative to EF, and (iv) the fact that CE > BC > DF. These ratings are consistent with revaluation on an elemental basis, but not with configural models employing fixed generalisation coefficients.

Levels of Processing and Picture Memory: An Eye movement Analysis

Yuh-shiow Lee (psyysl@ccunix.ccu.edu.tw)
Department of Psychology, National Chung-Cheng University
Chiayi, 621, Taiwan, ROC

Introduction

This study examined the underlying mechanisms of the levels-of-processing and picture superiority effects. In contrast to most of the memory research using off-line measurements, this study recorded participant's eye movements during study and testing. Levels-of-processing effects were found not only in verbal materials, but also in pictorial materials such as pictures of faces (e.g., Mueller, Courtois, & Bailis, 1981) and common objects (Lee, 1999). However, using different sets of pictorial materials, Intraub and Nicklos (1985) found the physical superiority effect. They suggest that when visually distinctive pictures are used, having attention drawn to the pictures' unique visual characteristics would lead to a more elaborate trace, than having attention drawn to their semantic attributes. To resolve these inconsistencies, further research examining the role of both semantic distinctiveness and perceptual distinctiveness in producing a better memory for various kinds of pictorial materials is needed. A related issue is that pictures are remembered better than words on conceptually driven memory tests such as free recall and recognition. One of the earliest theories to explain the picture superiority effect is Paivio's dual coding hypothesis. Other researchers focus on the importance of conceptual processing in producing the picture superiority effect. Pictures access meaning codes more directly than words do, and so pictures naturally engage more conceptual processing, which leads to a better memory for pictures than for words.

Eye Movement Analyses

In a typical memory study, participants' differences in encoding or storage of information is inferred from their memory performance in the subsequent testing. In contrast to this off-line measurement, measuring participants' eye movements during study or learning provides an on-line measurement of information processing. Moreover, it has been assumed that the number of features attended to is positively correlated with the number of features actually encoded by participants. Recording the number of eye movements during learning thus makes it possible to observe how many features of a target stimulus were examined. On the other hand, physiological measures can be used to measure the conceptual processing, which is related to the semantic quality of stimuli. In particular, the pupil diameter has been shown to be related to the cognitive processing level in the standard matching paradigm.

Bloom & Mudd (1991) tested *the semantic quality hypothesis* and *the feature quantity hypothesis* in face recognition and found that a deeper processing of face led to an increase in the number of eye movements and an improvement in subsequent recognition performance. Along with evidence from the measure of pupillary dilation, which is considered an index of cognitive effort or processing load, they concluded that the feature quantity hypothesis and not the semantic quality hypothesis was supported. This study investigated whether eye movement analyses can be valid indexes of perceptual distinctiveness/richness and conceptual processing/effort. This question was tested by examining the relationship between eye movement analyses and memory performance.

Results and Discussion

Participant's eye movements during study and testing were recorded. During the study phase, participants studied object pictures, object names, photos of faces, and persons' names. After a distractor task, participants performed a recognition test. The results in memory performance showed that both object pictures and persons' names revealed a ceiling effect. The effects of study condition were significant for object names and photos of faces. Deeper processing produced a better recognition performance. Numbers of eye movements and amount of inspection time were not related to recognition performance, even when the ceiling effect was avoided. Analyses on the pupil sizes also did not reflect the differences in memory performance. In conclusion, recognition accuracy of either verbal or pictorial materials and eye movement behaviors were affected by different variables.

An Alternative Method of Problem Solving: The Goal-Induced Attractor

William B Levy (wbl@virginia.edu)

Charlottesville, VA 22908-0420 USA

One theory of problem solving posits solutions by search. That is, the generic problem has a starting point and a goal, where the goal might be precisely known or only sketchily describable. Successful problem solving entails finding a legal (i.e., biologically consistent) path from the starting state to the, or to an, acceptable goal. Influential theories of problem solving, including Newell's work, emphasize the importance of search. That is, the strategy is to try out various paths in hopes that one will lead to the goal. Such searching techniques are computationally intractable in many situations and, in our day-to-day life, we often consider a problem and then find the answer. That is, we find the logical path to the goal without much thought at all and certainly without being consciously aware of trying multiple paths. Here we present a neural network model that solves paradigmatic cognitive problems without search. The alternative to the search strategy in a recurrent neural network is the use of an attractor. An attractor affects the states of a network, and the states of a network are its representations of the world itself. When a network is designed as a sequence-learning network and when it has enough freedom to create its own solutions, i.e., to create novel paths through state space, such a network can find paths from an initial state to a goal state and can find such paths where a path has never before been experienced (Levy, 1996).

The principle of the goal-induced attractor requires or assumes that the system solving the problem has a vague knowledge of the solution. For instance, if I am hungry, I might know I want something to eat, but I might not know exactly where I want to go to eat. We propose that such notions of the goal weakly turn on certain representations. These representations heighten the probability that paths to that goal will be discovered. At the same time, because networks have activity control mechanisms, there will be a tendency not to explore or move towards other goal states. Of course, if the network is not to depend on total randomness, there must be a history of paths learned by the network that can in some way be pieced together by network dynamics.

We use a model of hippocampal region CA3 because this is a sequence-learning region that is capable of coding novel sequences. In particular, and in contrast to error correction-based models, our model is used when mammals do not know the answer and must recode the environment in order to produce simple, usable codes by other brain regions or, from our point of view, by other networks. The problems solved by the CA3 model using the goal-induced attractor are not unlimited but include the simple goal finding problem that is analogous to a rat or a human going from a starting point to a goal by piecing together small paths that have been previously learned but have taken the organism to other places. Other cognitive problems, and some that may even appear to be logical in Nature, can be cast in terms that the goal finding hippocampal model can solve. For instance, the task of transitive inference can be taught to rats, and it can be taught to people in a nonverbal mode. The hippocampal model solves this problem, and it solves the problem, in a sense, by wanting to get the right answer. That is, the goal in performing transitive inference is to get the right answer as opposed to the wrong answer. In this case, the network would have a crude version of the reinforcement "yes, you're right" turned on while it is being presented with the stimuli of the transitive inference task. The task itself is viewed as a sequence but just barely. In particular, the sequence is stimulus, decision/response followed by knowledge of whether the outcome is a success or failure (right or wrong). The model is able to make the right decision for novel, transitive pairings. Another problem that can be solved in a similar manner is the transverse patterning problem.

Our poster will discuss the critical characteristics of our CA3 model that lead to its problem-solving abilities.

Submarine navigation proceeds without the benefit of windows. Instead, experienced submarine Officers develop complex skills for mentally turning acoustic information conveyed in displays and in the alphanumerics of passive sonar into spatial representations of other vessels, their paths, intentions, and the high uncertainty of the undersea world (Kirschenbaum, Gray, & Ehret, 1997). We lack data about the psychological space of experts as they reason about distant space in such areas.

Gesture analysis is a promising methodology for observing and understanding the spatial representations that people build to solve difficult problems. It has been used to examine how astronomers reason about the movement of objects when only static representations are visually available (Schunn, Trickett, & Trafton, 1999) and to examine representations of abstractions such as rates of change in algebra word problems (Alibali et al., 1999).

In the current study, we videotaped and analyzed the speech and spontaneous hand gestures of submarine Officers who were instructors in the Submarine Officers Basic Course. Four instructors participated in hour-long, interviews designed to prompt explanations about basic issues in submarining. We transcribed the speech, and then we transcribed the physical aspects of gesture such as the hand or finger shapes, motion, or location in the speaker's personal space.

We found a small set of common gestures that all Officers use similarly (e.g., "bearing" is usually a straight arm/hand, fingers close together pointing not just a direction but a path). We also found a number of topics that Officers convey in gesture.

Our data show that when Officers' gestures convey **perspective** these are more likely to represent an egocentric, as opposed to a removed, exocentric, view. One example is a gesture about sound propagation from the perspective solely of a sensor that is receiving a signal. In other examples, Officers gestured phenomena as relative to themselves physically, as if they were standing in own-ship.

Officers' speech and gesture both convey **uncertainty**, or hedging/estimation. This is important because less experienced Officers are over-certain at times. Often, the only hint that an Officer is hedging or expressing uncertainty will come through one modality only (hands alternate in box-shape up and down; hands circling). About 20 percent of speech and 20 percent of gesture were coded as reflecting uncertainty.

It is common for Officers to gesture complex **spatial dimensions** of the relative positions and motion of the target of interest and own-ship. Officers also gesture complex spatial representations about the shape and degree of angle of conical beams and the effects on signal processing of effects such as the position of the towed array (an array of sensors towed behind the ship) when the ship turns, etc.

Spatial features commonly represented in gesture were shapes (e.g., conical beam, hyperbolic wave front) relative distance and position, direction (bearing, course), and motion (e.g., across or in the line of sight).

Many of the iconic gestures represented or replicated pieces of **common displays** or figures that Officers use. However, other iconic gestures seemed more physical, as if the Officer were relying on an internal, **visual analogy** to describe an idea. In a gesture about beam forming, one hand played the part of the towed array and the other was a vessel being tracked. Each hand moved through the "water," suggesting not only a world-view/bird's-eye view of the contact and own-ship, but the gesture superimposed relative motion on that view, in a way we think is different from other displays and figures.

A Criticism of the Conception of Ecological Rationality

Daniel Hsi-wen Liu (hwliu@pu.edu.tw)
Division of Humanities, Providence University
200 Chung-Chi Rd, Shalu, Taichung County 433, Taiwan

The embedded and embodied nature of cognition has been noticed in the 1990s, and has gradually more discussions in philosophy. Discussions centre around the idea that representations are dispensable to a certain extent in the modelling and explanation of cognition (Brooks, 1991; Clark, 1998; Clark & Grush, 1999; Keijzer, 1998; Wheeler and Clark, 1999). Recently, discussions of this nature proceed to explaining the mechanisms of organisms' adaptive flexibility in the ecological niche. The embedded characters of cognition are subtly explored in the notion of 'ecological rationality' (Bullock and Todd, 1999). An interactive-constructive (I-C) approach to modelling intelligence is recently raised, to take into account the dynamical embodied form of adaptiveness (Christensen & Hooker, 2000). This project follows the above trend of discussion but criticises the discussions of organisms' adaptive flexibility.

The primary target of criticism is Christensen & Hooker's (2000) vague account, against which this research will criticise that it begs the question: how is their notion of a 'capacity of coherent, context-sensitive, self-directed management of interaction' carried out on the basis of simple automata? To answer this question will this project argue that the embodied dynamics of cognition is maintained through the recurrent loops of external assessment and internal modification, with a view to manifesting the autopoietic unity of a system's factors, which is originally evident in the maintenance of life. 'Interactive skill construction' is a notion to which Christensen & Hooker (2000) resort in support of the process of 'anticipative skill construction'. At this point they also beg a question: how is self-directed anticipation constructed if no notion of self can be presumed in the cognitive systems? While Christensen & Hooker (2000) see their account as a primary model for cognitive learning, instead will I research in the context of perception, where no obvert functionality of self-control is as evident as learning. With this research will I put their notion of self-directed anticipation in a better profile of explanation.

The explanation envisaged in this research will be cast in terms of stepwise exploitation of environmental information on the basis of inherent a priori representations of the ecological niche. Conceptions that appear in Bullock and Todd (1999) are mainly the domain of decision-making, while I will argue grounded on the domain of perception. Largely against the aforementioned trend of embodied and embedded approach to cognition, but responding to Wheeler and Clark (1999), in this project will I argue for the importance of representations in the embodied and embedded capacities of cognition. On the top of Wheeler and Clark (1999), the previous discussion in this project has provided significant amount of argument, which would in turn bridge a link between representation and the embodied and embedded characters of cognition. With the above argument, this project will criticise Christensen & Hooker (2000) and consequently help the aforementioned trend of embodied and embedded cognition to move ahead.

The main idea of my criticism is that higher-level representations provide guidance in support of low-level organism, while low-level real-time adaptive activities serve to mandate system's processes. Hence the ecological rationality is recurrent between higher and lower level of representations.

Thinking through Doing: Manipulative Abduction?

Lorenzo Magnani (lmagnani@cc.gatech.edu)
Department of Philosophy and Computational Philosophy Laboratory, Piazza Botta 6

Introduction

An interesting and neglected point of contention about human reasoning is whether or not concrete manipulations of external objects influence the generation of hypotheses. I am focusing on the first features of what I call *manipulative abduction* showing how we can find in scientific and everyday reasoning methods of constructivity based on external models.

The Task and the Method

I am analyzing the problem in the light of the so-called historical-cognitive method (Nersessian, 1998). While it tries to integrate findings from research on cognition and findings from historical-epistemological research into models of actual scientific practices, assessments of the fit between cognitive findings and historical-epistemological practices aid in elaborating richer and more realistic models of cognition. There are interesting parallels that can be exploited by cognitive scientists; the relevance of the concept of abduction can contribute to a central issue in cognitive science: hypothesis formation both in science and in everyday reasoning.

Manipulative Abduction in Science

It is well known that many reasoning conclusions that do not proceed in a deductive manner are *abductive*. What I call *theoretical* abduction (Magnani, 2001) is, from a cognitive point of view, an internal process of reasoning. What about the "external" ways of finding hypotheses?

Manipulative abduction happens when we are thinking *through* doing and not only, in a pragmatic sense, about doing. It refers to an extra-theoretical behavior that aims at creating communicable accounts of new experiences to integrate them into previously existing systems of experimental and linguistic (theoretical) practices. Gooding (1990) refers to this kind of concrete manipulative reasoning when he illustrates the role in science of the so-called "construals" that embody tacit inferences in procedures that are often apparatus and machine based.

Epistemic Action

Recent research, taking an ecological approach to the analysis and design of human-machine systems, has shown how expert performers use action in everyday life to create an *external* model of task dynamics that can be used in lieu of an internal model (Kirlik, 1998). Not only a way for moving the world to desirable states, action performs an *epistemic* and not merely performatory role that is very relevant to abductive reasoning.

Experiments and the "World of Paper"

Already in the *Dialogues Concerning the Two Chief World Systems* (1632), accentuating the role of observational manipulations Galileo presents an anatomist that, manipulating a cadaver, is able to get new, not speculative, information that goes beyond the "world of paper" of the Peripatetic philosophy. It is well known that recent philosophy of science has paid a great attention to the so-called theory-ladenness of scientific facts (Hanson, Popper, Kuhn). Nevertheless a lot of new information in science is reached by observations and experiments, and experiments are the fruit of various kinds of artifactual manipulations: the different strategies correspond to the expert manipulations of objects in a highly constrained experimental environment, directed by *abductive* movements that imply the application of old and new extra-theoretical *templates* of behavior.

What I Expect to Find

We still know very little about what governs the manipulative abduction. I plan to better delineating some of the manipulative *templates* of behavior that are active in creative abduction comparing scientific and everyday reasoning: 1. *simplification* of the reasoning task; 2. capacity of overcoming situations of *incomplete* or *inconsistent* information; 3. *control of sense data*: we can change the position of our body (and/or of the external objects) and exploit various kinds of prostheses (instruments, etc.); 4. *external "models"* of task mechanisms.

Spatial Priming of Recognition in Virtual Space

Gareth E. Miles (MilesGE@cf.ac.uk)
School of Psychology, University of Wales, Cardiff, P.O. Box 901, CF1 3YG, UK.

Andrew Howes (HowesA@cf.ac.uk)
School of Psychology, University of Wales, Cardiff, P.O. Box 901, CF1 3YG, UK.

Introduction

Virtual environments are often not veridical facsimiles of reality. Efficiencies of navigation are often made available to users with the use of hyperlinks but other schemes that violate the normal rules of Euclidean space are also possible (Ruddle, Howes, Payne & Jones, 2000). A virtual environment user may experience hundreds of different locations all with the same apparent Euclidean co-ordinates if space is allowed to overlap itself. It is anticipated that methods for probing subjects spatial representation that involve strategic processes (such as distance estimation and map drawing) will be poor for evaluating how subjects represent the discontinuities and spatial overlaps that occur in this kind of space. In most cases the unusual features of the space will be highly salient and are likely to input into any strategic process, distorting evidence about the representation of spatial information. An important advantage of a priming methodology in this case is the absence of any strategic processes – priming data are claimed to derive directly from the underlying representation of a stimuli. One aim of our current work is to establish the validity of priming methodologies for revealing human representation of virtual environments. We hope to achieve this by replicating work done using 2D map representations.

McNamara, Halpin & Hardy (1992) used priming in item recognition and location judgement to assess the relative contributions of order of presentation (temporal proximity) and spatial proximity on their participants representation of a two dimensional map. The experiment summarised in this paper used a similar design, however, instead of using a two dimensional map with object locations represented as dots we use a 3-dimensional virtual environment with object locations represented by small virtual cubes.

Experiment

Thirty-two participants navigated an experimental environment. Participants used the mouse to control where they looked in the 3D environment and the space bar to 'walk' through the environment in the direction faced. The experimental environment consisted of a large 'warehouse-like' triangular room, in which twelve items were located, and an antechamber from where subjects began. Subjects completed a training phase in which they were shown the location of the twelve items and then completed a test phase during which they had to indicate the correct location of each item. Training and test phases were iterated until the subject had successfully remembered the location of all the items. The twelve items were divided into four filler items, and four sets of pairs. Each pair was assigned to one of the experimental conditions (a 2x2 design with spatial: close-distant, and temporal: close-distant).

After the experiment, subjects were given recognition and then location judgement tasks. Immediately following a warm-up task the subjects were told that in the next section they had to decide whether the named items were included in the 3D environment they had learned. The twelve items from the 3D environment and twelve foils made up the list of item names presented. The paired items were presented consecutively, with one item, in each pair, acting as a prime and one acting as the target. These 24 item names were presented three times in the same order.

Results and discussion

A repeated measures ANOVA on the recognition response time data found a main effect of spatial proximity, $F(1, 31) = 4.62$, $MSE = 6980$, $p < .05$, no effect of temporal proximity, $F(1, 31) = 2.00$, and no interaction of spatial and temporal proximity, $F(1, 31) = .309$.

We are using these results to inform the building of computational models that learns the locations of the objects in the virtual environment. Spatial priming at close spatial and temporal proximity can be explained by a model that encodes each item's heading from the antechamber and any errors that are made whilst trying to find that item. However, to account for the main effect of spatial proximity a model using either metric or propositional information about relative object locations is required.

The frequency of connectives in preschool children's language environment

Bradley J. Morris (bmorris@andrew.cmu.edu)
Dept. of Psychology, Carnegie Mellon University
5000 Forbes Ave., Pittsburgh, PA 15213

The basis of logical reasoning is a set of logical connectives such as AND, OR, and NOT. The rate at which each is produced and comprehended by young children differs significantly between connectives. For example, on average children produce AND and NOT around 27 months, yet do not produce OR until age 5 (Fenson, et al, 1994). One possible explanation for these differences is the frequency of logical connectives in children's language environment. The little research jointly examining children's logical reasoning and their language environment (e.g., Scholnick & Wing, 1992) suggests that children's language environment does influence the rate of understanding and production of logical connectives.

The present study examined transcriptions of audiotaped conversations obtained through the CHILDES database (MacWhinney, 2000) to compare the frequency of production and reception of connectives by children between the ages of 2.0-5.5 in conversational situations with at least one adult. The connectives selected were AND, OR, NO/NOT (NOT was also coded for the number of uses as a word and in the form of a contraction). A total of 187 databases were coded containing 81,676 conversational turns (mean = 456.2, SD = 282.6).

Results and Discussion

A total of 10,201 No/Nots, 5,149 Ands, and 396 Ors were produced. Table 1 displays the distribution of connectives per 100 conversational turns by producer (adult/child) and age of the child (six-month intervals based on the child's age during data collection).

Overall, NOT was more frequent than AND and OR (Fs (2, 165) = 4.9 and 22.7 respectively, ps <.01), while AND was more frequent than OR (F (2, 165) = 10.6, p<.01). Results suggest significant differences in the use of NOT across age groups (F (6, 102) = 3.7, p<.002) but no significant differences for AND and OR (p>.10).

When split by producer (adult v. child), adults produced OR and AND significantly more than children (Fs (6, 102) = 4.3 and 3.2 respectively, ps <.05 and significantly more negations as contractions than non-contractions (F (6, 102) = 3.7, p<.002).

Age-related changes for children's connective use indicate significant increases in the use of OR (F (6, 123) = 5.2, p<.001), AND (F (6, 123) = 3, p<.01), and the contraction form of NOT (F (6, 123) = 4.1, p<.001) from age 2 to 5.5. Changes in adult usage by child's age were significant only for NOT as a contraction (F (6, 132) = 3.4, p<.01).

Table 1- Connectives per 100 conversational turns

	NOT (Contractions)		AND		OR	
Age	Adult	Child	Adult	Child	Adult	Child
2-2.5	2.63 (2.80)	2.23 (0.53)	2.98	0.98	0.26	0.01
2.5-3	2.06 (3.69)	2.82 (1.68)	3.23	2.97	0.40	0.02
3-3.5	2.60 (3.98)	3.06 (2.47)	3.97	2.59	0.38	0.05
3.5-4	2.93 (4.38)	3.45 (3.21)	3.39	3.00	0.37	0.19
4-4.5	2.99 (3.97)	3.08 (3.16)	3.32	2.99	0.45	0.21
4.5-5	3.00 (5.02)	3.04 (3.58)	3.63	3.95	0.46	0.11
5-5.5	3.47 (2.62)	2.70 (3.45)	3.79	2.86	0.32	0.14
Mean	2.73 (3.81)	2.90 (2.38)	3.46	2.62	0.37	0.09

Overall, the most notable difference is the overall production levels of each connective. NO/NOT is approximately 25.7x as frequent as OR and twice as frequent as AND while AND is 13x as frequent as OR in conversation. Children's use of contractions (e.g., don't) increases significantly with age. AND use by children increases dramatically from ages 2-4 to a level by age 3.5 that is similar to the levels adults use when talking to children. The use of OR by both children and adults is significantly lower than AND and NOT and children's production rates remain well below the levels adults use when talking to children. Thus, results suggest that those connectives produced at earlier ages (e.g., NOT) are associated with higher levels of adult production than connectives produced at later ages. One explanation for these results is that adult production rates may vary in proportion to child comprehension rates exhibiting a reciprocally causal relationship.

A Soar model of human video-game players

Introduction

The real world environment around humans is mostly dynamic. Choosing a video-game "Pac-Man" as a representative of the dynamic situation typical of everyday life, we have explored players' behavior through psychological experiments and a case study (Ogasawara & Ohno, 1999). "Pac-Man" is a game where a player controls a character called Pac-Man to eat dots on a maze while escaping from four enemies called ghosts which chase Pac-Man. Also, under some specific conditions, Pac-Man can kill ghosts to get extra points.

In this presentation, we discuss a computational model of the player implemented in the Soar architecture. To model the real time task performance, we extended the Soar architecture by adding perceptual and motor processors, and by synchronizing both the game progress and I/O processor with the cycles of the model. In the following section, we explain our Soar extensions and a player model on the extended Soar architecture.

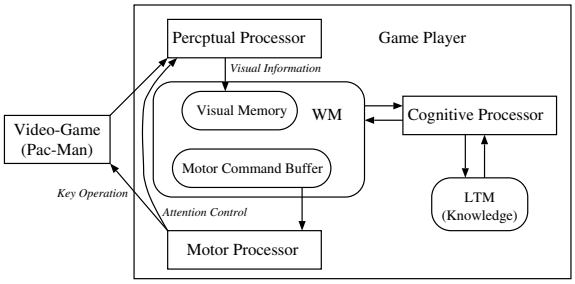

Figure 1: Diagram of the Model

Model

The Soar-8 architecture is the base of our model. The perceptual (input) and motor (output) processors are added to interact with the game (Fig. 1). The basic concept of the architecture is similar to another extended Soar architecture, NOVA (Wiesmeyer, 1992), with a few differences in visual information representation and a synchronization method.

The perceptual processor generates visual information in the working memory (WM). The visual information of the game is represented by relations between static objects (e.g., "road", "corner", etc...), dynamic objects ("Pac-Man", "ghost", etc...), and their state. Some meta-representations like "sequence of dots" are also included in the visual information. The quality of visual information differs between the attended area and the unattended area. This attention mechanism is modeled by controlling "focus" through the motor processor, and by obscuring some relations, like connection information between "roads" and "corners", in the peripheral area.

Synchronization between the game and the model is based on the "decision cycle" of Soar, which is estimated about 100 ms (Newell, 1990). Also, the delay for perceptual and motor processing is implemented by delaying transfer between WM and the processors for one decision cycle.

We test this extended architecture with a player model that uses keystroke level operators and attention control operators directly. The model is based on an "escaping from enemies" strategy that is effective for many action-type video-games. This naive model "looks at" Pac-Man, and attempts to chase dots and avoid ghosts. Our human player data shows that novices mainly depend on this strategy and look at Pac-Man more often than experts do. Though we have not examined its behavior with the human players' data closely, this model earns about the same points as novices do. We will construct another model grounded on our extended GOMS analysis (Ohno & Ogasawara, 1999) of a human player's data.

Practical Cognition in the Assessment of Goals

Luis A. Pérez-Miranda (ylppermil@sf.ehu.es)
Institute for Logic, Cognition, Language, and Information (ILCLI, UPV-EHU)
P.O. Box 220, 20080 Donostia-San Sebastian (Spain)

1. Practical Cognition

Practical cognition seems to help the agent in the way of constructing strategies and plans in his pursuit of a better situation for him. The goals and objectives of an agent can be of diverse nature, from mere intrinsic desires to sub-goals of already pretended plans. Practical cognition can be seen as the basis on which the process of selecting and executing courses of actions for achieving those goals (using plans or operators) takes place. One of the tasks of practical cognition is to cope with conflict situations of decision-making among agent's potential goals. Because agents have incomplete knowledge about the world, it is inevitable that some of these goals will conflict (Ferguson, 1992; Pryor, 1994). Sometimes an agent is forced to choose among different relevant options that are jointly incompatible to pursue.

Our approach assumes that, not always, but in many cases, the adoption of goals is plan dependent. Generally, it happens that a goal cannot be adopted before the agent realizes that is able to bring a plan about for the occasion. Often an important amount of the value of a goal is directly obtained from the expected utility value of the plan where it is embedded (Beaudoin, 1994). The adoption of a goal is related to three factors: the value of the goal itself, the possibility of constructing a plan pursuing a previously learnt strategy for that goal, and agent's commitments related to previous plans (Pérez Miranda, 1997).

Once the agent has recognized that a potential goal is obtainable, the next step in determining the adoption of a goal is to detect any adverse effects between that goal and other likely pretended goals derived from previous intended plans or single urgencies that ought to be accomplished without delay. Hence the agent must look for scenarios in which both potential goals and ongoing adopted goals fit together insofar as fulfilling one may be at odds with fulfilling another or with maximum fulfillment of the overall set. We are concerned with explaining how an agent could arrive to manage and fit these factors in a suitable way as to behave, so to speak, following some rational patterns.

2. The Filtering Mechanism

The evaluative mechanism proposed here only concerns with those goals that have a motivational or cognitive grounding (or both together). Beliefs are the unique available evidence for an agent to make decisions about whether what he wants to do is or not justified under the circumstances. We think this connection between beliefs (or motivations) and goals can be encoded into an ordered pair, the reason supporting the goal, and be evaluated according to order and strength criteria.

Order among supporting reasons constraints the decision process to only those decisions that are relevant for the agent while just excluding or postponing the others. In particular, high order reasons override low order reasons, ruling them out from the process of assessment. Furthermore, ordering reasons is a way of facing situations of apparent incomparability, for instance, among supporting reasons that are desires and reasons that are beliefs. Strength determines the expected degree of utility derived from adopting or not a goal at a point time given the evidence available.

Our filtering mechanism selects only those goals whose supporting reasons result undefeated according to agent's doxastic states. The mechanism embodies two levels of decision-making attending to the order and strength of the supporting reasons. An agent only would be justified in adopting a goal when the reason that supports that goal results undefeated.

Exceptional and temporal effects in counterfactual thinking

Susana Segura (s_segura@uma.es)
University of Malaga. Facultad de Psicologia.Campus de Teatinos, s/n 29071 Malaga. Spain.
Rachel McCloy (rmccloy@tcd.ie)
University of Dublin. Department of Psychology. Trinity College. Dublin 2. Ireland.

Introduction

Counterfactual thinking is the comparison of a factual situation to a simulated alternative situation. When people think about how things could have been different, they tend to change some kinds of factual events more often than others, for example, people have been shown to be more likely to undo the *last* event in an independent sequence (the *temporal order* effect; Byrne, Segura, Culhane, Tasso, Berrocal, 2000; Miller and Gunasegaram, 1990). Research has to date focussed on separating out each of the different factors that determine the events which people choose to change. We know little about how such factors interact.

McCloy and Byrne (2000) showed that people are more likely to change inappropriate controllable events, which are exceptional with regards to interpersonal norms for behavior, than to change appropriate events, which are normal. The first aim of this study was to establish whether varying interpersonal normality on a different dimension (selfishness) could affect the mutability of events. We predicted that controllable events which were *selfish* (i.e., done purely for the self) would be more mutable than controllable events which were *selfless* (i.e., done for more than just the self), because selfish events are exceptional with respect to interpersonal norms and selfless events are normal. The second aim of this study was to explore the interaction between interpersonal normality and the temporal order effect described above. We predicted that the selfishness of an event would interact with its position in a temporal sequence, in that selfish events which occur last in an independent temporal sequence should be changed more often than selfish events which occur earlier.

Method

We constructed a scenario describing a morning in the life of a woman (Maria). On this day, Maria carried out nine tasks before leaving the house. Of these, eight were everyday household tasks (e.g., dusting, ironing) while one was an event carried out purely for Maria herself (reading a magazine). On leaving the house she had a car accident. Participants were asked to imagine how the outcome might have been different if she had not done one of the tasks.

The within-subjects variable was the nature of the tasks (selfish vs. selfless). The between-subjects variable was the position in which the selfish event appeared in the scenario. The selfish event could appear as either the first event, the fifth (middle) event, or the ninth (last) event in the scenario. The dependent variable was the task that participants chose to undo. The participants were 117 undergraduates from the University of Malaga, Spain. They were assigned at random to one of the three experimental conditions regarding the position of the selfish event (first, n = 35; middle, n = 42; last, n = 40).

Results and Discussion

The results corroborated both of our hypotheses. Overall, the selfish event (30%) was more mutable than any of the selfless events (all <9%). These results provide a replication of the effects of *interpersonal normality*, and they extend this effect to events that deviate from prevailing interpersonal norms along another dimension (selfishness). As predicted, the results show that there is an interaction between the effects of interpersonal normality and temporal order. The selfish event was more mutable when it occurred in the last position (40%) than when it occurred in the first (31%) or middle (19%) positions. However, the results do show that the selfish event is still highly mutable in the first position. One explanation may be that the occurrence of the selfish event early in the scenario may violate people's assumptions about when people normally carry out such actions. A selfish action carried out when there are selfless waiting to be done may be seen as more exceptional than one carried out after the completion of such tasks. Nevertheless, the results of this experiment do show that selfish event are more mutable than selfless events, and that the effects of interpersonal normality and temporal order can interact in determining counterfactual mutability.

Children's Algorithmic Sense-making through Verbalization

Hajime Shirouzu (shirouzu@sccs.chukyo-u.ac.jp)
School of Computer and Cognitive Sciences, Chukyo University
Toyota, Aichi 470-0393 JAPAN

Introduction

This paper demonstrates the effectiveness of children's own verbalization on their conceptual understanding of why they do what they do to solve a simple arithmetic problem. The problem was solvable by the interaction with the external resources, and the externalized answers could be described verbally as they were seen. Verbalization, however, in its essence, could include talker's own interpretation or explanation of the externalized records (Pine & Messer, 2000; Shirouzu, Miyake & Masukawa, 2001).

I conducted a small-case learning experiment, asking six sixth-graders in a class to cut out the 3/4 of 2/3 of the origami paper's area. They were of roughly same performance on the math and had already mastered the fractional multiplication. Initially, all of them manipulated the paper directly to solve the task. Yet, gradually guided by a teacher-experimenter, through multiple collections of the solutions and explicit comparisons among them, four students actively worked out why the answer was equal to the one-half of the whole and finally verbalized its algorithmic solution (2/3X3/4=1/2). Six months later, these students described the task by mentioning its algorithmic aspect as "devising various ways to make the one-half area," but the remaining two could not do so even though they also gave explicit consent to the algorithmic solution proposed at the end of the lesson. I hypothesize that the key to the individual differences is in their verbalization on how they interpreted own externalized solutions, differences or similarities among peers' solutions, and the task itself.

Learning Setting

The data come from a 6th grade classroom in a remote branch school of Japan, which had six students (2 girls, 4 boys) as a whole. I visited there twice as a teacher-experimenter to conduct a lesson and make a follow-up inquiry, both of which were recorded by videotape for analyses.

There were three intended phases in the lesson, to make students solve the problem and explain their solving steps, to have them reflect upon the differences or similarities among solutions, and to ask them why the goal area was constant as one-half. For the first phase, I prepared sheets of origami paper, a pencil, and a pair of scissors, and then asked them a problem. Every time the student presented his answer, I accepted it and made him explain to all how he made it with visualizing solving processes by extra origami papers. For the second phase, I let the students compare each two solutions chosen from what they had made. For the third phase, I asked what was common among all answers and why it was.

Six months later from the lesson, I visited the class again with the inquiry: "Please write down anything that you remember about what happened at the last lesson."

Analysis

Overall, the performance of this class "appears" to be quite high. Everyone solved the given task actively and correctly. Newer interpretations were frequently made and easily shared under "one voice." Hidden by such seemingly one voice, however, crucial differences in their understanding occurred through chances of verbalizing their own interpretations.

If a student replied to the question about the sameness of the answers as, "They are the same not in form but in area," instead of only as, "Different," I coded that he verbalized more than what was seen actually. When the others only consented to such interpretation, I defined that they did not take initiative of explicit verbalization. In this way I coded what child mentioned what interpretation. Although space prevents me from describing the entire shifting-process of interpretation, the interpretations they made and articulated in the lesson appeared in their reports in the follow-up inquiry clearly.

Child 1, for example, answered to why all the solutions were the same as, "If I multiply these two fractions, we can see the answer in the frame of the whole, which equals one-half. So, all of these are equal to the one-half of original." In the following-up, he tied his experience of using origami to the fractional multiplication. On the other hand, Child 2 consented vigorously to Child 1's explanation above, but answered to the inquiry, "I remembered two-thirds and three-fourths," which reveals his remembrance of fragmental facts. Child 3 explained her solving step of the second try as, "If a part of the rest (1/4 of 2/3) of my first answer is combined with this area (1/3), I can get three folded rectangles. This (the answer, 3/4 of 2/3) has also the three rectangles. So if I folded the paper into the half of six parts, the three-sixths, I thought that I could make the 3/4 of 2/3." Even though this early reference to the one-half-ness could not be shared among others, she was explainable at the end of the lesson why the answer was one-half based on her diagrammatic understanding, which could be also recognized in her following-up report.

The result implies that the students who verbalized their interpretations could produce durable abstract understanding. This proposes a protest to the lecture style instruction in which a teacher delivered well-structured explanations and students are only silent. Instead, we have to make careful analyses on each student's talk and trigger finer interactions to promote the externalization of their own explanations, ultimately to let them deepen their learning by themselves.

Prosodic Guidance: Evidence for the Early Use of Capricious Parsing Constraint

Jesse Snedeker (jessned@psych.upenn.edu),
John Trueswell (trueswel@ psych.upenn.edu)
Institute for Research in Cognitive Science; 3401 Walnut Street, Suite 400A
Philadelphia, PA 19104 USA

Abstract

This experiment examines the use of naturally occurring prosodic cues to syntactic structure. Earlier work suggests that the production of informative prosodic cues depends upon speakers' knowledge of the situation: speakers provide prosodic cues when needed; listeners use these prosodic cues when present (Snedeker et al., 2001). The present experiment explores the online use of prosodic information in a world-situated eyegaze task. A referential communication paradigm was used to elicit productions of ambiguous sentences (*Tap the frog with the flower*) and determine whether listeners could use prosodic cues to correctly interpret them. Acoustic analyses indicated that Speakers produced potentially informative prosodic cues. Listeners' responses to the ambiguous sentences strongly reflected the demonstration the Speaker had seen, indicating that they were able to use this information. Analyses of the eye-movements indicate that listeners use prosodic information to inform their parse shortly after the onset of the direct-object noun.

Introduction

Prior work on the use of prosody in online sentence processing suggests that strong cues can have an early influence on parsing preferences (for review see, Kjelgaard & Speer, 1999). Prosody in these studies was typically manipulated by splicing pauses into speech to indicate clause boundaries, manipulating synthesized speech, or asking trained speakers to produce particular prosodic variants of an utterance. But in naturally occurring speech, syntactic structure is only a weak predictor of prosodic variation (for review see Fernald & McRoberts, 1996) Unsurprisingly, a number of researchers have found that naïve speakers produce less consistent prosodic cues for syntactic disambiguation than the informed speakers typically used in comprehension experiments (e.g., Allbritton, McKoon, & Ratcliffe, 1996) The research reported here examines whether listeners' use the prosodic cues produced by naïve speakers in real time.

Methods

This experiment employed a referential communication task, in which a Speaker and a Listener were separated by a divider, allowing for only verbal communication between the two participants. Both participants were given identical sets of objects. The Speaker delivered memorized directions, in an attempt to get the Listener perform particular actions on the set of objects on her side of the screen.

The critical sentences contained globally ambiguous prepositional phrase attachments, such as "Tap the frog with the flower". The phrase "with the flower" can be taken as Instrument (VP-Attachment) or a Modifier (NP-attachment). On each trial both of the subjects received: 1) a Target Instrument, a full scale object that could be used to carry out the action (e.g., a large flower); 2) a Marked Animal, a animal carrying a small replica of the instrument (e.g., a frog holding a little flower); 3) an Unmarked Animal (e.g., an empty-handed frog); and 4) two unrelated objects. The set of toys supported both interpretations of the ambiguous sentence. The Experimenter demonstrated one of two possible actions: an Instrument action (e.g., the Experimenter picked up the large flower and tapped the plain frog) or a Modifier action (e.g., using her hand, the Experimenter tapped the frog that had the small flower).

The Listener wore a head-mounted eyetracker. Trained coders viewed the videotape of the Listener's eye-movements and recorded the onset of each word in the target sentence and the onset and location of each fixation that occurred from the beginning of the instruction until the subject began the action.

Results and Discussion

Demonstration Type (Instrument or Modifier) had a reliable effect on the Listener's actions, the length of the post-verbal pause, the length of the direct-object noun and the pause that followed it, and the length of the prepositional phrase. Demonstration Type also had an early effect on Listener's eye-movements. Within 400 ms after the onset of the direct object noun, Listeners in the Modifier condition showed a preference for the Marked Animal, while Listener's in the Instrument condition divided their fixations between the Marked and Unmarked Animals. We conclude that prosody can be used to rapidly resolve an attachment ambiguity.

Learning and Memory: A Cognitive Approach About The Role of Memory in Text Comprehension

Soares, Adriana Benevides Soares (adriana@uenf.br)
Universidade Estadual do Norte Fluminense, Brazil
Corrêa, Carla Patrícia Quintanilha (cpcorrea@zipmail.com.br)
Universidade Estadual do Norte Fluminense, Brazil

This work tries to understand the organization of knowledge in memory. There are two theories about the mnemonic system. One of them says that memory is formed by two distinct memory stores: a short-term memory, and a long-term memory. The other theory involves semantic activation models to explain memory working. We have carried out three experiments to investigate this subject. In these experiments, we have employed a probe technique to observe the semantic representation in memory during text comprehension. Our results showed response times increasing as a function of time, and that seems to be consistent with models involving semantic activation. This conclusion supports the study of learning and comprehension texts. Our goal is to offer a learning strategy which would improve text comprehension. This strategy, based on the work of Yekovich and Walker (1986), allows the possibility of building a text in order to improve the process of comprehension. This improvement ocurrs through the activation of informations by peripheral concepts. An experiment has been conducted to verify this strategy. We have built two different texts to observe which one would be better understood. The results showed that the text built through our strategy was indeed better understood. Therefore, we argue that using peripheral concepts is relevant to the process of comprehension, because it activates the text's central concept, improving the comprehension's process.

Cambridge, CB2 3EB, UK

This hybrid associative/cognitive model simulates the results of our other paper at this conference, in which we demonstrated that a particular sequence learning task cannot be explained by the entirely associative SRN alone. Our model adds cognitive mechanisms to the SRN, for which we had found evidence in the structured interviews given to subjects (2001a,c). Subjects had verbalized repetitions of circle flashes, symmetries within each sequence and that each sequence had the basic structure ABCBA. The interview also revealed that they made analogies between the sequences they had experienced in training, and we hypothesized that this may have helped them to generalize to the novel sequences on which they were tested. Each cognitive mechanism was implemented as an autonomous agent and was assigned a certain probability of being carried out, e.g. 14.29 percent of the subjects verbalized symmetries, hence p=.1429. The other probabilities can be found in (2001c). More detailed explanations of SARAH (Sequential Adaptive Recurrent Analogy Hacker) and a related hybrid model can be found in Spiegel and McLaren (2001b,c).

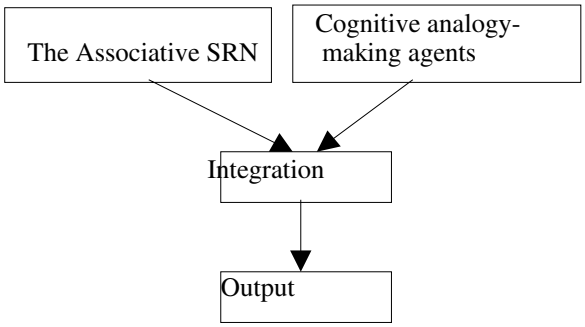

Figure 1: The SARAH model architecture

Training the same number of SARAHs (30) as there were people in the experiment (2001a) on entirely the same task, with six hidden units, a learning rate of .1, 40000 training trials and carrying out the same kind of ANOVA as on the empirical data revealed a significant main effect for the between subjects factor *group*, $F(1,28)=52.78$, $p<.001$, $f=1.37$, $\eta^2=.65$. The Experimental SARAHs ($M_e=.43$, $\pm SE_e=.05$) reveal a significantly higher activity difference when compared with the Control SARAHs ($M_c=.09$, $\pm SE_c=.01$). When considering the novel sequence type (2 Cs), the results resemble the human subjects (2001a) in the way that the SARAHs in the Experimental group show significantly better generalization when compared with the SARAHs

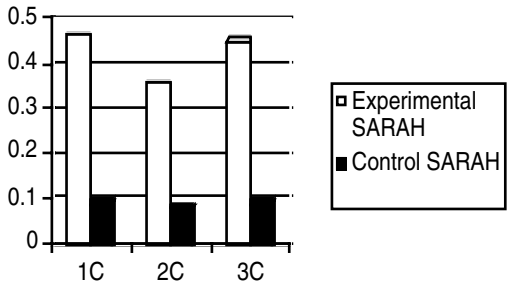

Figure 2: Simulation results for SARAH

in the Control group, $F(1,28)=37.33$, $p<.001$, ($M_e=.36$, $\pm SE_e=.04$ vs. $M_c=.09$, $\pm SE_c=.02$). The results are displayed in Figure 2. Interestingly, when running 30 SRNs with the same parameters on this task, learning of the trained sequences can be obtained, $F(1,28)=12.42$, $p<.01$, $f=.67$, $\eta^2=.31$, $M_e=.11$, $\pm SE_e=.03$ vs. $M_c=-.01$, $\pm SE_c=.01$, but no generalization to novel sequences, $F(1,28)=.44$, $p>.5$. As a result, SARAH may be better able to model the interplay between associative and cognitive processes found in (2001a).

The Relationship between Learned Categories and Structural Alignment

Daisuke Tanaka (daisuke@srt.L.u-tokyo.ac.jp)
Department of Psychology, University of Tokyo; 7-3-1 Hongo Bunkyo-ku
Tokyo, 113-0033 Japan

Recent researches suggest that similarity is well characterized as a comparison of structured representations and two kinds of differences yielded through the alignment process were influenced on similarity judgement differently (Markman, & Gentner, 1996). This study applied structural alignment view to category learning and tested the hypothesis that features of categories with alignability between categories are more important than features without alignability in classification of exemplars.

Method

Subjects

18 university students participated in the experiment.

Materials & Procedure

Subjects learned a pair of categories in the learning phase. Category structure composed of short descriptions as features (Table 1). Those features could classified into 3 groups; alignable features (AF), non-alignable features (NF), and common features (CF). AF had a relation to other features composed alternative category as alignable differences. NF did not make alignable differences and were characteristic of one category. CF are in common with two categories. In the learning phase, learning exemplars were used and one learning exemplar had 3 features; one of AF, one of NF, and one of CF. Subjects were presented with the exemplars one at a time and identified them as being in category 1 or 2. After each choice, subjects were given feedback. This procedure was repeated in blocks of 18 exemplars until the subjects had correctly classified over 90% of 18 exemplars. After reaching criterion, subjects entered the test phase which was similar to the learning phase without feedback. In the test phase, test exemplars were used, which composed of "appropriate" and "inappropriate" exemplars. "appropriate" exemplars, used as fillers, could be classified one category using the knowledge of category structure, like learning exemplars. On the other hand, "inappropriate" exemplars could not be classified correctly, and divided into 3 subtypes, subtype A, subtype B, and subtypes C by the difference of component patterns of features (see Table 2).

Table 1: A part of category structure.

Category 1		Category 2
Summer sports	(AF)	Winter sports
In a group		By oneself
Indoor sports	(NF)	Popular with kids
In fashion		With ease
Need the special education		(CF)

Table 2: Examples of "inappropriate" exemplars

Subtype A	Subtype B	Subtype C
Summer sports	Summer sports	By oneself
By oneself	With ease	In fashion
Need the special education	Need the special education	Need the special education

Results and Discussion

The main result are presented in figure 1. The hypothesis of this study predicted that the subtype A exemplars were classified as members of category 1 or 2 by chance, the subtype B tended to be classified as category 1, and the subtype C as category 2. The choice tendency for category 1 was different among subtypes significantly ($F(2,34)=6.56$, $p<.01$). The percentage to be classified into category 1 in subtype B was higher than in subtype C. This result suggests that alignable features were used for two categories learning and classified exemplars into categories.

Timing and Rhythm in Multimodal Communication for Conversational Agents

Ipke Wachsmuth (ipke@techfak.uni-bielefeld.de)
Faculty of Technology, University of Bielefeld
D-33594 Bielefeld, Germany

Motivation

Synthesis of lifelike gesture is finding growing attention in human-computer interaction. In particular, synchronization of synthetic gestures with speech output is one of the goals for embodied conversational agents which have become a new paradigm for the study of gesture and for human-computer interface (Cassell et al., 2000). Embodied conversational agents are computer-generated characters that resemble similar properties as humans in verbal and nonverbal face-to-face conversation.

Gesture production in humans is a complex process leading to characteristic shape and dynamic properties of gestures which enable humans to distinguish them from subsidiary movement and recognize them as meaningful. In coverbal gestures the stroke (the most effortful part of the gesture) is tightly coupled to accompanying speech, yielding semantic, pragmatic, and temporal synchrony between the two modalities (McNeill, 1992).

Although promising work exists for the production of synthetic gestures, natural timing for the gesture stroke and synchronizing it with speech output remains a research challenge. For instance, the REA system by Cassell and coworkers (in Cassell et al., 2000) implements an embodied agent that produces verbal and gestural output. Yet though precise timing of spoken and gestural utterances is targetted in their work, the authors state that it has not been satisfactorily solved.

Articulated Communicator

A mid-range goal of our research is the conception of an "articulated communicator" that conducts multimodal dialog with a human partner in cooperating on a model airplane construction task. In this context an operational model was developed that enables lifelike gesture animations to be rendered in real time from representations of spatiotemporal gesture knowledge (Kopp & Wachsmuth, 2000). Based on various findings on the production of human gesture, the model provides means for motion representation, planning, and control to drive the kinematic skeleton of a figure which comprises 43 degrees of freedom in 29 joints for the main body and 20 DOF for each hand (see Figure 1). A movement plan is formed as a tree representation of a temporally ordered set of movement constraints in three steps:

(1) retrieve feature-based specification from a gestuary
(2) adapt it to the individual gesture context
(3) qualify temporal movement constraints in accordance with external timing constraints.

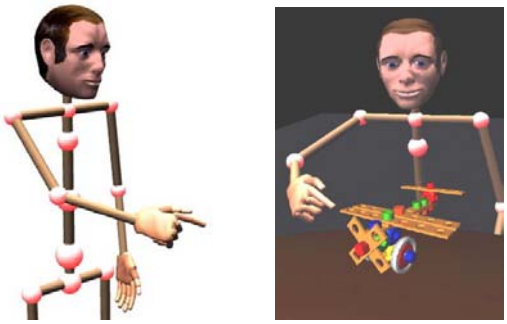

Figure 1: Articulated Communicator.

Hence our model is conceived to enable cross-modal synchrony with respect to the coordination of gestures with the signal generated by a text-to-speech system. In multimodal communication, by which we mean the concurrent formation of utterances that include gesture and speech, a rhythmic alternation of phases of tension and relaxation can be observed. The issue of rhythm in communication has been addressed widely and has been a key idea in our earlier work on synchronizing gesture and speech in HCI input devices (Wachsmuth, 1999). Achieving precise timing for accented parts in the gesture stroke as a basis to synchronize them with stressed syllables in speech is work currently in progress.

Background

Task switching involves rapidly switching back and forth between multiple tasks and is part of an executive control system (e.g., Rogers & Monsell, 1995). Using a variable training approach, we found training on attention switching tasks and transfer of training to related tasks. These findings have potential for those with impairments of executive function, such as older adults or people with Attention Deficit Hyperactivity Disorder (ADHD). Kramer, Hahn, and Gopher (1999) trained younger and older adults on a task of attention switching. Results showed that age-related switch costs evident early in practice disappeared after training.

Cepeda, Cepeda, and Kramer (2000) studied task switching with ADHD and non-ADHD children and found that non-medicated ADHD children showed larger switch costs compared to non-ADHD children. Dowsett and Livesey (2000) trained children on several tasks of executive control and found that a variable training procedure resulted in improvement of generalized response capabilities, such as inhibitory control. The present study applied the variable training procedure to adults with characteristics of ADHD and demonstrated that training effects are not limited to task-specific strategies.

Methods

Undergraduate students from the University of Memphis were recruited to participate in the study on the basis of their responses to a questionnaire used to assess adult ADHD. Participants were divided into ADHD and non-ADHD groups and assigned to either the training or control condition. The training condition included a pretest, six training blocks, and a posttest. The control condition included a pretest, six filler blocks (non-executive control tasks), and a posttest. The training tasks were variants of the number-letter task used by Rogers and Monsell (1995).

Results and Discussion

The ADHD and non-ADHD groups showed training effects greater than the control groups. Additionally, training effects transferred to related tasks of attention switching. These results may have implications for efforts directed at cognitive rehabilitation of ADHD individuals. In future research, we would like to examine the mechanisms underlying training, perhaps using neuroimaging. Such research may help to determine whether subjects are using compensatory strategies or actually improving some underlying attentional process. Future research will also be directed at examing the scope of training. Specifically, how much transfer occurs for less related tasks (e.g., WCST)? How long do the effects of training last, and will children show training comparable to that seen in adults? Perhaps training, in the form of cognitive rehabilitation, will be helpful in place of, or in combination with, the stimulant medications traditionally used to treat ADHD.

Pictures and diagrams have long played an important role in human societies (Novick, 2001). Prehistoric peoples painted pictures on cave walls. The Bayeux Tapestry, from the 11th century, records the events surrounding the Battle of Hastings. In the 15th century, da Vinci made thousands of anatomical, mechanical, geographical, and other drawings. Today, diagrams are found on blackboards in most university departments (McKim, 1980). In our increasingly technical and technological society, diagrams (especially abstract ones) are likely to gain in importance. Even the traditionally text-driven field of computer programming now includes languages whose representations are diagrammatic rather than textual (Whitley, 1997).

LabVIEW™ (National Instruments, 1998), for example, features a programming language based on the dataflow paradigm in which the flow of information through the program is expressed using a notation that resembles circuit diagrams. LabVIEW™ was designed to facilitate the development of data acquisition, analysis, display, and control applications for science and engineering laboratories.

In an experiment with a 2 × 3 mixed-factors design, we assessed the comprehensibility of LabVIEW™'s representation. Representation type was manipulated between subjects, with 15 upper-level computer science students randomly assigned to receive LabVIEW™'s visual representation and 16 such students randomly assigned to receive an equivalent textual dataflow representation. The second factor – problem type (tracing, parallelism, debugging) – was manipulated within subjects.

The experiment involved a 90 min lecture, during which subjects were taught a subset of the LabVIEW™ language, followed by a 90 min test session. The test problems required subjects to read and understand code segments. For the three tracing problems, subjects were given input values for variables in the code and had to determine what the output values would be if the code were to execute. For the three parallelism problems, several program operators were highlighted, and subjects had to specify the order in which pairs of operators could execute. For the three debugging problems, subjects were given written specifications for the code and had to find the (single) error in the code.

For both solution accuracy and time, representation type interacted with problem type. For the more difficult parallelism and debugging problems, the visual representation was clearly superior to the textual representation: The visual subjects had higher accuracy scores and spent less time working on the problems. For the tracing problems, accuracy was similar for the two representations, but the visual subjects spent more time working on them. Overall, these results provide compelling evidence for the superiority of LabVIEW™'s visual representation over an equivalent textual representation.

The comprehensibility effects we found seem likely to generalize to novice LabVIEW™ programmers in more naturalistic situations. The subset of LabVIEW™ we used included a fair portion of the language. Moreover, our experimental tasks were representative of actual programming tasks and were sequenced in a natural instructional order. Although it is an open question whether the superiority of the visual representation will apply to other types of programming tasks (e.g., writing new code, modifying existing code), we suspect that it will under a variety of conditions.

Mass and *Count* in Language and Cognition: Some Evidence from Language Comprehension

In linguistics and the philosophy of language, the mass/count distinction has traditionally been regarded as a bi-partition on the nominal domain, where typical instances are nouns like 'beef' (*mass*) vs. 'cow' (*count*).

In the present paper, we argue that this partition reveals a system that is based on both syntactic features and conceptual features, and present experimental evidence suggesting that the discrimination of the two kinds of features has a psychological reality.

We account for the mass/count distinction by a binary classification of nouns based on a syntactic feature [± tn] ('transnumeral') and a conceptual feature [± mn] ('mass'), with the following diagnostics: Nouns are [-tn] if and only if they obligatorily occur in their plural form when denoting more than one realisation of the nominal concept. Nouns are [+mn] if they refer to homogeneous masses, and [-mn] if they refer to objects.

According to this classification, 'beef' is [+tn, +mn] and 'cow' is [-tn, -mn]; syntactic differences go together with conceptual differences here. However, this is not necessarily so. Collective nouns like 'cattle' behave like 'beef' syntactically, but fall into one class with 'cow' conceptually: they are not marked for number, and are therefore [+tn], but they refer to objects, i.e., they are [-mn]. Hence conceptual features are not in a one-to-one correspondence with syntactic features:

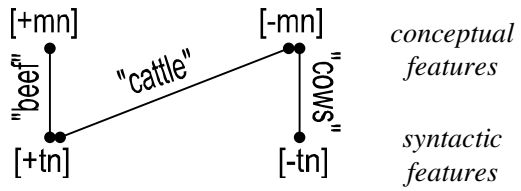

Figure 1: Dissociation of conceptual and syntactic correlates of the mass/count distinction

Does this distinction have a psychological reality? We addressed this question by investigating whether facilitation of lexical activation (in the form of priming) can be obtained for [-mn] versus [+mn] nouns in language comprehension: we investigated whether exposure to a [-mn] noun (the *prime*; e.g. 'furniture') reduces the time needed for the subsequent activation of another [-mn] noun (the *related target*; e.g. 'cattle'), in comparison to the activation of a [+mn] noun (the *unrelated target*; e.g. 'beef').

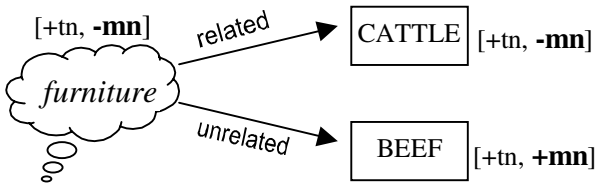

Figure 2: Experimental prime-target pairs

Since the [-mn] nouns we used were collectives (i.e., they were syntactically [+tn], like all [+mn] nouns), the difference between related and unrelated targets was restricted to the conceptual feature [± mn].

We conducted two studies. In study 1, primes were presented auditorily (via headphones) in a sentential context; in study 2, primes were presented visually (on a computer screen) as isolated words. All targets were presented visually and appeared immediately after the prime was heard (study 1) or seen (study 2). Subjects performed a lexical decision on the targets (and on non-experimental probes), i.e., they had to decide whether they saw a word or a non-word. Reaction times were measured for related versus unrelated targets.

In both studies, after [-mn] primes reaction times were faster for [-mn] targets than for [+mn] targets: facilitation for [± mn] was evident both in sentential contexts (study 1) and in word lists (study 2), and for auditory input (study 1) as well as for visual input (study 2).

We interpret this as evidence that the [± mn] distinction, as a conceptual correlate of the nominal mass / count partition, has a psychological reality independently of the syntactic distinction of nouns.

Inhibition Mechanism of Phonological Short-term Memory in Foreign Language Processing

Takashi Yagyu (yagyu@srt.L.u-tokyo.ac.jp)
Department of Psychology, University of Tokyo; 7-3-1 Hongo Bunkyo-ku
Tokyo, 113-0033 Japan

This study examined phonological short-term memory (phonological STM) capacity and the individual difference of the range for inhibition. About the relation between phonological STM capacity and foreign language processing and acquisition, there are many antecedence studies (e.g., Baddeley, Gathercole & Papagno, 1998). However, the degree of similar of a native language and a foreign language and the relation of phonological STM are seldom clarified. Then, in this research, it investigated the relation between the degree of similar of the item to memorize and an interference item, and the individual difference of inhibition capability.

Method

Subjects

The subjects were 25 undergraduate and graduate students. They were all native Japanese speakers who had studied English for 6-10 years.

Materials

<Word-Span Task>The phonological STM capacity was measured with the use of a word-span task written in Japanese and English. In each span task, the first three sets consisted of three words, the next three sets of four words etc. The largest set size was seven words, making total number of items 75.

<Dual-Task of Word Retention> A total of 144 word-sentence pairs were grouped into four lists of 36 pairs each. The first list contained Japanese words and English sentences, and second list contained English words and Japanese sentences. The other two lists were same language structure in word-sentence pairs. In each list, the first four sets consisted of two word-sentence pairs, the next four sets of three word-sentence pairs etc. The largest set size was four word-sentence pairs.

Table 1: Correlation with the results of a dual-task and of the word-span task(n=25).

dual-task (word-sentence)	L1-L1	L1-L2	L2-L1	L2-L2
WST	0.56**	0.37+	0.30 n.s.	0.65**

+ p < .10 **p < .01

Procedure

<Word-Span Task>Word span was assessed in both Japanese and English. On each measure, subjects were required to recall a sequence of words immediately after visual presentation.

<Dual-Task of Word Retention>A primary task was to recall words. Reading sentences aloud have been used as a method of the background task. First words, first sentence, second word, second sentence were presented successively. After reading all words and sentences, the subject tries to recall.

Results and Discussion

Correlations between the Japanese and English version word-span tasks showed significant at $p<.01$ level($r=.51$). It divided into the high-span group and the low-span group by the mean score of the results of the Japanese and English version word-span task.

The main results are presented Figure 1. It is that the difference was found by the results pattern of a retention word between the group with high-span , and the low-span group with the combination of the language kind of a retention word and interference sentence. Then, the correlation with the results of a dual-task and the results of the word-span task was investigated (Table 1). It was suggested the memorizable number of words not only increases that a phonological STM capacity is large, but that it can be inhibited to what has the high degree of similar of the information used as interference.

Odd-Even effect in multiplication revisited: The role of equation presentation format

Michael C. W. YIP

School of Arts & Social Sciences, The Open University of Hong Kong

myip@ouhk.edu.hk

Introduction

Several studies suggested that people usually make use of many different strategies to solve simple arithmetic problems (digit-addition and digit-multiplication). (Lemaire & Fayol, 1995; LeFevre, Bisanz, Daley, Buffone, Greenham, & Sadesky, 1996; Krueger, 1986; Krueger & Hallford, 1984; Zbrodoff & Logan, 1990). For example, to verify simple multiplication questions, 2 x 3 = 7; 4 x 6 = 25, people will retrieve the answer of the question from their memory base and compared it with the mentioned answer (memory-retrieval hypothesis) *or* people will first check out if the mentioned answer of the question violates the parity rules of multiplication (parity-checking hypothesis). Recently, a similar study was conducted by Lochy, Seron, Delazer, & Butterworth, (2000), they proposed an alternative account to the odd-even effect: number evenness hypothesis. They reasoned the effects were mainly due to the familiarity of even numbers of the products rather than the parity-checking rule. However, the rationale of this hypothesis is basically in line with the memory-retrieve hypothesis because both of them emphasized the distributional information of the products or the mathematical equation from the memory. To further verify the odd-even effect in multiplication and to assess the validity of those hypotheses, I replicated the study by altering the presentation format of the mathematical equation in this paper. revising from the traditional standard format [a x b = c] to a reverse format [c = a x b]. The reverse presentation format will obviously affect the memory capacity of the equation because people would not normally remember the multiplication table in that specific format. Therefore, if the memory-retrieval hypothesis or the number evenness hypothesis are really the underlying mechanism of the multiplication processes, the similar pattern of results will be showed and should be consistent with the previous studies (Lochy et al., 2000). Otherwise, other explanations should be further sought. The present study attempts to evaluate the strengthen of those hypotheses and their roles played in the temporal course of simple multiplication process by using the presentation format as a crucial examination tool.

Experiment

The basic design of the present experiment is similar to the study of Lochy et al. (2000). Three main variables in the present experiment: (1) presentation format of the equation: (a x b = c) vs. (c = a x b); (2) types of problem: (even x even) vs. (odd x odd) vs. mixed; (3) size of split: +1 +2 +3 +4 –1 –2 –3 –4.

Procedure

A series of simple multiplication problems were randomly presented to each participant in one of the two forms (a x b = c) or (c = a x b). Participants were asked to verify whether the equation is true or false by pressing a key. Response latencies were recorded from the onset time of the equation that displayed on the computer screen to the manual response.

Results and Discussion

Three main findings in the present study were concluded.

First, the format of equation presentation is in fact influence the verification time of the participants (reverse mode takes longer time to verify than the traditional mode). It is sensible because the internal representation of the simple multiplication knowledge is initially encoded in the traditional form (2 x 3 = 6) instead of the reverse form (6 = 2 x 3).

Second, collapsed over the levels of presentation format, in the traditional format, results obtained from the present study were replicated the general pattern of results to the odd-even effects which were reported in Lochy et al., (2000). Third, the most interesting point here is that on the contrary, in the reverse presentation mode, the odd-even pattern of results was typically consistent with the parity-checking rule rather than the other hypotheses. Clearly, in the processing of simple multiplication, people will rely heavily on the mathematical knowledge stored in their memory base. However, once the relevant information cannot be easily triggered from the memory store, other alternatives will be used immediately (parity-checking rule) to solve the original arithmetic problem. These findings seem to support the multiple-strategy hypothesis in solving simple mathematical problems (Lemaire & Fayol, 1995).
